**ABOUT COVER**

Editorial Board Member of *World Journal of Clinical Cases*, Baharudin Abdullah, MMed, Professor, Surgeon, Department of Otorhinolaryngology-Head and Neck Surgery, School of Medical Sciences, Universiti Sains Malaysia, Kubang Kerian 16150, Kelantan, Malaysia. profbaha@gmail.com

**AIMS AND SCOPE**

The primary aim of *World Journal of Clinical Cases* (WJCC, *World J Clin Cases*) is to provide scholars and readers from various fields of clinical medicine with a platform to publish high-quality clinical research articles and communicate their research findings online.

WJCC mainly publishes articles reporting research results and findings obtained in the field of clinical medicine and covering a wide range of topics, including case control studies, retrospective cohort studies, retrospective studies, clinical trials studies, observational studies, prospective studies, randomized controlled trials, randomized clinical trials, systematic reviews, meta-analysis, and case reports.

**INDEXING/ABSTRACTING**

The WJCC is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Journal Citation Reports/Science Edition, Current Contents®/Clinical Medicine, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 Edition of Journal Citation Reports® cites the 2021 impact factor (IF) for WJCC as 1.534; IF without journal self cites: 1.491; 5-year IF: 1.599; Journal Citation Indicator: 0.28; Ranking: 135 among 172 journals in medicine, general and internal; and Quartile category: Q4. The WJCC's CiteScore for 2021 is 1.2 and Scopus CiteScore rank 2021: General Medicine is 443/826.

### Abstract

Despite improvement in cardiopulmonary resuscitation (CPR) performance, cardiac arrest (CA) is still associated with poor prognosis. The high mortality rate is due to multi-organ dysfunction caused by cerebral ischemia and reperfusion injury (I/R). The guidelines for CPR suggest the use of therapeutic hypothermia (TH) as an effective treatment to decrease mortality and the only approach confirmed to reduce I/R injury. During TH, sedative agents (propofol) and analgesia agents (fentanyl) are commonly used to prevent shiver and pain. However, propofol has been associated with a number of serious adverse effects such as metabolic acidosis, cardiac asystole, myocardial failure, and death. In addition, mild TH alters the pharmacokinetics of agents (propofol and fentanyl) and reduces their systemic clearance. For CA patients undergoing TH, propofol can be overdosed, leading to delayed awakening, prolonged mechanical ventilation, and other subsequent complications. Ciprofol (HSK3486) is a novel anesthetic agent that is convenient and easy to administer intravenously outside the operating room. Ciprofol is rapidly metabolized and accumulates at low concentrations after continuous infusion in a stable circulatory system compared to propofol. Therefore, we hypothesized that treatment with HSK3486 and mild TH after CA could protect the brain and other organs.

**Key Words:** HSK3486; Therapeutic; Cerebral ischemia-reperfusion injury; Hypothesis

**Core Tip:** Ciprofol (HSK3486) is a novel anesthetic agent that is convenient and easy to administer intravenously outside the operating room. Ciprofol is rapidly metabolized and accumulates at low concentrations after continuous infusion in a stable circulatory system compared to propofol. We hypothesize that HSK3486 can improve survival rates and achieve good neurological outcomes in cardiac arrest patients who receive therapeutic hypothermia.

## INTRODUCTION

Cardiac arrest (CA) is associated with poor prognosis. CA accounts for approximately 15% of all deaths and 50% of all cardiac deaths worldwide[1]. Survival rates with good neurological outcomes are low, in the range between 2% and 23%, depending on a variety of regional, social, and medical factors[2,3]. From a pathophysiology perspective, post-CA myocardial injury and brain injury are induced by ischemia/reperfusion injury (I/R injury)[4,5]. The guidelines for cardiopulmonary resuscitation (CPR) suggest that therapeutic hypothermia (TH) is an effective treatment to decrease mortality, and CPR is the only approach confirmed to reduce I/R injury[6,7].

During TH, sedative agents (propofol) and analgesia agents (fentanyl) are commonly used to prevent shiver and pain[6]. However, studies have shown that propofol has been associated with a number of serious adverse effects such as metabolic acidosis, cardiac asystole, myocardial failure, rhabdomyolysis, and death[7-9]. Low-grade myotoxicity can be associated with prolonged (weeks) exposure to propofol in the intensive care unit (ICU), especial in children. Several studies reported that prolonged propofol sedation of coronavirus disease 2019 (COVID-19) patients with long-term mechanical ventilation contributed to critical illness myopathy[8-10]. In addition, it has been shown that mild TH alters the pharmacokinetics of propofol and fentanyl and reduces their systemic clearance in rats after the return of spontaneous circulation (ROSC)[11,12]. For CA patients who have undergone TH, propofol can be overdosed, leading to delayed awakening, prolonged mechanical ventilation, and other subsequent complications, often referred to as propofol syndrome[12].

Ciprofol (HSK3486) (Figure 1), which is a 2,6-disubstituted alkylphenol phenol derivative, is a novel propofol analogue formulated in an injectable emulsion of medium- and long-chain triglycerides[13]. Its pharmacokinetics and distribution indicate that HSK3486 is rapidly metabolized and has low accumulation after continuous infusion[14]. One study reported that HSK3486, like propofol, exerts its sedative effects through binding to gamma-aminobutyric acid type A (GABAA) receptors, but showed higher liposolubility and potency than propofol[15]. Furthermore, to achieve the same level of anesthesia, fewer lipids from the HSK3486 emulsion enter into the circulatory system compared to propofol emulsion[16]. HSK3486 at a maintenance dose of 3-4 mg/kg/h showed good efficacy and safety in the treatment of long-term mechanically ventilated patients in the ICU[16,17]. However, whether HSK3486 can improve survival rates in CA patients who receive TH remains unclear.

## HYPOTHESIS

We hypothesize that HSK3486 can improve survival rates and achieve good neurological outcomes in CA patients who receive TH.

## RATIONALE FOR THE HYPOTHESIS

The high mortality rate of CA is attributed to whole-body I/R induced multi-organ dysfunction that is referred to as post-cardiac arrest syndrome (PCAS)[18-20]. Post-CA myocardial dysfunction, macrocirculatory dysfunction, and brain injury are the main clinical features of this complex pathophysiological process. Myocardial dysfunction after CA commonly results in death and hemodynamic instability[19]. Increased heart rate and blood pressure after ROSC are attributed to medications and catecholamine release. These effects cause a global stunning of the myocardium that usually resolves and returns to

**Figure 1 The chemical structure of Cipropofol.** Cipropofol introduces cyclopropyl on the basis of the chemical structure of propofol to form a chiral structure, which increases the steric effect and enhances the affinity for gamma-aminobutyric acid type A receptors. Cipropofol is a new type of intravenous anesthetic drug with rapid onset of action, rapid recovery, high potency, and less injection pain.

normal after 72 h[20].

Studies have shown that propofol is associated with a number of serious adverse effects such as metabolic acidosis, cardiac asystole, myocardial failure, rhabdomyolysis, and death[7-10]. Low-grade myotoxicity can be associated with prolonged (weeks) exposure to propofol in the ICU[11]. In both clinical and experimental studies where patients and animals have been exposed to long-term (10 d) controlled mechanical ventilation, patients and animals developed critical illness myopathy[8-12]. Thus, for CA patients, propofol infusion syndrome should be reduced to maintain a stable circulatory system, especial when TH treatment has been used.

Cipropofol (HSK3486), which is a 2,6-disubstituted alkylphenol phenol derivative, is a novel propofol analogue formulated in an injectable emulsion of medium- and long-chain triglycerides[13-15]. HSK3486 acts against the  $\alpha 1\beta 2\gamma 2$  subtype of GABAA receptors and inhibits a wide range of CYP450 isozymes in mammalian species. Its pharmacokinetics and distribution indicate that HSK3486 is rapidly metabolized and has low accumulation after continuous infusion. One study reported that HSK3486 showed better anesthesia potency over propofol, with an 83% lower ED50. Furthermore, fewer lipids from the HSK3486 emulsion enter into the stable circulatory system compared to a propofol emulsion. Thus, HSK3486 can achieve the same sedative depth during TH after CA and may improve survival rates compared to propofol.

## EVALUATION OF THE HYPOTHESIS

This hypothesis can be tested in two ways using rat models of CA. First, we could compare the protective effects of HSK3486 and propofol directly, and second we could test whether the combination of HSK3486 and TH confers greater protection than either HSK3486 or propofol alone.

The CA animal model was established in our previous study[11,21]. Here we would adapt it as follows. After anesthesia, we will induce CA by applying six minutes of asphyxia. We will then use CPR with mechanical ventilation of 100% oxygen, at a frequency of 80 breaths/min, tidal volume of 10 ml/kg, and sternal compressions (with two fingers) at a rate of 200 times/min (attempting to generate systolic arterial pressure peaks > 50 mmHg). We will continue CPR until return of spontaneous circulation (ROSC), defined as achieving a spontaneous mean arterial pressure (MAP) of 60 mmHg, that is maintained for more than 10 min[13,21]. We will simultaneously administer epinephrine (0.02 mg/kg i.v.) with the sternal compressions every 3 min if necessary, and 5% NaHCO<sub>3</sub> (1 mmol/kg i.v.) can also be provided if needed. If overall CPR attempts exceed 5 min, the experiment will be stopped. After ROSC, rats will be divided randomly into four groups: S group (sham-operate group), CPR group (infusion with saline 4 ml/kg for 30 min), HSK3486 group (infusion with HSK3486 at 0.4 mg/kg for 30 min), and propofol group (infusion with 2 mg/kg emulsion for 30 min). Survival conditions, behavioral evaluations, echocardiogram, and histopathologic analysis (including TUNEL staining of neurons and cardiomyocytes and Nissl staining of neurons) in each group will be evaluated on days 1 and 7 after ROSC. We will then compare the protective effects of HSK3486 and propofol post-conditioning. In the second set of experiments we will also evaluate the effects of TH. The CA model will be established as described above, but rats will be randomly divided into five groups after ROSC: CPR group, HSK3486 group (infusion with HSK3486 at 2 mg/kg for 30 min), TH group (maintaining rectal temperature at 33

$\pm 0.5^{\circ}\text{C}$  for 2 h), HSK3486-TH group (TH will be initiated with HSK3486 infusion at  $33 \pm 0.5^{\circ}\text{C}$  for 2 h), and propofol-TH group (TH will be initiated with propofol infusion at  $33 \pm 0.5^{\circ}\text{C}$  for 2 h). We will conduct the same evaluations at days 1 and 7 as described for first set of experiments. However, during these experiments, the left femoral artery and vein will be separately cannulated with catheters to measure blood pressure and for drug administration. The rectal temperature will be controlled throughout the experiment with the aid of a lamp or ice bag. Rectal temperature, MAP, electrocardiogram, and blood gas levels will be continuously monitored during the experiment.

## CONSEQUENCES AND DISCUSSION OF HYPOTHESIS

Despite the advances in treatment of PCAS, a significant proportion of patients still have a poor prognosis. The pathophysiological processes that occur after whole-body I/R injury following CA lead to multi-organ dysfunction. The subsequent reperfusion injury after ROSC causes cardiac and brain dysfunction. HSK3486, as an intravenous anesthetic, has advantages such as rapid metabolism and low accumulation in the circulation compared to propofol.

HSK3486 is a GABAA receptor agonist that has been shown to have an improved anesthetic profile and less injection pain compared to propofol in pre-clinical studies. HSK3486 is formulated in a 10% oil-in-water emulsion with a drug concentration of 10 mg/mL. Compared with lipophilic drugs, such as midazolam, HSK3486 is metabolized at faster rate and reduces the deepening of sedation. HSK3486 has been used for clinical endoscopy, but it has also been recommended for adult patients who may need general anesthesia for fiberoptic bronchoscopy. In a previous trial, Teng *et al*[22] demonstrated the safety of HSK3486 during colonoscopy with good tolerance. In addition, HSK3486 has shown good tolerance in some unpublished studies (NCT03698617, NCT03808844, NCT04048811, and NCT04511728). Furthermore, based on available data, HSK3486 causes less potential damage to cardiovascular and cerebrovascular function, as evidenced by stable hemodynamics and its reported safety profile[23]. Glucuronidation, oxidation, and sulfation are the major metabolic pathways targeted by HSK3486, and its glucuronidation metabolites are generally considered to be nonhypnotic, nontoxic, and rapidly cleared in from the plasma[14]. In summary, HSK3486 may become a promising anesthetic agent.

The available studies provide some useful guidance regarding the appropriate dose for post-conditioning and HSK3486 adaptation. Teng *et al*[22] reported that HSK3486 could be administered at a range of 0.1-0.5 mg/kg during colonoscopy. The study by Li *et al*[23] showed that a sedative effect could be achieved at 0.3 mg/kg in the elderly compared to 0.4 mg/kg in the non-elderly. Thus, 0.4 mg/kg of HSK3486 would be the chosen dose to test in combination with TH. However, due to the lack of research on the appropriate dose of HSK3486 for intravenous administration in CA, more studies are needed to test our hypothesis.

We hypothesize that HSK3486 in combination with TH would confer cardio-protective effects and less risks compared to propofol. The combination of HSK3486 and TH may synergistically prevent neuronal injuries caused by I/R following CA, due to the fact that HSK3486 can be rapidly metabolized. Additionally, this combination could potentially ameliorate the side effects of hypothermia. Therefore, HSK3486 treatment in combination with TH could be a novel treatment for CA patients.

Testing our hypothesis would provide new insight about the treatment of CA, providing a promising prevention strategy for post-arrest myocardial and neuronal reperfusion injury.

## LIMITATIONS

Here we propose one hypothesis for using a combined TH treatment after CA, but more experimental data is needed to test our hypothesis, and further studies are needed to elucidate the cardio-protective mechanism of ciprofol in the future.

## CONCLUSION

Based on the experimental laboratory data, we hypothesize that HSK3486 administered with TH after CA would improve patient survival rates and lead to good neurological outcomes.

### Abstract

During the early phase of the coronavirus disease 2019 (COVID-19) pandemic caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), diagnosis was difficult due to the diversity in symptoms and imaging findings and the variability of disease presentation. Pulmonary manifestations are reportedly the main clinical presentations of COVID-19 patients. Scientists are working hard on a myriad of clinical, epidemiological, and biological aspects to better understand SARS-CoV-2 infection, aiming to mitigate the ongoing disaster. Many reports have documented the involvement of various body systems and organs apart from the respiratory tract including the gastrointestinal, liver, immune system, renal, and neurological systems. Such involvement will result in diverse presentations related to effects on these systems. Other presentations such

as coagulation defects and cutaneous manifestation may also occur. Patients with specific comorbidities including obesity, diabetes, and hypertension have increased morbidity and mortality risks with COVID-19.

**Key Words:** COVID-19; Non-pulmonary; Extrapulmonary; Clinical manifestations; Systemic disease

## INTRODUCTION

Since January 30, 2020, the World Health Organization has declared the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) outbreak as a public health emergency of international concern [1]. This pandemic, which emerged in China, has rapidly spread to affect almost the entire globe within a few weeks. Currently, researchers are working hard on a myriad of aspects, clinical, epidemiological, and biological, to better understand SARS-CoV-2 infection aiming at mitigating the ongoing disaster. As the number of confirmed coronavirus disease 2019 (COVID-19) patients is increasing daily by tens of thousands, clinicians are struggling to understand the possible damage which can complicate SARS-CoV-2 infection [2]. During the early phase of the COVID-19 pandemic, the diagnosis was difficult due to the diversity in symptoms and imaging findings and variability of disease presentation [3,4]. The Centers for Disease Control and Prevention has identified interim clinical presenting features for COVID-19 as fever (83%-99%), cough (59%-82%), fatigue (44%-70%), anorexia (40%-84%), shortness of breath (31%-40%), sputum production (28%-33%) and myalgias (11%-35%) [5]. According to a large Chinese cohort studying disease patterns in more than 44000 patients, disease severity ranged from mild constitutional symptoms and/or mild pneumonia in 81% to shortness of breath and hypoxemia, which complicates about 14% of patients. Acute respiratory distress syndrome (ARDS), respiratory failure, shock, and multi-organ failure occur in only 5% of the affected population [6]. Chest imaging is non-specific in many settings. Although COVID-19 patients can be identified through the detection of bilateral peripheral ground-glass opacities and air-space consolidation, mild or early diseases might lack radiological chest changes [7,8]. Consequently, The American College of Radiology denied computed tomography of the chest as the first-line test for SARS-CoV-2. Medical practitioners realize that although the lungs are the most affected organs, the infection can extend to many other organs and systems, including the heart, blood vessels, kidneys, gut, and brain [2].

In this article, we focused on the non-pulmonary involvement in COVID-19 by reviewing the available evidence. Figure 1 summarizes the non-pulmonary involvement in COVID-19.

## MATERIALS AND METHODS

The main objectives of the study were to stress the involvement of various body systems and organs in COVID-19 apart from the respiratory tract including the gastrointestinal (GI), liver, immune system, renal, and neurological systems.

### Literature search

The literature search was conducted using the PubMed, Scopus, Web of Science (WOS), EBSCO, and Wiley databases. The following search items were used: ("non-pulmonary involvement OR "non-respiratory") AND ("COVID-19 OR "covid 19" OR "covid 19 associated") AND ("a systemic disease rather than a pure respiratory infection" OR "covid 19 associated multi-system inflammatory syndrome in adults" OR "covid 19 associated multi-system inflammatory" OR "covid 19 breakthrough infections"

**Figure 1 Summarizes non-pulmonary involvement in coronavirus disease 2019.** GI: Gastrointestinal; COVID-19: coronavirus disease 2019.

OR "covid 19 multi-system"), to retrieve relevant articles regardless the publishing year. For non-English articles, all relevant data were extracted from the English version of the abstract. The full text of these papers was translated into English to retrieve all other needed data. Reviews, meta-analyses, and all other articles containing non-original data were excluded from our review. All retrieved articles were screened and selected by two independent groups of authors (Mohamed El-Kassas and Mohamed Alboraie). Relevant data were extracted into a standardized data collection sheet by two independent authors (Mohamed Elbadry and Mohamed Eltabbakh).

### Statistical analysis

Descriptive statistics were used for data analysis.

## OBSERVATIONS AND DISCUSSION

### GI involvement

In one of the first articles describing the clinical presentation of patients infected with SARS-CoV-2 from Wuhan, diarrhea was one of the clinical presentations[9]. In another study by Gu and his colleague from Shanghai, they described GI manifestations in the form of diarrhea, vomiting, and abdominal pain in COVID-19 patients[10]. With further studies, SARS-CoV-2 RNA was identified in the anal/rectal swabs and stool specimens of COVID-19 patients, even after virus clearance from the upper respiratory tract [11-13]. Genome sequences for SARS-CoV-2 showed that it has about 79.6% similarity to SARS-CoV, encoding and expressing the spike (S) glycoproteins, which help the virus enter human cells through binding to the angiotensin-converting enzyme 2 (ACE2) receptors[14]. ACE2 is highly expressed in type II alveolar cells (AT2) in the lungs and the GI tract, especially the small and large intestines[15]. Previous experience with the severe acute respiratory syndrome (SARS) epidemic in 2003 indicated that coronavirus has tropism in the GI tract. Electron microscopic examination of biopsies and autopsies revealed a rapid increase in the virus in the small intestine and the colon[16,17]. Likewise, Middle Eastern Respiratory Syndrome (MERS in 2013) caused by MERS-CoV can lead to intestinal infection since the human intestinal cells are strongly liable for and support this viral replication[18]. The high susceptibility of the GI tract (GIT) to coronavirus can explain the presence of diarrhea in a proportion of patients infected with COVID-19, despite being less frequent than in SARS. The viral nucleocapsid protein could be stained and identified inside the cytoplasm of epithelial cells of the stomach, duodenum, and rectum[19]. The initial autopsy belonged to an 85-year-old male with COVID-19 revealed areas of dilatation and narrowing of the small bowel[20]. One of the largest and most comprehensive studies evaluating GIT manifestations in COVID-19 patients from Wuhan, with 1141 cases admitted in a single hospital over 7 wk, showed that about 16% of patients presented with GI symptoms only. The most common symptoms were loss of appetite, nausea, and vomiting, which occurred in

about 67% of the patients, diarrhea in 37%, and abdominal pain in 25%[21]. Another study from China stated that 48.5% of patients had GIT symptoms and the most common symptoms were as follows: anorexia (83.8%), diarrhea (29.3%), vomiting (8.1%), and abdominal pain (4.0%), with some patients having multiple symptoms. In this study, 7 patients had only GIT symptoms with no pulmonary symptoms, and those patients needed a longer hospital stay[22]. The same was reported by An *et al*[23], who described 9 adults with COVID-19 who initially presented with only GI manifestations. Five patients became febrile 2-4 d from the onset during their hospital admission, whereas the rest did not show any other symptoms. This should raise awareness about the possibility of SARS-CoV-2 infection in patients presenting with GIT manifestations during the pandemic, which may lead to the spread of infection if not detected early. The last point was specifically mentioned in a separate report describing a patient who suffered abdominal symptoms and was admitted to a surgical department, leading to the infection of more than 10 healthcare workers and 4 patients admitted in the same area[24]. In one of the largest review articles, Yuan and his colleagues analyzed data from 2023 patients, stating whether GI manifestations were present. The incidence of GIT manifestation was between 3% and 79% including anorexia (39.9%-50.2%), diarrhea (2%-49.5%), vomiting (3.6%-66.7%), nausea (1%-29.4%), abdominal pain (2.2%-6.0%), and GI bleeding (4%-13.7%). Both adults and children could present with GI manifestations without pulmonary symptoms. Fecal testing for viral ribonucleic acid (RNA) was as reliable as sputum in detecting SARS-CoV-2. In (36%-53%), fecal polymerase chain reaction (PCR) became positive 2-5 d following positive respiratory specimens. Fecal excretion continued after sputum excretion in (23%-82%) of patients for 1-11 d[25]. Another multicenter study that assessed patients with GIT manifestations in China reported that COVID-19 patients who suffered digestive symptoms had a longer time from symptom onset to admission and evidence of more laboratory derangements, including prolonged coagulation and higher liver enzymes, compared to those without GIT symptoms [22]. In another interesting case report, a 71-year-old woman developed abdominal pain and non-bloody diarrhea, followed by bloody diarrhea, nausea, vomiting, anorexia, and diffuse abdominal pain. Computed tomography showed severe colonic inflammation that was more in the ascending, transverse, and descending colon and had mild right pleural effusion. The patient underwent all investigations as infective diarrhea, which turned negative, and her sigmoidoscopy revealed mild mucosal inflammation. On the 4<sup>th</sup> day of hospital admission, the patient developed cough, and nasopharyngeal swabs turned positive for SARS-CoV-2[26]. The GI presentation of this case differed from all previously reported cases, thus highlighting the importance of taking all precautions when dealing with patients presenting with any GIT complaints during this pandemic.

### **Liver effects on patients with COVID-19**

There are insufficient data for direct viral-related liver injury in COVID-19 cases. Data from one of the biggest centers in China showed that 2%-11% of COVID-19 cases had liver problems, and 14%-53% had abnormal levels of alanine aminotransferase and aspartate aminotransferase during the disease. Patients with severe COVID-19 had higher values of liver enzymes than mild cases with the disease[27]. Some patients from China have undergone autopsies or post-mortem tissue biopsies to identify the nature of liver injury. The first report was for a 50-year-old man who died from severe COVID-19, and the autopsy specimen showed moderate microvascular steatosis with a mild portal and lobular activity in the liver[28]. Other autopsies revealed hepatomegaly with dark and red hepatocyte degeneration and focal necrosis areas. Also, there was neutrophilic and lymphocytic infiltration in the portal area with congested hepatic sinuses and micro thrombosis. No pathological features of liver failure or injury of bile ducts could be detected in these cases[29].

The liver is considered a target for direct infection, as ACE2 is expressed abundantly in cholangiocytes, which leads to direct cytotoxicity[30]. COVID-19 may cause a severe inflammatory response, which leads to the immune-mediated damage of many organs, including the liver, which is evident by increased peripheral blood levels of many inflammatory markers such as ferritin and many cytokines such as interleukin 2 (IL-2) and IL-6. Also, sepsis is a common complication in severe COVID-19 cases, which may lead to hypoxic and ischemic liver injury, cholestasis, and hepatocellular injury due to severe inflammation. Drug-induced liver injury may be a common cause of liver involvement in COVID-19. Many national recommendations are using multiple antiviral drugs such as oseltamivir, umifenovir, chloroquine, tocilizumab, and lopinavir/ritonavir, which can induce liver injury. Most antipyretic drugs contain paracetamol, which is considered a known cause of hepatotoxicity in high doses[31]. Patients with pre-existing chronic liver disease may be more susceptible to liver damage during COVID-19 infection and its sequelae of immune-mediated damage with severe inflammation[32, 33]. It seems that liver enzyme elevations are usually transient, and severe liver injury is rare with COVID-19. To the best of our knowledge, there are no documented deaths due to hepatic decompensation in cases without pre-existing liver disease. However, regular monitoring of the liver profile is warranted, especially in patients with severe COVID-19 infection[34].

### **Hematological effect of COVID-19**

Hematological effects from SARS-CoV-2 are not a recent finding. Cells with ACE2 receptors might be infected first by the virus, including immune cells. Immune cells produce antibodies that can generate immune hemolysis when they contact red blood cells. Hemoglobin is then infected and attacked. The

viral open reading frame 8 (ORF8) and surface glycoprotein can bind to porphyrin. Simultaneously, ORF1ab, ORF10, and ORF3a proteins can coordinate the attack of the beta chain of hemoglobin, leading to the dissociation of iron and the formation of porphyrin. This attack would cause a loss of hemoglobin, which is essential for carrying oxygen and carbon dioxide. The inability to frequently exchange carbon dioxide and oxygen has a too-intense poisoning and inflammatory effect on the lung cells, eventually resulting in characteristic ground glass-like lung images. The virus can also inhibit normal human heme anabolism[9,35].

That is why recent clinical studies believe that viral damage to the human body is systemic, not confined to the respiratory system. Additionally, overt disseminated intravascular coagulopathy (DIC) was found in 71.4% of non-survivors and 0.6% of survivors upon applying the validated International Society on Thrombosis and Hemostasis DIC score from a single center (the median time to DIC detection was 4 d). Based on these preliminary results, it was assumed that DIC can complicate COVID-19 pneumonia and be associated with mortality. Evidence of DIC, especially elevated D-dimer levels, may also be used to guide therapeutic interventions[36]. It was noticed that older patients with lymphopenia and high lactate dehydrogenase (LDH) levels on admission were associated with severe manifestations and required intensive care unit (ICU) admissions. Also, those patients who required ICU stay had a deeper nadir absolute lymphocyte count, nadir absolute monocyte count and nadir hemoglobin, and higher peak absolute neutrophil count and peak LDH levels compared to patients who did not require ICU[37]. Four possible mechanisms can explain why COVID-19 reduces blood lymphocyte levels: The virus might infect lymphocytes directly, resulting in death. The ACE2 coronavirus receptor is expressed on lymphocytes and may be directly targeted by the viruses[38]. The novel coronavirus virus might directly destroy lymphatic organs such as the thymus and spleen, and this hypothesis needs to be confirmed by pathological dissection in the future. Enhanced lymphocyte apoptosis due to inflammatory cytokines release (*e.g.*, tumor necrosis factor alpha, IL-6, and other pro-inflammatory cytokines) could induce lymphocyte deficiency and lymphocyte inhibitions by metabolic molecules such as hyperlactic acidemia produced by metabolic disorders. In severe forms of COVID-19, patients had elevated blood levels of lactic acid, which might suppress lymphocyte proliferation[39]. The mechanisms mentioned above or beyond might work together or separately to cause lymphopenia, so further research is recommended. That is why lymphopenia is considered an effective and reliable indicator of disease severity and an indication for hospitalization in patients with COVID-19[40].

### **Renal manifestations of COVID 19**

Renal involvement in COVID-19 (coronavirus-nephropathy) has a complex etiology. However, some studies suggest that acute kidney injury (AKI) does not complicate COVID-19, but when it occurs in COVID-19 patients, it is associated with higher morbidity and mortality and is a strong indicator of survival[41]. Renal affection is mutual in COVID-19 patients and manifests mainly with proteinuria in about 44% to 63% of patients, hematuria in 26.9% of patients, elevated serum creatinine (SCr) in 15.5% to 19%, and urea blood nitrogen (BUN) in 14.1% to 27% of the patients. AKI was also reported in 3.2% of infected individuals. Computed tomography (CT) scan of the kidneys illustrated that the renal parenchyma's inflammation and edema were evident in all patients. Renal failure in COVID-19 patients had a greater risk of in-hospital mortality. AKI, proteinuria, hematuria, raised plasma creatinine, and urea nitrogen were evident predictors of in-hospital patients' mortality as well[42,43]. Many mechanisms have been suggested to explain how SARS-CoV-2 impacts renal functions, one of which is attributed to dehydration, which may result from fever; and decreased fluid intake, which leads to a reduction of glomerular filtration rate and causes AKI. This can be reversible in early stages by fluid therapy. However, if dehydration leads to hypoperfusion and ischemia, as in cases of cytokine storm, sepsis and shock, acute tubular necrosis might supervene[44,45]. Rhabdomyolysis and hypoxia are other possibilities, as well as direct virus invasion to the renal tubular cells, interstitium, or glomeruli with direct cytopathic effect. Coronaviruses have a three-dimensional spike protein structure, which is closely bound to human cell receptor 2, where it enters into the cells *via* ACE2 receptors, which are vastly expressed in the renal cells. This explains how the renal cells are targeted and infected by SARS-CoV-2. Although the virus-induced glomerulopathy in the coronaviruses family was low, immune complexes deposition of viral particles or virus-induced specific immunological abnormalities is still possible[46,47]. However, another opinion was that COVID-19 does not induce AKI or deterioration of the renal condition in patients with chronic kidney disease (CKD). In a study including 116 cases confirmed with COVID-19, only 10.8% of patients without CKD showed a mild increase in BUN or SCr, and these elevations were all less than 26  $\mu\text{mol/L}$  within 48 h, which does not match with the AKI standard definition. Only 7.2% of the patients without CKD showed mild albuminuria and gradually returned to normal without needing specific treatment[41].

### **Cardiological manifestations of COVID-19**

The cardiovascular system is sometimes involved during the COVID-19 course by different proposed mechanisms, such as direct myocardial injury by binding to ACE2 receptors, which leads to alteration of signaling pathways that result in acute myocardial injury. Another supposed mechanism is the systemic inflammatory response and cytokine storm, which ultimately leads to multiple end-organ damage proven by the high circulatory levels of proinflammatory cytokines in patients with critical COVID-19.

This may also lead to increased coronary blood flow with increased shear stress that can precipitate plaque rupture and increase vascular thrombosis leading to acute myocardial infarction[48,49]. The hypoxia resulting from acute lung injury may cause a significant imbalance of the oxygen demand-supply ratio to the cardiac muscle and increases cardio-metabolic demand. Electrolyte disturbance, especially hypokalemia (of particular concern in patients with COVID-19), adversely affects various therapies, such as antiviral drugs, which affect QT interval prolongation and corticosteroids, and other therapies can also have deleterious effects on the cardiovascular system[50]. Although cardiovascular risk factors do not increase the chance of getting SARS-CoV-2 infection, they inversely affect the prognosis of COVID-19. These risk factors include diabetes, cardio-cerebrovascular disease, and hypertension, and they were associated with a 2-3 fold greater risk of severe disease, respectively, or requiring ICU admission[6]. Acute myocardial injury is the most commonly described cardiac presentation in COVID-19. Different biomarkers cut-offs and/or electrocardiographic abnormalities have been used to define acute cardiac injury. The most commonly used definition is an elevation of high-sensitivity cardiac troponin above the 99th percentile upper reference limit. The incidence of acute myocardial injury is roughly estimated to be 8%-12% among positive cases of SARS-CoV-2 with a robust unfavorable prognosis of COVID-19. The incidence of ST-segment elevation myocardial infarction in COVID-19 patients seems to be lower, as well as the incidence of left ventricular systolic dysfunction, acute left ventricular failure, and cardiogenic shock. Heart failure has been reported in 52% of COVID-19 patients who subsequently died and 12% of patients discharged from the hospital. Tachy- and bradyarrhythmias were also reported in the severe and morbid form of the disease requiring ICU admission, while acute coronary events and left ventricular systolic dysfunction were not reported and seemed to have very low incidence[51-53]. Interestingly, although myocardial injury is significantly associated with the fatal outcome of COVID-19, the prognosis of patients with underlying cardiovascular disease (excluding myocardial) injury is relatively favorable[54].

### **Endocrinal involvement in COVID-19**

Diabetes, hypertension, and metabolic syndrome significantly impact morbidity and mortality in COVID-19. Hyperglycemia and diabetes are associated with suppression of the immune state and increase the risk of infectious diseases. About 51% of COVID-19 patients reportedly have hyperglycemia, similar to what has been observed with other viral infections such as SARS and MERS. The transient pancreatic cell function impairment can explain the mechanism of hyperglycemia in this situation by the virus itself or by modulation in glucose metabolism. The impact of hyperglycemia in SARS-CoV-2 infection cannot be underestimated due to its effect on the immune status and its further complications[55]. About 50%-60% of impaired glucose tolerance and diabetic patients have a higher incidence of pulmonary infections. Diabetic patients carry a high risk of getting SARS-CoV-2 infection. A study from Wuhan concluded that other diseases accompanied 32% of the infected cases; the highest was for diabetes in 20% of cases, followed by hypertension in 15% and cardiovascular disease in 15% of cases[9]. Another study retrospectively analyzed data from 138 COVID-19 patients and found that 46.4% had one or more underlying diseases, of which diabetes was represented in 10% of cases and 22.2% of ICU cases[24]. Unsurprising that patients with diabetes have a high rate of mortality among SARS-CoV-2 infected patients, it reached 77.7% of critically ill COVID-19 patients[56]. Also, of the 72,314 reported cases of COVID-19 in the Chinese Center for Disease Control and Prevention, diabetic patients had a high mortality rate (7.3% in diabetes mellitus *vs* 2.3% overall)[6].

Generally, there are a lack of data about the effect of obesity on COVID-19 patients. However, some hospitals in Spain showed that obese patients infected with SARS-CoV-2 were more susceptible to severe ARDS, respiratory failure, and even death; this can be explained by sleep apnea syndrome and surfactant dysfunction that occur with severe obesity[57]. Undernourished patients are more susceptible to infection with SARS-CoV-2. Also, COVID-19 itself can lead to malnutrition, which affects outcome and prognosis; therefore, COVID-19 outcome could be improved with improved nutritional status[58].

Unfortunately, there are no currently available data about the outcome of COVID-19 patients with adrenal insufficiency; however, it is expected they may have a high risk for acquiring SARS-CoV-2 infection and high incidence of mortality due to defects in their natural immunity, neutrophils, and natural killer cell action[59]. Similarly, few published data are available about the effect of SARS-CoV infection on male gonads and the risk of infertility. Germ cell destruction, few or no spermatozoon in the seminiferous tubules, a thickened basement membrane, and leukocyte infiltration were found in some SARS-COV-infected patients. This may be explained by sharing the same ACE2 receptor to enter the host cells for reproduction and transmission[60]. Whether a similar effect can occur in SARS-CoV-2 infected patients; needs more research to explore.

### **Immune involvement in COVID-19**

Both innate and adaptive immunity are involved in SARS-CoV-2 infection, with lymphopenia being dominant; however, the severely uncontrollable inflammatory response with markedly elevated levels of proinflammatory cytokines such as IL-6 and IL-1 $\beta$ , as well as IL-2, IL-8, and IL-17, known as cytokine storm, has been seen in severely infected COVID-19 patients. This cytokine storm leads to multiple unwanted harmful effects that can be manifested with severe tissue damage, extensive pulmonary destruction, respiratory failure, multi-organ failure, and even death. In addition to elevated levels of

proinflammatory cytokines, complement activation has also been seen to add another immune-based pathology associated with COVID-19; this may contribute to further hope for using complement inhibitors to decrease inflammatory damage[61].

SARS-CoV-2-specific immunoglobulin G (IgG) and IgM antibodies have been detected in high titer upon analysis of 222 and 173 COVID-19-infected patients; this may be explained by an antibody-mediated immune mechanism that has also been observed with many other viral infections. Hopefully, this can be helpful for antibody-based therapies and vaccine development[62].

### **Cutaneous manifestation in COVID-19 patients**

Available data about the skin manifestations of COVID-19 are scarce. COVID-19 patients may initially present with a skin rash, which may be misdiagnosed as other common skin diseases[9]. A study conducted in Italy collected data from 88 COVID-19 patients; 20.4% developed cutaneous manifestations. Eight patients developed skin manifestations at the onset and ten patients after hospitalization. The developed cutaneous manifestations were variable and included: erythematous rash, widespread urticaria, and chickenpox-like vesicles. Lesions were more evident on the trunk. Most of the lesions were itchy and usually healed in a few days. No correlation was observed between disease severity and cutaneous symptoms. This study reported that skin manifestations recorded in COVID-19 patients are similar to those in common viral infections[63]. A case report from Thailand presented a patient with a petechial skin rash that was first diagnosed as dengue fever because of the endemicity of Dengue in Thailand and the presence of thrombocytopenia, later on, the patient developed respiratory symptoms and all viral causes that might be associated with fever, rash, and the respiratory problem was excluded by laboratory investigation. The final diagnosis of the SARS-CoV-2 infection was made using real-time PCR[64]. Urticaria also was reported as a common skin manifestation associated with COVID-19 in Chinese patients[65,66].

### **Neurological and musculoskeletal systems are affected in COVID-19**

Due to the similarities in structure and modes of transmission with SARS-CoV and MERS-CoV, SARS-CoV-2 showed growing evidence of affinity affecting the central nervous system and causing other neurological manifestations. Many early reported data described symptoms of neurological affection, commonly headache, which was severe and intolerable in many cases, dizziness, and unsteadiness of gait[67]. In the first retrospective observational study about the neurological involvement among 214 hospitalized patients in Wuhan, headache was the most common neurologic symptom, affecting 25% of the patients, followed by dizziness in 17%, then a disturbance in their level of consciousness in 8% of cases and acute cerebrovascular events in 3%. Less commonly, ataxia and convulsions occurred in 0.5% of each[68]. In another single-center retrospective observational study, including 221 patients, acute ischemic strokes were found in 5% of patients, with cerebral venous sinus thrombosis in 0.5% and cerebral hemorrhage in 0.5% of cases without the mention of other neurologic deficits. It is worth considering that almost all of these patients were old with accompanying risk factors like hypertension and diabetes mellitus[69]. It was suggested that metabolic and electrolyte imbalances, along with the accompanying hypoxia and/or multiple organ failure in critically ill patients, might represent a plausible explanation for altering mental status[70]. The presence of seizures ranging from subtle subclinical forms to clinically overt seizures and status epilepticus in many patients points to the possibility of having non-convulsive status epilepticus as an explanation, and hence the importance of electroencephalogram monitoring of such patients and the application of Salzburg Consensus Criteria for Non-Convulsive Status Epilepticus[71].

Moreover, some reports have linked Guillain-Barré syndrome and post-infectious acute myelitis to COVID-19. A similar para-infectious association with the Zika virus encouraged the suggestion of a phenomenon with COVID-19 instead of the classic post-infectious form[72,73]. The current piling data and reports of COVID-19 render the pandemic's central nervous system and other neurological manifestations more than just an epiphenomenon as concrete evidence is accumulated. The first reports of substantial evidence include a case of a 24-years-old man who presented with fever and fatigue. COVID-19 RNA was not detected in his nasopharyngeal swab until the 9<sup>th</sup> day when he was found unconscious and soaking in his vomit with evident neck stiffness and was diagnosed with meningoencephalitis. Despite the negative nasopharyngeal swab, COVID-19 RNA was found in his CSF fluid, while his serum varicella-zoster IgM and anti-herpes simplex virus type 1 were negative. Furthermore, magnetic resonance imaging showed hyperintensity signals in the right lateral ventricle, hippocampus, and right mesial temporal lobe, linking SARS-CoV-2 with his illness[74].

### **Psychiatric manifestations**

During the COVID-19 pandemic, additional anxiety results from fear of acquiring infection, especially in the presence of uncertainty, whether other modes of transmission than droplet infection exist. The uncertain incubation period of the virus and its possible asymptomatic transmission can also cause additional stress. The obligation to social distancing in many countries worldwide resulted in changes in national behavioral patterns and the shutdown of the usual day-to-day functioning[75]. Additionally, reports of shortages in medical protective equipment, medical staff, and hospital beds have raised major

worries worldwide. Lastly, a unique “infodemic” due to a plethora of information from unofficial and unreliable sources poses a significant risk to public mental health during this crisis[76].

The spectrum of psychological distresses can be classified into immediate and long-term effects. Immediate stress during an infectious disease outbreak can include fear and worriedness about a person’s health and the health of his family; changes in sleep or eating patterns; difficulty sleeping or concentrating; worsening of chronic health problems; worsening of mental health conditions; and increased use of alcohol, tobacco, or illicit drugs[77]. Panic disorders (resulting from fear of the unknown and the unpredicted) and infomania (the obsessive demand to frequently check media) can also be among the immediate effects. Stigma, xenophobia, and racism related to COVID-19 may also occur. Increased fear and suspicion towards people from China and other countries in which SARS-CoV-2 had widely spread led to social stigmatization and refusal to house, employ, or provide health care for certain races. Theories of conspiracy (mistrust, the detection of real and hidden designs, and the meaning behind the apparent causes) are also present. They have widely spread during the COVID-19 pandemic as different accusations of the virus as a biological war or designed to create an economic crisis are widespread[78]. Studies assessing mental health during the SARS outbreak in 2003 found that the main psychiatric problems were adjustment reactions with increased anxiety levels. Studies have also shown that 10%-35% of SARS survivors reported having features of anxiety, depression, or both during the early recovery phase[79].

Long-term psychiatric consequences of SARS-CoV-2 are still unknown; guided by the last SARS epidemic in 2003, a significant impact on mental health can be expected. In 2003, posttraumatic stress disorder was the most typical psychiatric condition as its cumulative incidence rate of 30 mo after SARS was (47.8%) and then depressive disorders were the second most common impact[80]. Healthcare workers (HCWs) carrying the responsibility to provide care to infected patients and to search for the best therapies for unknown dangerous pathogens are put under significant stress in addition to being exposed to infection. Exposure to infected patients necessitates the social isolation of HCWs with its added psychiatric consequences. When HCWs become infected and turn out to be patients, this change in their role leads to behavior adjustment challenges, frustration, and feeling of helplessness[81].

### **Special senses**

Anosmia and ageusia (loss of smell and taste, respectively) were reported as frequent symptoms in patients with COVID-19[82]. In Italy, of 59 patients with COVID-19, 34% self-reported either smell or taste alteration, and 19% reported both[83]. The same finding was reported by a European multicenter cross-sectional study that showed that out of 417 mild-to-moderate COVID-19 patients, 85.6% reported smell dysfunction, and 88% reported taste dysfunction[82]. An American study on 237 COVID-19 patients showed that anosmia was experienced in 73% of subjects before COVID-19 diagnosis, and it was the initial symptom in about 27% of them[84]. Quantitative smell testing of confirmed 60 COVID-19 patients showed that 98% have some smell dysfunction but not always anosmia[85]. Considering these symptoms as characteristic early diagnostic features of COVID-19 is controversial as the earlier data from China did not stress olfactory or taste disorders in COVID-19 patients. The increasing evidence on the importance of olfactory and gustatory symptoms as a precedent event to the full-blown clinical disease suggests its use as a clinical screening tool to determine the need for early testing, treatment, or quarantine of asymptomatic individuals.

### **Ophthalmic manifestations**

COVID-19 transmission through the ocular route remains uncertain[86]. Animal studies showed that coronaviruses, including SARS-CoV-2, can produce a broad spectrum of ocular manifestations from diseases that involve the anterior segment, like conjunctivitis and anterior uveitis, to posterior segment conditions like retinitis and optic neuritis[87]. The human eye has its intraocular renin-angiotensin system, as ACE2 was detected in the aqueous humor[88]. However, the expression of ACE2 in the conjunctiva or cornea is not well documented. So, ocular infection through ACE2 should be further investigated. A Chinese case series showed that about one-third of patients with COVID-19 had ocular abnormalities. Their ocular manifestations varied between epiphora, conjunctival congestion, or chemosis and were encountered in patients with advanced systemic manifestations[89]. Few case reports have described acute conjunctivitis as a presenting symptom of COVID-19 patients[90,91].

### **Audio vestibular manifestations**

Viral infections are well known for causing sensorineural hearing loss. The evidence of inner ear involvement in COVID-19 patients is scarce and needs further studies. In a recent pilot study that explored the audiological profile of asymptomatic COVID-19 PCR-positive cases, the authors reported a significant worsening of the high-frequency pure-tone thresholds, as well as the transient, evoked otoacoustic emissions amplitudes. This indicates suspected deleterious effects of COVID-19 on the hair cells in the cochlea, but larger studies and follow-ups of these patients after recovery are pivotal to determining the exact mechanism and fate of these effects[92]. Furthermore, Fidan and his colleagues reported a 35-year-old female patient with otalgia and tinnitus. None of the classic COVID-19 symptoms with no comorbidities upon investigation proved to have acute otitis media, bilateral lung involvement

in chest X-ray, and positive RT-PCR result for SARS-CoV-2[93].

## CONCLUSION

In this review article, we highlighted multisystemic involvement of COVID-19 infection. Involvement of various body systems and organs apart from the respiratory tract, including the GI, liver, immune system, renal, and neurological systems have been reported with COVID-19 infection.

## ACKNOWLEDGEMENTS

The authors acknowledge the tremendous effort and sacrifice of the medical staff working in COVID-19 quarantine hospitals worldwide.

## Abstract

Impaired wound healing presents great health risks to diabetics. Encouragingly, the current clinical successfully found out meaningful method to repair wound tissue, and stem cell therapy could be an effective method for diabetic wound healing with its ability to accelerate wound closure and avoid amputation. This minireview aims at introducing stem cell therapy for facilitating tissue repair in diabetic wounds, discussing the possible therapeutic mechanism and clinical application status and problems.

**Key Words:** Stem cell; Diabetic wound; Wound healing; Immunoregulation

**Core Tip:** Diabetic wound is a common complication of diabetes and stem cell therapy is an effective treatment for diabetic wounds. It helps improve wounds mainly by regulating inflammation and blood circulation. At present, many kinds of stem cells have been used and studied, and good results have been achieved. However, there are still problems that need to be solved. Here we discuss the current role and progress of stem cells in the treatment of diabetic wounds.

## INTRODUCTION

Diabetes with neurological abnormalities as well as peripheral artery disease of the lower extremities[1] can lead to diabetic wounds, particularly diabetic foot ulcers, which are considered one of the most serious complications. The international diabetes federation (IDF) reported that in 2021, there were nearly 536.6 million people living with diabetes[2], and the global diabetic foot ulcer prevalence was 6.3%[3]. Due to some risk factors, including poor glycemic control, peripheral neuropathy, peripheral vascular disease and immunosuppression[4], the progression of diabetic wounds can be accelerated, often resulting in complications demanding an amputation. At present, the treatment for diabetic wounds includes improving vascularization, debridement with pharmacological therapy, negative pressure wound therapy or using growth factors and skin substitutes, aiming at epithelial growth across the ulcer bed[4-7].

Stem cell therapies for wounds have vast prospects by using autologous or allogeneic stem cell transplantation for wound closure. It has been shown to help at all stages of wound healing and plays an important role in inflammation regulation, increasing both epithelialization and angiogenesis[8-11]. This minireview concentrates on the progress of stem cell therapy for facilitating tissue repair in diabetic wounds.

## POSSIBLE MECHANISM OF STEM CELL THERAPY

Diabetes patients often suffer hyperglycemia, chronic inflammation, microvascular and macrovascular dysfunction, autonomic and sensory neuropathy, hypoxia and impaired neuropeptide signaling[12]. Necroptosis and apoptosis can be increased by reactive oxygen species (ROS), advanced glycation end products and methylglyoxal, leading to diabetes complications[13]. Long term hyperglycemia leads to metabolic disorders because of the activation of additional polyol glucose metabolic pathway and the accumulation of toxic sorbitol in nerve tissue cells increases, leading to vascular damage[14,15]. With diabetic peripheral neuropathy as well as peripheral artery disease playing a central role, diabetes patients frequently suffer diabetic foot ulcer[16]. At present, stem cell therapies have been reported to contribute to diabetic wound healing in the following ways.

## POSSESSING THE FUNCTION OF ANGIOGENESIS

First, stem cells help secrete vascular endothelial growth factor (VEGF), which promotes angiogenesis and the differentiation of endothelial progenitor cells into endothelial cells[17] and the extracellular matrix through the PI3K/threonine kinase (AKT) signaling pathway[18,19]. And they increase epithelialization, granulation tissue formation and capillary formation[20]. In a high glucose environment, stem cell-secreted exosomes contribute to angiopoiesis in endothelial progenitor cells, and overexpression of the transcription factor nuclear factor-E2-related factor 2 synergizes as a protective factor[21]. Moreover, including angiopoietin-1 (Ang-1), stromal cell-derived factor 1, inducible nitric oxide synthase (iNOS), epidermal growth factor (EGF), keratinocyte growth factor 2, erythropoietin, insulin-like growth factor 1 (IGF-1), basic fibroblast growth factor and placental growth factor, there are still many paracrine cytokines helping angiopoiesis, improving microcirculation in diabetic foot ulcer[22-24].

## MODULATING INFLAMMATION

Stem cells are able to switch classically activated macrophages, which are called M1 macrophages and have proinflammatory effects, into optionally activated macrophages, which are called M2 macrophages and have anti-inflammatory effects[8,25-27]. In addition, it has been shown that together with exosomes, stem cells can decrease oxidative stress injuries of endothelial cells, providing immunomodulatory effects[28], and the level of Tregs is also upregulated at the same time[29,30]. Cytokines also play an important role in inflammation, and stem cells have the ability to lower the levels of proinflammatory cytokines, including interleukin-1 (IL-1), IL-6, IFN- $\beta$  and TNF- $\alpha$ , while increasing the levels of anti-inflammatory cytokines, such as IL-10 and IL-4[31,32]. In a recent study mesenchymal stromal cells (MSCs) expressing IL-6, signaled by activating STAT-3 transcription factor, inhibited ROS by protecting neutrophils from apoptosis, preserving the excessive or inappropriate activation of the oxidative metabolism[33].

## IMPROVING THE REMODELING PHASE

By cell differentiation, stem cells can translate into keratinocytes as well as endotheliocytes[34]. It has been reported that microvesicles from stem cells help to reprogram injured cells, thus achieving differentiation[35]. Recent studies have shown that stem cells might offer an important early signal to dermal fibroblast responses for their proliferation and migration[9,18]. Additionally, they lower the levels of matrix metalloproteinase-9 (MMP-9) to decrease proteolysis[36]. By reducing expression of phosphorylated focal adhesion kinase and increase the levels of MMP-2, EGF and IGF-1, MSCs improve the function of keratinocytes[37].

## REGULATION OF MICRORNAS

MicroRNAs (miRNAs) have been discovered regulators of gene expression in the regulation of inflammation[38]. Generally, miRNAs promote wound healing by activating multiple pathways directly or indirectly. For example, after MSC treatment it is found that the increased levels of miR-146a result in attenuating expression of proinflammatory and inflammatory genes, including IL-1 receptor-associated kinase 1 (IRAK1), TNF receptor-associated factor 6 (TRAF6), and nuclear factor- $\kappa$ B (NF- $\kappa$ B)[39]. MSCs also enhance diabetic wound healing by improving collagen I content through increasing miR-29b expression[36]. A research has revealed that miR-21-5p promoted angiogenesis through upregulations of vascular endothelial growth factor receptor, activations of serine/ AKT and mitogen-activated protein kinase[40]. In addition, miR-126-3p from MSCs contributes to wound healing by increasing the formation of granulation tissue and angiogenesis[41]. MiRNA mediates the cell microenvironment, regulates the biological activity and phenotype of specific target cells, induces changes in the function of target cells, and leads to a series of biological reactions to play a variety of biological functions[42,43].

In conclusion, stem cells accelerate diabetic wound healing in many ways. Nevertheless, more connections between stem cells and diabetic wounds are under exploration.

## STEM CELL THERAPIES FOR DIABETIC WOUNDS IN CLINICAL WORK

Over the past few years, it has been revealed that different types of stem cell therapies have been used in clinical work[44], as shown in Table 1. Although clinical data drew the conclusion that using stem cells benefits diabetic wounds, various types of stem cells with diversified methods still need to be identified. Attention should be given to adverse effects that have appeared in some research. For example, increased exudation from diabetic wounds may be associated with stem cells[45]. However, some clinical studies and analyses support its safety[46-48]. There are several types of cells used in clinical work. For example, adipose-derived mesenchymal stromal cells (ADMSCs) have been proven to be able to accelerate the time to wound closure[49] and the level of wound healing[50]. By intravascular and intralesional injection, umbilical cord mesenchymal stromal cells (UCMSCs) can not only improve the completion of wound closure[51] but also increase the number of vessels[52]. One case in which bone marrow mesenchymal stem cells (BMMSCs) were used for diabetic wound healing showed a good result in the next 10 years[53]. In addition, it has been revealed that BMMSC therapy might be better tolerated and more effective than bone marrow-derived mononuclear cells (BMMNCs) for increasing lower limb perfusion and promoting foot ulcer healing in diabetic patients with critical limb ischemia [54]. By treating with different doses of granulocyte colony stimulating factor (G-CSF), peripheral blood stem cells can be gained to promote the establishment of collateral circulation[55].

Although stem cell therapy has been shown to be a relatively safe treatment for diabetic wounds, unavoidable transplantation complications have appeared in diabetics, including febrile neutropenia, alopecia and gastrointestinal reaction[56]. A clinical trial reported one diabetes patient died of pseudomonas sepsis in the course of neutropenia after autologous hematopoietic stem cell transplantation[57]. Thus, complications as well as adverse events still can't be ignored while the safety of stem cell transplantation has been reported in some studies[58].

## CONCLUSION

Stem Cell therapy could be an effective treatment for diabetic wounds[59,60], which contains endless medical value together with a wide scientific perspective accelerating diabetic wound healing. Stem cells have also demonstrated their therapeutic potential in the field even if infection is present[61]. However, there are still problems that need to be solved.

First, the mechanisms of stem cell therapy are still considered as a vital part of the theoretical basis of clinical study. Although animal experiments and clinical trials provide us with great results, studies based on the molecular level should be carried out to gain more molecular mechanisms.

**Table 1** Recent clinical trials regarding stem cell therapies for diabetic wounds

Ref.	Type of stem cells	Number of cases	Mean age (year)	Methods of treatment	Possible mechanism	Outcome	Adverse events	Conclusion
Uzun <i>et al</i> [49], 2021	ADMSCs	10	57.5	Intralesional injection	The release of angiogenic cytokines, increasing epithelialization, granulation tissue formation, anti-inflammatory, and anti-apoptotic effects	Time to wound closure (d): ADMSCs group ( $n = 10$ ): $31.0 \pm 10.7$ ; Control group ( $n = 10$ ): $54.8 \pm 15.0$ ; $P = 0.002$	No found	Allogeneic ADMSCs injection is a safe and effective method with a positive contribution to wound-healing time in the treatment of chronic diabetic foot ulcers
Suzdaltseva <i>et al</i> [51], 2020	UCMSCs	31	58.5	Intralesional injection	The release of angiogenic cytokines, cell differentiation, and immunomodulation	Complete wound closure or significant improvement (% in group) <sup>a</sup> : UCMSCs group ( $n = 59$ ): 22%; Placebo group ( $n = 49$ ): 8.2%; $P < 0.05$	No found	Locally delivered allogeneic UCMSCs can contribute to chronic wound repair and provide an additional support toward new therapeutic strategies
Moon <i>et al</i> [50], 2019	ADMSCs	30	59.9	Topical	Synthesizing higher amounts of collagen, fibroblast growth factor, and vascular endothelial growth factor in vitro	Complete wound closure at Week 12 (% in group): ADMSCs group ( $n = 30$ ): 82%; Control group ( $n = 29$ ): 53%; $P < 0.05$	No found	Allogeneic ADMSCs might be effective and safe to treat diabetic foot ulcers
Chen <i>et al</i> [53], 2018	BMMSCs	1	64	Intramuscular injection	The release of angiogenic cytokines, differentiation and angiogen	No recurrence in the next 10-yr follow-up span	No found	Autologous BMMSC transplantation therapy may be an effective measure for recurrent bullosis diabeticorum
Qin <i>et al</i> [52], 2016	UCMSCs	28	75	Intravascular and intralesional injection	The release of signalling or growth factors, and differentiation of injected precursor cells into functional tissue	Increased number of vessels: Experimental group ( $n = 28$ ): $9.3 \pm 2.7$ ; Control group ( $n = 25$ ): $5.9 \pm 3.3$ ; $P < 0.05$	No found	UCMSC transplantation after angioplasty is a safe and effective clinical therapy for severe diabetic foot
Xu <i>et al</i> [55], 2016	Peripheral blood stem cells	63	69	Intralesional injection	Angiogenesis and vascularization	CTA score <sup>b</sup> : Pre-transplantation ( $n = 63$ ): $1.22 \pm 0.15$ ; Post-transplantation ( $n = 63$ ): $2.35 \pm 0.784$ ; $P < 0.01$	No found	Autologous peripheral blood stem cell transplantation can promote the establishment of collateral circulation in patients with diabetic foot
Lu <i>et al</i> [54], 2011	BMMSCs	18	63	Intramuscular injection	The release of angiogenic cytokines, differentiation and angiogenesis	Angiographic score of MRA in limbs at 24 wk <sup>b</sup> : BMMSCs ( $n = 18$ ): $1.9 \pm 0.5$ ; BMMNCs ( $n = 19$ ): $1.5 \pm 0.6$ ; $P = 0.018$	No found	BMMSCs therapy may be better tolerated and more effective than BMMNCs for increasing lower limb perfusion and promoting foot ulcer healing in diabetic patients with critical limb ischemia

<sup>a</sup>108 patients, including 31 patients (28.7%) suffering from diabetic foot, were randomized to the umbilical cord mesenchymal stromal cell group and placebo group.

<sup>b</sup>0 points, no new collateral vessels; 1 point, little new collateral circulation; 2 points, moderate new collateral circulation; 3 points, abundant new collateral circulation.

ADMSCs: Adipose-derived mesenchymal stromal cells; UCMSCs: Umbilical cord mesenchymal stromal cells; BMMSCs: Bone marrow mesenchymal stem cells; CTA: Computed tomography angiography; MRA: Magnetic resonance angiography; BMMNCs: Bone marrow-derived mononuclear cells.

Second, the safety of treatment cannot be ignored, although only a few adverse events have been reported, which urges more clinical trials. At the same time, more specific therapeutic doses and administration routes should be revealed, which accounts for how to reduce side effects and adverse reactions. For example, on account of its differentiative capacity, surgical dressing with stem cells may have the ability to decrease bleeding as well as accelerate operative incision closure, since it has been reported that advanced dressings for the delivery of progenitor cells are at the point in research[62]. Moreover, considering patients with cancer who cannot receive stem cell treatment[63], alternative solutions need to be identified.

Third, it is still important for physicians to simplify the approach of gathering as well as preconditioning stem cells because preconditioning MSCs with pretreatment agents significantly hastened healing in delayed-healing wounds[64]. In addition, evidence has shown that the ability of stem cells in elderly people to proliferate and differentiate diminishes with age[65]. Therefore, the differences between autotransplantation and allotransplantation should be taken into consideration to improve the success rate of transplantation.

Last, the questions of ethics also matter. Promising and effective stem cell therapy has raised serious ethical problems[66]. Not only do social responsibility and moral constraints regularize approaches of treatment, but relevant laws and medical guidelines also need to be improved.

The answers to these questions will lead to better and more appropriate treatments for different patients.

## FOOTNOTES

### Abstract

Coronavirus disease 2019 (COVID-19), caused by severe acute respiratory syndrome coronavirus 2, broke out in December 2019 in Wuhan city of China and spread rapidly worldwide. Therefore, by March 2020, the World Health Organization declared the disease a global pandemic. Apart from the respiratory system, various other organs of the human body are also seriously affected by the virus. Liver injury in patients with a severe form of COVID-19 is estimated to be 14.8%-53.0%. Elevated levels of total bilirubin, aspartate aminotransferase and alanine aminotransferase and low levels of serum albumin and prealbumin are the main laboratory findings. Patients with pre-existing chronic liver disease and cirrhosis are much more prone to develop severe liver injury. This literature review presented the recent scientific findings regarding the pathophysiological mechanisms responsible for liver injury in critically ill patients with COVID-19, the various interactions between drugs used to treat the disease and the function of the liver and the specific tests providing the possibility of early diagnosis of severe liver injury in these patients. Moreover, it highlighted the burden that COVID-19 put on health systems worldwide and its effect on transplant programs and the care provided to critically ill patients in general and particularly to those with chronic liver disease.

**Key Words:** Coronavirus disease 2019; Severe acute respiratory syndrome coronavirus 2; Liver disease; Intensive care unit; Liver unit; Prealbumin

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core Tip:** The liver follows the respiratory system with a lower but considerable frequency of affection by severe acute respiratory syndrome coronavirus 2. Coronavirus disease 2019 causes acute and acute-on-chronic liver injury. The pathophysiological mechanisms are complex. Certain biomarkers such as fibrosis-4 score and non-invasive point-of-care methods such as ultrasonography or transient elastography can be extremely helpful in the early diagnosis of liver injury and the assessment of its progression. Health systems, intensive care units, liver units and transplant programs were seriously affected by the pandemic. The clinician should recognize the symptoms and signs of liver injury early and take the appropriate measures to reverse it.

## INTRODUCTION

In December 2019, an epidemic of pneumonia of unknown origin broke out in Wuhan city, in the Hubei province of China, causing global concern because of its ease of transmission and the significant rates of morbidity and mortality that accompanied it. To diagnose and control this highly infectious disease, patients were immediately isolated, and their clinical and epidemiological data were studied thoroughly. The immediate mobilization of the global scientific community rapidly identified the cause (severe acute respiratory syndrome coronavirus 2 [SARS-CoV-2]) of coronavirus disease 2019 (COVID-19)[1]. In the immediate aftermath, the disease spread very rapidly to all the regions of the world, forcing the World Health Organization to declare the COVID-19 outbreak as a “global pandemic” on March 11, 2020.

Over the next years, the pandemic greatly affected the health systems of all the countries of the world causing until September 16, 2022 more than 611550000 cases and more than 6525000 deaths[2,3]. SARS-CoV-2 has been associated with three primary modes of transmission, known as “contact,” “droplet” and “airborne” transmission[4].

Among the organs affected by COVID-19 is the liver, with several early scientific reports describing various degrees of liver dysfunction and injury[5]. The liver is responsible for the regulation of levels of many chemical substances and biomarkers in the human blood, carrying out crucial functions including but not limited to: the production and excretion of bile; the excretion of bilirubin, cholesterol, hormones and drugs; the metabolism of fats, proteins and carbohydrates; enzyme activation; the storage of glycogen, vitamins and minerals; synthesis of plasma proteins, such as albumin and clotting factors; the conversion of ammonia to urea; blood detoxification and purification; and the metabolism of hemoglobin for the use of its iron content. Chronic liver diseases are prevalent all over the world, imposing a significant burden on healthcare systems. According to Mohammed *et al*[6], patients with known chronic liver disease present a higher risk of complications from COVID-19 in comparison with the general population, with a mortality rate as high as 12%. Mortality from secondary liver injury in the intensive care unit (ICU) is significantly higher, ranging between 27%-48% for critically ill patients with cholestasis and between 40%-60% for critically ill patients with hypoxic liver injury[7].

This literature review presented the recent scientific findings regarding the pathophysiological mechanisms responsible for the induction of liver injury in critically ill patients with COVID-19, the various interactions between drugs used to treat the disease and the function of the liver, the tests providing the possibility of early diagnosis of severe liver injury in these patients, and the effect of the pandemic on health systems, transplant programs and critically ill patients with or without pre-existing chronic liver disease.

An advanced search strategy was made to identify studies published until August 2022 using the key words “COVID-19,” “Liver” and “Intensive Care Unit” in the PubMed electronic bibliographic database. Initially, 560 studies were identified. These studies were reviewed based on their title and abstract, thus excluding 301 studies. The full texts of the remaining 259 studies were assessed for

eligibility based on their relevance to the subject of our review, particularly focusing on critical illness and liver disease. Most of these studies were excluded because they referred to patients with mild or moderate COVID-19. A total of 97 studies were finally included and analyzed for this systematic review. Overall, limited evidence exists regarding liver disease, critical illness and COVID-19.

## EFFECT OF COVID-19 ON THE LIVER

SARS-CoV-2 just like its predecessors SARS-CoV (responsible for the SARS epidemic in 2003) and MERS-CoV (responsible for the Middle East respiratory syndrome epidemic in 2012) is a coronavirus and shares sequence homology and genome similarities with them[5]. The main symptoms caused by SARS-CoV-2, affecting men more severely than women, include fever, upper and lower respiratory symptomatology (cough, rhinorrhea, sore throat, flu-like symptoms and dyspnea), general muscle aches, anosmia, ageusia and increased likelihood of occurrence of vascular thrombosis.

Several reports regarding SARS-CoV and MERS-CoV reported that both of them caused liver injury in a significant number of patients. For example, Chau *et al*[8] reported 3 cases of hepatitis directly associated with SARS disease and revealed that various degrees of impairment of liver function had been reported in up to 60% of the patients suffering from SARS. Alsaad *et al*[9], after 14 years reported portal and lobular hepatitis at post-mortem histopathological findings in a 33-year-old male patient who died from MERS-CoV infection.

In May 2020, the results of a multicenter observational cohort study from 208 hospitals in the United Kingdom (20133 patients) were published. They investigated the outcome of patients with severe disease who were admitted to these hospitals[10]. Their median age was 73 years (range: 0–104 years), and 60% of them were men. The mortality rate in the cohort was 26%, whereas 41% of the patients were discharged alive, and the rest (34%) continued to be hospitalized at the end of the study. Liver disease was among the pathological conditions associated with increased in-hospital mortality, along with sex (male sex), age, obesity and chronic pulmonary, chronic kidney and chronic cardiac diseases.

Liver injury caused in patients severely affected by COVID-19 is estimated to be at levels of 14.8%–53.0%[11]. The imaging findings in these patients include hepatomegaly, gall bladder thickness and prominence of the common bile duct in the ultrasonography, along with pericholecystic fat stranding and hypodensity of the liver in the computed tomography (CT) images[12].

According to Nardo *et al*[13], the most likely pathophysiological mechanisms involved in causing liver injury after severe infection from SARS-CoV-2 are as follows:

(1) Moderate hepatic steatosis: There is growing evidence that SARS-CoV-2 modifies the function and the activity of the mitochondria, downregulating nuclear-encoded mitochondrial genes that are associated with cellular respiration[14]. Another cause of steatosis seems to be the induction of endoplasmic reticulum stress by SARS-CoV-2, which in turn has been shown to cause lipogenesis in the hepatic cells[15]. Finally, another proposed possible mechanism is directly associated with the characteristic “cytokine storm”/cytokine release syndrome (CRS) observed in the severe forms of COVID-19. Interleukin (IL)-6 produced by the cytokine storm most probably causes hyperactivation of the mammalian target of rapamycin, which can induce lipogenesis inside the hepatic cell[16]. In conclusion, the above-mentioned process of excessive lipogenesis seems to be detrimental to the function of the hepatic cell and the liver as a whole, and on the other hand it enhances the potential of the virus, providing it with the necessary nutrient material to achieve its replication and exocytosis[13,17].

(2) Cholestasis and bile duct alterations: Apart from IL-6, during the cytokine storm a large number of other inflammatory cytokines are released, including IL-1 and tumor necrosis factor- $\alpha$ . These cytokines cause hepatocellular cholestasis, closely resembling cholestasis observed in severe cases of sepsis[18]. An additional pathophysiological lesion that has been observed in these patients comes from the so-called “triple hit” to the bile ducts, consisting of hypoxia due to respiratory failure, systemic inflammatory response syndrome resulting in inflammation and fibrosis of the bile ducts and direct infection of the cholangiocytes from the virus[19].

(3) Hypoxic hepatitis (HH): Pathophysiologically, the causes of HH during the course of severe COVID-19 are multifactorial, including acute respiratory failure, severe sepsis, heart failure, including right-sided heart failure, acute respiratory distress syndrome (ARDS), a hyper-coagulate state, deteriorating the congestion of the liver and the hemodynamic effects of positive-pressure ventilation[20].

(4) The gut-liver axis: Symptomatology from the gastrointestinal tract is common in patients with severe COVID-19, with relevant rates ranging from 4.9% to 74.0%. The most common symptoms are nausea, vomiting, diarrhea, loss of appetite and abdominal pain[21]. It is speculated that the damage caused by SARS-CoV-2 to the epithelial barrier of the small intestine may lead to the transmission of the virus into the hepatocytes through the portal vein, aggravating the lesions of the liver parenchyma. In addition, alterations in gut microbiota caused either by drugs for COVID-19 or by the virus itself may play a significant role through the gut-liver axis.

(5) Injury induced by treating medications: As SARS-CoV-2 is novel to the scientific community and no specific therapy for COVID-19 has been found, numerous different drugs have been used in several cases outside their officially approved indications. Typical examples are the antimalarial drug hydroxy-

chloroquine, antibiotics (mainly from the family of macrolides), antiviral agents such as lopinavir, ritonavir and remdesivir, immunomodulating medications such as tocilizumab and dexamethasone and even anti-inflammatory and antipyretics in high doses[22]. Many of them presented already-known hepatotoxic side effects. For example, corticosteroids have been implicated as a cause of glycogenosis or steatosis[23], whereas tocilizumab is reported to cause drug-induced liver injury (DILI) in critically ill patients with COVID-19[24]. Specific reference should be made to paracetamol, the most commonly used analgesic and antipyretic medication in the elderly, prescribed in many cases in high doses and for a long time. According to Mian *et al*[25], old age and frailty decrease the clearance of paracetamol at percentages of 29.0%-45.7%, varying between 0.20-0.38 L/h/kg in older patients in comparison with values between 0.28-0.7 L/h/kg in younger patients. Another important influence of aging is on the volume of distribution of paracetamol, which decreases in older patients because of its incomplete distribution into body fat, with a consequent increase in the plasma concentration of paracetamol in the elderly.

In the United States of America, severe DILI presents the leading cause of acute liver failure (ALF), ahead of all the other causes even viral hepatitis. More than 1000 pharmaceutical agents have been identified as causes of serious liver disease, a figure that will increase significantly in the near future, as the pharmaceutical industry is constantly developing new drugs for use by the general population and patients. There are two main types of adverse reactions induced by drugs[26,27]: (1) Type A (intrinsic adverse reactions) are dose dependent and produce predictable toxicities; and (2) Type B (idiosyncratic adverse reactions) are difficult to be explained by their pharmacologic response or their dose and are associated with patient, drug or environmental risk factors, making them difficult to be predicted.

In order to predict the occurrence of a severe DILI early and take the appropriate preventive measures, various methods have been proposed. Hy's Law is one of the most commonly used, named after Dr. Hyman Zimmerman. It is based on the observation that patients with elevated serum total bilirubin who have received a medication causing hepatocellular (not hepatobiliary) injury, with the absence of other possible causes that could explain these disorders, are at high risk for fatal or requiring transplantation DILI, with mortality ranging between 10%-50%[28]. Another valuable tool is the LiverTox free online database, which allows clinicians to be informed about the latest data of the hepatotoxicity of various pharmaceutical agents, while at the same time they are assisted in the diagnosis and treatment of DILI[29].

Another important area of scientific research is the way by which liver dysfunction of any etiology has the potential to affect the accumulation and the toxicity of various drugs. According to Bosilkovska *et al*[30], the physiologic changes that accompany any hepatic impairment alter the disposition of most of the drugs. Portosystemic shunting decreases the initial metabolism, increasing the oral bioavailability of highly extracted drugs, whereas a coexisting disorder in the production of drug-binding proteins can change the distribution of the drug. In addition, both the amount and the function of enzymes that are produced by the liver and are responsible for the metabolism of drugs are affected by hepatic damage. The final result is the reduction of drug clearance, along with increased plasma drug concentration, which are both difficult to be predicted. Thus, the pharmacologic properties of most of the drugs are altered during severe liver disease.

In conclusion, the mechanism of liver injury during COVID-19 is twofold[31]. Either SARS-CoV-2 directly attacks the hepatic cells and the cholangiocytes, or it causes damage to the liver parenchyma by activating (and dysregulating) the patient's immune system, probably in a similar way to the severe lung injury caused by the cytokine storm process. In several cases, the damage is caused by a combination of the above two mechanisms. In other cases, the liver is affected by the medication used against COVID-19.

The histopathological features that have been described in critically ill patients with COVID-19 and concurrent hepatic involvement are various and, in most cases, nonspecific. Characteristic and specific for the disease is the detection of SARS-CoV-2 RNA in liver tissue in up to 55% of patients with severe liver injury[32]. Lagana *et al*[32] in a series of 40 critically ill patients who died from complications of COVID-19 reported that the most common hepatic histopathological findings were: (1) Macrovesicular steatosis (75% of the patients); (2) Lobular and portal necroinflammation (50% of the patients); and (3) Vascular pathology (primarily sinusoidal microthrombi) in a significantly smaller number of patients (15%). Finally, in another post-mortem report, the commonest findings in 22 critically ill patients who died from the disease were liver parenchymal congestion along with sinusoidal congestion and congestion of the small hepatic veins, extravasation of red cells into the Disse's space, necrosis of a large number of hepatic cells and macro- and micro- vacuolar steatosis[33]. Nevertheless, all the above-mentioned findings seemed to be because of the combination of the organism's systemic response to inflammation and its comorbidities, rather than the direct action of SARS-CoV-2 on the liver[34].

## DIAGNOSTIC AND PROGNOSTIC TOOLS FOR LIVER INJURY IN PATIENTS WITH COVID-19

Studies on the evolution of liver injury from SARS-CoV-2 and on factors that can predict the outcome

are relatively few. Various outcome measures have been studied[35] including liver function tests (LFTs). A broad spectrum of abnormal LFTs has been described in patients with COVID-19. Aminotransferases (aspartate aminotransferase [AST] and alanine aminotransferase [ALT]), alkaline phosphatase, gamma-glutamyl transpeptidase (GGT) and bilirubin have been the most extensively studied markers of liver function in patients with COVID-19. Various studies have demonstrated a correlation between liver injury and disease severity, albeit most of these data are not strictly limited to critically ill patients[36-39]. In several studies including severe and non-severe patients with COVID-19 strong association was found between LFT (particularly AST) abnormalities and disease severity and mortality[40-44]. Lok *et al*[45], reporting similar results, suggested that immune system dysregulation may be a plausible contributing factor to the former association.

The role of microRNAs, which are considered to alter the immune response, is notable. To the best of our knowledge, only one study has found an association between liver-derived miR-122 and patient mortality in a cohort including patients with severe COVID-19[46]. Whereas the role of microRNAs in the inflammatory process is well documented, their specific role in COVID-19 is yet to be clarified.

Focusing on critically ill patients, a wide range of abnormal LFTs has been reported, whereas the vast majority of published data deliberate on aminotransferases. The prevalence of abnormal LFTs seems to be higher in ICU patients than in ward patients with COVID-19, according to a large meta-analysis including 31 studies from various countries[47]. In a study including 166 patients requiring mechanical ventilation, AST and ALT elevation served as predictive factors for the requirement of invasive mechanical ventilation[48]. Similar results were reported by Yip *et al*[49]. An independent association was found between aminotransferases elevation and ICU admission, mechanical ventilation and/or death. In addition, an association was found between aminotransferase elevation and lopinavir/ritonavir plus interferon beta and corticosteroid use, and the researchers suggested a cautious use of medications to minimize hepatotoxicity.

Nevertheless, Roman *et al*[50], in a study including exclusively critically ill patients with laboratory-proven liver damage, failed to demonstrate a correlation between liver injury severity and mortality. Azad Allarakia *et al*[51] examined plausible associations between routine laboratory tests and disease severity. No difference was found regarding LFTs between ICU and ward patients; however, confounding factors were not adjusted. Similarly, in a study conducted early during the pandemic era, no association was found between disease severity and LFTs[52].

Regarding mortality, in a large cohort including 3812 patients with COVID-19, an association between elevated ALT, AST, GGT levels and ICU admission was reported, and AST elevation was associated with the risk of death after adjusting for confounding factors such as age, obesity and previous liver disease[41]. Following the aforementioned study, in the study of Salik *et al*[53], which included exclusively critically ill patients, liver dysfunction and liver injury were associated with higher 7-d and 28-d mortality in comparison with patients with COVID-19 without liver biochemistry abnormalities. Interestingly, in the study of Kasapoglu *et al*[54], although ICU patients had higher values of AST and GGT, only GGT among LFTs was found to be predictive of mortality in ICU patients.

In addition to the aforementioned biomarkers, interest has been drawn to the role of albumin and prealbumin as prognostic markers of COVID-19 outcome. Hypoalbuminemia is common among critically ill patients with COVID-19. There are various mechanisms not directly related to hepatocellular damage that lead to hypoalbuminemia in these patients, including malnutrition, extravasation due to capillary leakage and a decreased rate of synthesis. Furthermore, measurements of serum albumin in hospitalized patients are often affected by exogenous albumin administration. Prealbumin is a precursor of albumin with a shorter half-life and can be used to assess protein status during a shorter time-frame. Low prealbumin levels were associated with disease severity and may be of prognostic value as they were identified as independent predictors of mortality in critically ill patients with COVID-19[55,56].

Various non-invasive fibrosis estimators include the fibrosis-4 (FIB-4) score, the Forns index for liver fibrosis, the AST to platelet ratio index (APRI) score, the nonalcoholic fatty liver disease (NAFLD) fibrosis score (NFS) and the AST to ALT ratio.

Of the above-mentioned biomarkers and scores, the FIB-4 score attracted interest and applicability. It is a scoring system that uses four simple parameters, readily available in all in-patients: the age, the platelet count, and the values of AST and ALT. A score of < 1.45 has a negative predictive value of more than 90% for advanced fibrosis of the liver, whereas a score of > 3.25 has a positive predictive value of 65%, with 97% specificity[57].

Crisan *et al*[58] published the results of a retrospective cohort study (370 consecutive patients with COVID-19, from whom 289 presented with abnormal liver biomarkers at admission) to evaluate the predictive value of the various liver tests and estimators. They concluded that an elevated FIB-4 score (values > 3.25) and elevated AST were the only two tests that were independently associated with higher mortality in these patients. The FIB-4 score is a valuable tool that can help clinicians identify existing undiagnosed liver disease or the possibility of rapid deterioration of liver function during COVID-19, so that patients with abnormal values receive priority in their inpatient management[58].

Findings in association with the value of the FIB-4 score were also verified in the systematic review and meta-analysis of Liu *et al*[59], who concluded that along with the FIB-4 score, the APRI score, the NFS and the Forns index could also serve as indicators for identifying patients at high risk of

developing severe COVID-19 with worse outcomes. More specifically, one unit elevation of the APRI score increases the risk of death by 178%, higher NFS ( $\geq -1.5$ ) increases the risk of developing severe COVID-19 by ten-fold, and an increase of the Forns index by one point increases the risk of death by 41%.

## CRITICALLY ILL PATIENTS WITH ACUTE LIVER DISEASE AND COVID-19

Acute liver injury (ALI) has been reported in approximately 19% of patients with COVID-19; however, the percentage increases dramatically, up to 89.2%, in ICU patients[60,61]. The spectrum of ALI in critically ill patients with COVID-19 is wide, varying from simple elevations of LFTs to ALF, the need for advanced support and even the need for transplantation<sup>[62-64]</sup>. For patients with severe liver injury (approximately 6.4% of all patients with distorted liver biochemistry), a severe disease course is expected[65]. The correlation of impaired liver function with sudden death in patients with COVID-19 is another outstanding association[66]. Most studies reported a predominance of the hepatocellular pattern[67]. However, other distributions of liver injury pattern have been reported as well[62].

HH as a clinical presentation of COVID-19 is observed in approximately 5.9% of ICU patients with COVID-19 and has a significant effect on patient survival[68]. The diagnosis is made when the following criteria are met: (1) A massive but transiently elevated ALT level (more than 20-fold the upper limit of normal); (2) The presence of respiratory, cardiac or circulatory failure; and (3) Exclusion of other causes of liver injury[69]. The close monitoring of cardiac and respiratory function and early etiologic management of hemodynamic instability/shock is crucial for patient survival when HH is suspected [68].

Secondary sclerosing cholangitis is another devastating form of liver disease in COVID-19, which is associated with considerable morbidity and mortality. Contributing pathophysiological mechanisms include bile duct ischemia and toxic bile formation[70]. The underlying histopathological findings consist of ischemic damage to the perihilar bile ducts[71]. Ursodeoxycholic acid (UDCA) has been reported to give promising results; however, for a proportion of these patients, transplantation is required[72]. Rare but devastating clinical presentations include liver abscess with necrosis[73] and vascular thrombotic events in abdominal vessels such as portal and mesenteric vein thrombosis[74].

ALF is a life-threatening condition characterized by hepatic encephalopathy and coagulopathy in patients without pre-existing liver disease[75]. During the pandemic, an increased incidence of hepatitis of unknown etiology in the pediatric population has been reported with subsequent liver failure and the need for liver transplantation (LT) for a proportion of these children. This raised great concern about the possible vulnerability of children to this extremely severe complication. Although adenovirus is the main etiological agent suspected to be responsible, the association with COVID-19 and the role of other contributing factors remain to be clarified[76]. In adults, there are reports on other viruses as causative factors of ALF, such as the infection from or the reactivation of herpes simplex virus-1 following the immunosuppression that patients with COVID-19 receive for treating the CRS[77].

When assessing critically ill patients with COVID-19 and ALI, the diagnostic approach basically remains the same as for any patient who has ALI and is severely ill. However, some differences exist that must be pointed out.

Current guidelines recommend against unnecessary imaging [*e.g.*, ultrasound (unless performed at the bedside), CT-magnetic resonance (MR) imaging/MR cholangiopancreatography][78]. The transport of these patients requires special knowledge, equipment and experience and should be kept for patients where the examination results may change the patient's management.

Approaches that do not require patient transportation are preferred. An approach regarding the hemodynamic monitoring of these patients uses invasive cardiac monitors based on the thermodilution method. These methods are invasive, expensive and present septic and other catheter-related complications. Moreover, they have limitations in critically ill patients with liver failure such as the presence of ascites (extravascular third space fluid) or hepatic hydrothorax (extravascular lung water), which confuse the measurements and the lack of validation of these techniques on such patients. Remote point-of-care ultrasonography (POCUS) by a hepatologist or an ICU physician, with real-time interpretation by a cardiologist through telemedicine, is a trend that has been adopted in the COVID-19 era[79]. Information on the hemodynamic status and the cause of the hemodynamic compromise of these patients is safely and accurately collected. Basic diagnoses such as pulmonary embolism or myocardial infarction are made at the bedside. The evaluation of intravascular volume status helps to differentiate between prerenal acute kidney injury and hepatorenal syndrome or between transfusion-related acute lung injury and transfusion-associated circulatory overload. In addition, this powerful and non-invasive tool contributes to the prompt identification of liver-related pathologies, including portal vein or hepatic vein thrombosis, the presence of ascites, suspected pneumothorax and hemothorax. This approach has provided several solutions for liver units and ICUs during the pandemic.

Another non-invasive method that has been evaluated for the assessment of liver injury during COVID-19 is the vibration-controlled transient elastography/FibroScan. It may serve as a tool for identifying patients with elevated liver stiffness and thus at greater risk of developing ALI and

progressing to severe COVID-19 with worse clinical outcomes, even when no history of pre-existing liver disease is present[80,81].

No special recommendations or measures exist which could prevent liver injury from COVID-19. The prophylaxis of the liver can only be achieved through measures that prevent infection from SARS-CoV-2. Thus, current guidelines suggest using personal protective equipment for healthcare personnel in the liver and other departments, cancelling all elective/nonurgent procedures and vaccinating with the approved vaccines the vulnerable population with or without pre-existing liver disease[78,82]. Another approach is the use of dietary supplements as prophylaxis for severe disease and liver involvement. Among the supplements used for the prevention of COVID-19, several pieces of evidence exist on the possible protective role of vitamins C and D in humans, whereas in animal models, xanthohumol has an anti-inflammatory action on liver injury[83].

Accordingly, no separate protocols exist for the treatment of liver injury from COVID-19. The implementation of the general therapeutic protocols for the disease is applicable[84], with special care for liver protection and early detection of liver injury in patients with COVID-19[85]. In cases of patients with progressive ALF, when the applied standard supportive care (hemodynamic, nutritional, respiratory support, avoidance of all unnecessary hepatotoxic factors) does not lead to the resolution of ALF, LT can be the final solution[75]. Removing hepatotoxic metabolites such as conjugated or unconjugated bilirubin, bile acids, phenols, fatty acids, cytokines, ammonia or amino acids with the use of extracorporeal blood purification techniques presents an interesting alternative approach, particularly when LT is not a feasible option or even as a bridging therapy toward transplantation[86,87]. These techniques eliminate not only hepatic metabolites but also inflammatory mediators responsible for the CRS, leading to the preservation of organ function and prevention of organ failure, while advanced support is offered in patients with COVID-19[86].

## CRITICALLY ILL PATIENTS WITH CHRONIC LIVER DISEASE AND COVID-19

Acute-on-chronic liver failure has been reported in patients with pre-existing liver disease[40]. Particularly in patients with cirrhosis, the associated state of immunosuppression in conjunction with COVID-19 can lead to acute decompensation, most frequently manifested as worsening ascites with spontaneous bacterial peritonitis and to hepatic failure in patients with impaired and limited reserves [40,88]. Liver injury has been observed in 26.7% of patients with severe pneumonia[88]. Despite the lack of coagulation factors in decompensated liver disease, a hypercoagulable state may be present in COVID-19, and hepatic impairment may be associated with greater activation of the coagulation pathways[75,89].

In critically ill patients with COVID-19, pre-existing liver disease and evidence of liver impairment, LFTs must be frequently monitored[85]. Typically, no specific treatment is indicated, and emphasis should be placed on cause-directed therapy.

UDCA may be added as a treatment in patients with liver injury because of its anti-inflammatory and immunomodulatory properties[88]. In the ICU setting, treatment with vasopressors should be administered with caution in patients with cirrhosis and COVID-19, to avoid detrimental effects on cardiac output. Moreover, caution should be taken while administering immunosuppressive agents, such as tocilizumab and baricitinib, as they may cause the reactivation of chronic hepatitis B. In such cases, antiviral prophylaxis is indicated[88].

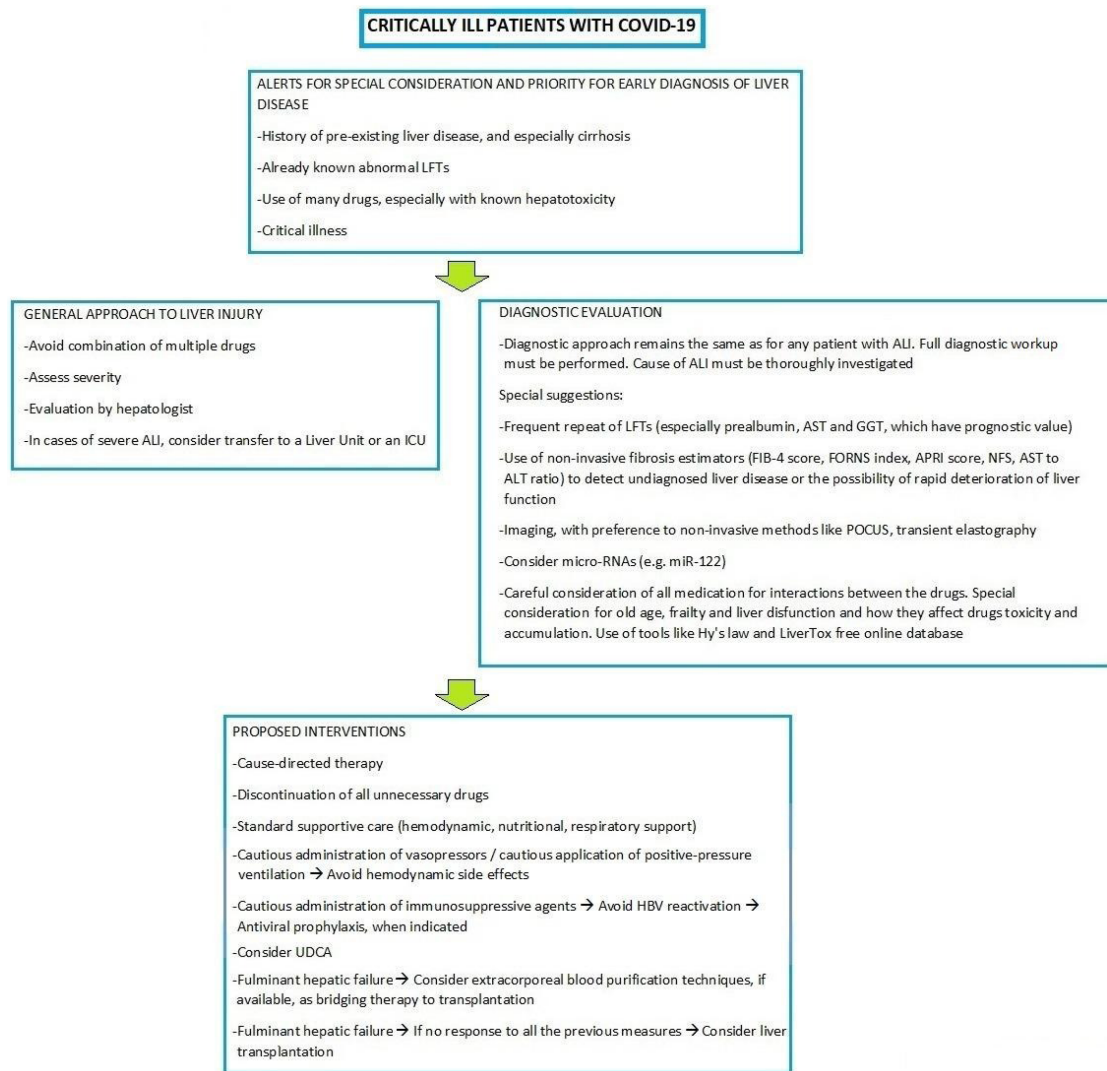

In terms of prognosis, it has been hypothesized that patients with chronic liver disease may be particularly vulnerable to developing severe COVID-19[90]. Higher mortality rates have been observed in patients with COVID-19, pre-existing chronic liver disease and cirrhosis caused by chronic hepatitis B and C[40]. Moreover, patients with NAFLD present a higher risk for progression to severe COVID-19 [91]. Patients with cirrhosis having ARDS have a worse prognosis than patients without cirrhosis, and pre-existing liver fibrosis is independently associated with a significantly higher risk of death in patients with severe COVID-19 admitted to the ICU[92].

An approach to liver disease in critically ill patients with COVID-19 is proposed by the authors (Figure 1).

## EFFECT OF THE PANDEMIC ON HEALTH SYSTEMS, ICUS, LIVER UNITS AND TRANSPLANT PROGRAMS

During the pandemic, health systems and ICUs were overburdened by critically ill patients. Higher mortality risk was observed and was associated with ICU patient load[4,93,94]. In line with this, patients with chronic liver disease had significantly high mortality during the pandemic, leading to suggestions regarding their primary and emergency care and their access to intensive care and high-dependency units[95]. In addition, the effect of the pandemic was significant on the treatment of complications of chronic liver disease such as hepatocellular carcinoma (HCC); surveillance for HCC and treatment of

**Figure 1 Proposed approach to liver disease in critically ill patients with coronavirus disease 2019.** Apart from general rules regarding all patients, special measures can help clinicians identify and confront liver disease in severely ill patients with coronavirus disease 2019. ALI: Acute liver injury; ALT: Alanine aminotransferase; APRI: Aspartate aminotransferase to platelet ratio index; AST: Aspartate aminotransferase; COVID-19: Coronavirus disease 2019; FIB-4: Fibrosis-4; GGT: Gamma-glutamyl transpeptidase; HBV: Hepatitis B virus; ICU: Intensive care unit; LFTs: Liver function tests; NFS: Nonalcoholic fatty liver disease fibrosis score; POCUS: Point-of-care ultrasonography; UDCA: Ursodeoxycholic acid.

early-stage HCC were modified. Another significant change was the extensive use of telemedicine to minimize patients' and healthcare workers' exposure to COVID-19[96].

Transplant programs and care provided to LT recipients were also greatly affected. Living donor LT was suspended in some centers worldwide[96]. As a response to these issues, national protocols were specially prepared[97], and transplantation centers implemented special strategies to increase their successful transplantation rates[98]. Recommendations point out the need for the restoration of LT programs; however, prioritization of patients with poor short-term prognosis (with acute/acute-on-chronic liver failure, high Model for End-stage Liver Disease score and HCC at the upper limits of the Milan criteria) may be necessary in some cases[67].

In general, transplant recipients present higher rates of severe disease and higher mortality rates than nontransplant patients; thus, their exposure to COVID-19 should remain minimal[78]. Immunosuppression should be reduced only under special circumstances, *e.g.*, symptomatic COVID-19, and with caution[78,99]. COVID-19 screening should be performed for both donors and recipients. Charts regarding LT organ offers are available to optimize the management of the procedures associated with LT in the COVID-19 era[78].

## CONCLUSION

Apart from the upper and lower respiratory system, the liver is also greatly affected by COVID-19. The pathophysiological mechanisms include cholestasis, bile duct alterations, hepatic steatosis, involvement of the gut-liver axis, HH and hepatitis induced by the drugs that are used to treat the actual disease. The hepatocyte seems to be affected both directly, by SARS-CoV-2 itself, and by the disruption and dysregulation of the immune system. Not only patients with or without pre-existing liver disease individually but also health systems and transplant programs were greatly affected by the pandemic, and great effort has been made, which needs to be continued to minimize the consequences. Scientific research over the past 2 years has shown that certain biomarkers can be extremely useful in the early diagnosis of liver injury and the evaluation of its progression. Non-invasive assessment with transient elastography or POCUS is the trend for evaluating particularly patients in the ICU setting where biopsy is difficult to perform because of coagulation abnormalities and transport for CT or MR imaging is difficult and potentially dangerous. Although in most cases, liver involvement in COVID-19 is mild, the clinician should be able to recognize the symptoms and signs of liver dysfunction early and not focus exclusively on symptomatology from the respiratory system.

## ACKNOWLEDGEMENTS

This paper is dedicated to the memory of the exceptional doctor Tilemachos Zafeiridis (1974-2021), 1 year after his premature death, to remind us how much we miss him.

### Abstract

The incidence and mortality of hepatic carcinoma (HCC) remain high, and early diagnosis of HCC is seen as a key approach in improving clinical outcomes. However, the sensitivity and specificity of current early screening methods for HCC are not satisfactory. In recent years, research around exosomal miRNA has gradually increased, and these molecules have emerged as attractive candidates for early diagnosis and treatment of HCC. This review summarizes the feasibility of using miRNAs in peripheral blood exosomes as early diagnostic tools for HCC.

**Key Words:** Hepatic carcinoma; Early diagnosis; Exosomal miRNA; Biomarker

## INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common malignant tumors in the world, with the seventh highest incidence and second highest mortality among all malignant cancer types[1,2]. About 905000 patients are newly diagnosed with liver cancers each year around the world, with 75% of these being accounted for by HCC alone, and altogether causing about 830000 deaths[3]. Infection with hepatitis B virus (HBV) is the most common cause of HCC, and more than half of the world's new cases of HCC were detected in China[4]. The high incidence and mortality of HCC pose a significant threat to the health of Chinese people and place a heavy burden on society[5].

It is considered that the best stage for treatment of HCC is Stage I, or subclinical liver cancer[6]. However, HCC symptoms in this period are not obvious, and most patients are not diagnosed until the middle or late stages. Therefore, development of more effective screening methods that allow earlier detection of HCC represents an important research focus. The five-year survival rate for patients with early-stage HCC is more than 70%, but this rate drops to less than 12.5% for patients with advanced HCC[7].

Tumor markers represent one approach for the early diagnosis of HCC, allowing earlier detection of primary tumors, recurrent tumors, and metastatic tumors than other methods. Yet, the accuracy of prediction and diagnosis achieved by tumor markers could still be improved, and such improvements would confer parallel improvements in prognosis and patient outcomes (Table 1)[8-12]. Alpha-fetoprotein (AFP), which has been widely used as a marker for HCC diagnosis and monitoring, is not highly sensitive to early HCC, and may also be increased in patients without HCC but with chronic viral hepatitis and cirrhosis[13]. As such, AFP can lead to misdiagnoses or unclear clinical interpretation, particularly if detected alone[14]. Despite the obvious limitations of using AFP as an early screening marker for HCC, its ubiquity has precluded its replacement by other clinical markers. At present, a variety of molecular markers are used in the diagnosis of HCC, but they all have the problems of low sensitivity and insufficient specificity. The sensitivity of AFP-L3, a glycoform of AFP, for the diagnosis of early HCC is less than 28%[15]. Another biomarker, protein induced by vitamin K absence II (PIVKA II), is also relatively insensitive for diagnosing early HCC[7]. Therefore, it is an urgent research direction to identify tumor markers with high sensitivity and specificity for the early diagnosis of HCC.

## RELATIONSHIP BETWEEN RNA AND HCC

In recent years, non-coding RNA has attracted ever-increasing attention in the field of biological medicine. Our understanding of these RNA molecules has progressed rapidly, yielding a new understanding of cellular life and providing new opportunities for the diagnosis and treatment of various diseases. Among such non-coding RNA, the most extensively studied, to date, is microRNA (miRNA) - a class of small non-coding single-stranded RNA molecules containing 19-25 nucleotides. They are formed from double-stranded RNA precursors composed of 70-100 nucleotides in a hairpin structure. The sequences of miRNA are highly conserved across different species, suggesting that these very small molecules may play important roles in various cellular processes such as development, proliferation, differentiation, and apoptosis[16]. Significant differences in miRNA expression profiles have also been identified in some diseases[17,18], indicating that miRNA may be used as biomarkers for the diagnosis and prognosis of such diseases, including malignant tumors. Due to their structure, miRNAs can stably exist in the blood circulation, but the form of miRNAs in the circulation is not clear. Since RNA exposed to the blood is degraded within a short period of time, some researchers have pointed out that the stable existence of miRNAs in plasma must indicate the presence of protective macromolecules. Increasing evidence has shown that the main components of such protective macromolecular complexes are exosomes[19].

The correlation between miRNA and HCC was first proposed by Murakami, who analyzed the expression of microRNAs in tumor and adjacent tissues of HCC patients, as well as the liver tissues of hepatitis patients. It was found that miRNA-99a was positively correlated with the degree of pathological differentiation of HCC, while miRNA-20, miRNA-18 and pre-miRNA-18 were negatively correlated with the differentiation of HCC and positively correlated with the occurrence of HCC[20]. Since then, additional studies have confirmed close associations between miRNAs and HCC. These miRNAs can be roughly divided into two categories: "non-liver-specific miRNAs," such as miRNA-21, miRNA-221/222, and let-7, which are abnormally expressed in various tumors such as liver cancer, pancreatic cancer, and lung cancer[21-23], and "liver-specific miRNAs," which are only abnormally expressed in HCC. An example of a liver-specific miRNA is miRNA-122, which is up-regulated in HCC and suppresses the expression of the proto-oncogene c-myc through transcriptional activators[24]. Studies have shown that miRNA-122 is up-regulated in 70% of human liver cancer tissues and 100% of liver cancer cell models[25].

HCC is the result of multiple genetic mutations, which can occur in oncogenes or tumor suppressor genes, growth factors or their receptors, and myriad signaling pathways controlling cellular prolifer-

**Table 1 Biomarkers for the diagnosis of hepatocellular carcinoma**

Biomarker	Ref.	Country	Sensitivity (%)	Specificity (%)
AFP	Trevisani <i>et al</i> [8]	Italy	60	90
DCP	Feng <i>et al</i> [9]	China	83	91
AFP-L3	Toyoda <i>et al</i> [10]	Japan	41	85
GP73	Marrero <i>et al</i> [11]	United States	62	88
miR-21-5p	Ghosh <i>et al</i> [12]	India	74	68

AFP: Alpha-fetoprotein; DCP: Des-γ-carboxyprothrombin.

eration or behavior. Gene mutations also play a very important role in the progression of a tumor. When the expression of a gene or a class of molecules is silenced or enhanced, the possibility of tumorigenesis is present[26], and microRNA is gradually becoming the focus of this kind of research. miRNAs - small RNA molecules with very simple structures that regulate hundreds of mRNAs - play an unusual role in gene expression networks. Abnormally expressed miRNA may play a role similar to oncogenes such as myc or tumor suppressor genes such as p53, inducing or inhibiting liver tumorigenesis according to the specific cellular function of the target gene or genes regulated by that specific miRNA[27]. Meanwhile, and critically, miRNA can also influence the therapeutic effects of chemotherapy and intervene in the process of drug tolerance[28,29].

Regarding the use of miRNAs as molecular markers for tumors, miRNA-21 has gained attention as the first miRNA used in the clinic[30]. Many studies have confirmed that miRNA-21 is an oncogene, promoting liver tumor growth and metastasis by inhibiting the tumor suppressor genes PTEN and MAP2K3[31,32]. In 2012, Tomimaru *et al*[33] found that expression of miRNA-21 was increased in the plasma and tumor tissues of HCC patients, and that there was a correlation between them. Further investigation revealed that plasma miRNA-21 had clinical application value and could be used to diagnose HCC. Several additional studies have also shown that various miRNAs can be used for the diagnosis or prognosis of HCC patients. For example, serum miRNA-122 can also be used as a tumor marker for the diagnosis of HCC[34], while miRNA-125 and miRNA-233 can further be used for the early diagnosis of HCC patients who are HBV-positive[35]. miR-140 can also be used to determine the prognosis of HCC patients[36].

## EXOSOMAL MIRNA IN HCC

The stability of miRNAs in plasma depends on exosomes. Exosomes are bilayer lipid membrane-coated vesicles with diameters of about 30-100 nm that can be released out of the cell and into the blood, urine, saliva, and other body fluids. It is generally believed that exosomes are composed of such lipid molecules as well as myriad amino acids and proteins, among which the common markers of exosomes have been identified as CD9, CD63, CD81, CD82, and others[37]. Nucleic acids in exosomes include mRNA, DNA, miRNA and other non-coding RNAs. Exosomes can carry these functional substances between cells and mediate communication between cells, thus regulating protein synthesis, cellular proliferation and differentiation, antiviral activity, and myriad other physiological and pathological activities.

Exosomal miRNAs have multiple potential functions in cell-to-cell communication. As such, they can be used to detect pathophysiological changes in the body, track changes in tumors, and aid in the diagnosis and prognosis of various diseases[38]. Down-regulation of exosomal miRNA expression has been shown to play a certain role in the mechanism of tumorigenesis[39]. Because exosomes and their contents (mainly miRNAs) can reflect the state of the cell they were released from - including whether that cell was of a tumorigenic or healthy state - exosomal miRNAs may hold a high value in the clinical diagnosis of tumors[40]. Detection of exosomes derived from tumor cells and their miRNA levels may become a novel biological tool with clinical potential and utility in people at high risk of cancer[41].

Protein and miRNA profiles in exosomes produced by HCC cells have been shown to be significantly different from those produced by normal cells[42,43]. Such exosomes can be ingested and internalized by other cells to deliver genes with certain functions[44]. Similar to the screening of serum tumor markers for liver cancer, exosomal miRNA can also be used as a valuable, non-invasive biomarker to distinguish the type and grade of liver inflammation, and then assist in the early diagnosis of liver cancer. Studies have also shown that circulating miRNAs may become biomarkers for HCC diagnosis due to the large number of miRNA variants in HCC cells[45]. Ghosh *et al*[12] identified a liver-specific exosomal miRNA, miR-21-5p, as an early circulating diagnostic marker for HCC with low AFP. The sensitivity, specificity, and accuracy of miR-21-5p differential diagnosis of HCC are 74%, 68%, and 71%,

respectively.

## CONCLUSION

In conclusion, although many miRNAs have been identified as tumor markers for early diagnosis of liver cancer in recent years, most of them have some defects and deficiencies, meaning that there is no clear consensus on which one or few miRNAs can improve the early diagnostics of HCC. Remaining challenges include a lack of further study on the specificity and sensitivity of target miRNAs in the diagnosis of liver cancer, a lack of robust clinical comparison between candidate miRNAs and the current tumor marker, AFP, and an expensive and cumbersome detection method for target miRNAs in HCC patients. As increased attention is placed upon exosomal miRNAs and their application at home and abroad, it is necessary and urgent to fully explore and realize the potential for exosomal miRNAs in the early diagnosis and treatment of liver cancer in clinical practice.

### Abstract

Patients with cirrhosis have an increased risk of infection and differently from other complications, that over the years are improving in their outcomes, infections in cirrhotic patients are still a major cause of hospitalization and death

(up to 50% in-hospital mortality). Infections by multidrug-resistant organisms (MDRO) have become a major challenge in the management of cirrhotic patients with significant prognostic and cost-related impact. About one third of cirrhotic patients with bacterial infections is infected with MDR bacteria and their prevalence has increased in recent years. MDR infections have a worse prognosis compared to infections by non-resistant bacteria because they are associated with lower rate of infection resolution. An adequate management of cirrhotic patients with infections caused by MDR bacteria depends on the knowledge of some epidemiological aspects, such as the type of infection (spontaneous bacterial peritonitis, pneumonia, urinary tract infection and spontaneous bacteremia), bacteriological profile of antibiotic resistance at each health care unit and site of infection acquisition (community acquired, healthcare associated or nosocomial). Furthermore, regional variations in the prevalence of MDR infections determine that the choice of empirical antibiotic therapy must be adapted to the local microbiological epidemiology. Antibiotic treatment is the most effective measure to treat infections caused by MDRO. Therefore, optimizing antibiotic prescribing is critical to effectively treat these infections. Identification of risk factors for multidrug resistance is essential to define the best antibiotic treatment strategy in each case and the choice of an effective empirical antibiotic therapy and its early administration is cardinal to reduce mortality. On the other hand, the supply of new agents to treat these infections is very limited. Thus, specific protocols that include preventive measures must be implemented in order to limit the negative impact of this severe complication in cirrhotic patients.

**Key Words:** Cirrhosis; Infection; Multidrug-resistance; Bacterial; Antibiotics; Microbiota

## INTRODUCTION

The rising prevalence of multidrug-resistant organisms (MDRO) (resistant at least to one agent in three or more antimicrobial categories), extensively drug-resistant organisms (a resistance profile that compromised at least one agent in all but two or fewer antimicrobial categories), and pan drug-resistant organisms (PDRO) (resistant to all known antimicrobial agents) represents a global threat to human health[1,2]. At same time, active agents against MDRO are limited despite an increase in the availability of novel antibiotics in recent years.

Reports from the United States and Europe estimate a death toll of 29-33 patients each year associated with antimicrobial resistant microorganisms, with a huge attributable healthcare cost[2-5]. The so called “ESKAPE” pathogens [*Enterococcus faecium*, *Staphylococcus aureus* (*S. aureus*), *Klebsiella pneumoniae*, *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, and *Enterobacteriaceae* species] are especially worrisome: The acquisition of antimicrobial resistance genes, in association to the classical mechanisms of antimicrobial resistance (inactivation or alteration of the antimicrobial molecule, bacterial target site modifications, reduced antibiotic penetration/accumulation, and the formation of bacterial biofilms), make ESKAPE pathogens challenging to surveillance and subsequent infections difficult to treat. The SKAPE pathogens have developed resistance against almost all antibiotics used in the clinical setting (oxazolidinones, lipopeptides, macrolides, fluoroquinolones, B-lactams, and also to antibiotics that are considered “the last line of defense”, like carbapenems, glycopeptides and polymyxins). Face to the increased burden of disease and death rates due to treatment failure, the World Health Organization has designated the SKAPE group as “priority organisms” to focus and guide research and development related to new antibiotics[1].

Over the last years cirrhosis complications are improving their outcomes with new strategies and technologies. However, infections in cirrhotic patients are still a major cause of hospitalization and death (up to 50% in-hospital mortality)[6]. Although the reasons for these imbalanced morbidity and

mortality are not totally elucidated, MDR infections may play an important role. In a recent multicentric study that assessed the epidemiology of bacterial infections in hospitalized cirrhotic patients, the overall prevalence of MDRO was 34%[7]. Another report concerning critically ill patients with decompensated cirrhosis points to 46% of isolates being MDROs at admissions. Meanwhile, MDRO isolates responsible for infection during intensive care unit stay were at 60%[8]. Different studies confirm the ominous prognosis of cirrhotic patients with infections by MDRO[9,10] (Table 1). Antimicrobial standard prescription for infection in liver cirrhosis doesn't routinely comprehend the MDRO spectrum. Cirrhosis itself increases the risk for sepsis and septic shock and when associated with an inappropriate choice of empirical antimicrobial treatment may be determinant of a worst outcome.

In this review, we describe the epidemiology, clinical settings and the current evidence-based strategies for early recognition and treatment alternatives for MDR infection in cirrhotic patients.

## EPIDEMIOLOGY

Bacterial infections affect 25%-35% of hospitalized patients with cirrhosis and lead to a four-fold increase in their mortality when compared to noninfected counterparts[11]. The prognostic impact of infections is such that they are considered defining events of state 6 (end-state, late decompensation) in the clinical course of cirrhosis[12]. Moreover, infections (together with alcoholic hepatitis) are the most important drivers of acute decompensation of cirrhosis and acute-on-chronic liver failure (ACLF)[9,13,14].

Despite the evolution in medical care, there is evidence suggesting that mortality associated with infections in individuals with cirrhosis might be increasing. Our group, for instance, has demonstrated that mortality associated with spontaneous bacterial peritonitis increased from 22% to 40% in a decade [15,16]. An explanation for this finding might be the growing importance of infections caused by MDRO. In our setting, after evaluating 5800 isolates from hospitalized patients, we have shown that 38% and 44% of individuals with and without cirrhosis respectively were infected with MDRO. Furthermore, in that study, 20% of *Escherichia coli* and *Klebsiella sp* strains infecting patients with cirrhosis were extended-spectrum beta-lactamase (ESBL)-producing bacteria, and 44% of *S. aureus* strains were methicillin-resistant[17].

Additionally, a recent European study has clearly demonstrated that infections associated with MDRO are increasing in individuals with cirrhosis. The study evaluated two prospective multicenter cohorts of patients hospitalized for acute decompensation of cirrhosis or ACLF. The first cohort consisted of 1146 individuals evaluated in 2011, of which 39.7% were infected. The second cohort consisted of 883 individuals evaluated in 2018, of which 32.2% were infected. In that study, infections associated with MDRO were diagnosed in 29.2% of subjects with positive cultures in the 2011 cohort and in 37.9% of those pertaining to the 2018 cohort[10].

On a global level, another prospective cohort study has demonstrated the relevance of infections associated with MDRO in individuals with cirrhosis worldwide. The authors included 1302 infected patients with cirrhosis from 46 different centers in Europe, America and Asia. The most common infections were spontaneous bacterial peritonitis [spontaneous bacterial peritonitis (SBP), 27%], urinary tract infection (22%) and pneumonia (19%), and 57% of isolates consisted of Gram-negative bacteria. Among individuals with positive cultures, 34% were infected with MDRO, most commonly ESBL-producing *Enterobacteriaceae*, methicillin-resistant *S. aureus*, vancomycin-resistant *Enterococci*, *Pseudomonas aeruginosa*, and *Acinetobacter baumannii*. The prevalence of infections caused by MDRO was higher in Asia (51%), than in Europe (29%) or America (27%). Independent risk factors for infections with MDRO were being from Asia (and mostly from India, where MDRO were present in 73% of isolates), using antibiotics in the three months previous to hospital admission, being exposed to healthcare facilities, and the site of infection (pneumonia, skin and soft tissue infection and urinary tract infection had higher odds of being caused by MDRO)[7].

Africa and Oceania are poorly represented in studies evaluating the prevalence of MDRO in patients with cirrhosis. However, a recent retrospective cohort study has demonstrated a low prevalence of MDRO in blood cultures of patients with cirrhosis hospitalized in Australia (5.6% of admissions). Despite the low prevalence, the study has shown a significant increase in infections caused by MDRO over a decade[18], similarly to what had been previously verified in Europe[10].

## PROGNOSTIC IMPACT OF MULTIDRUG RESISTANT BACTERIAL INFECTIONS

Different abnormalities related to the immune system and the occurrence of bacterial translocation from the intestinal lumen increase the susceptibility to infections in cirrhotic patients[19]. Bacterial infections are very common in cirrhosis affecting approximately 1/3 of patients with decompensated cirrhosis and are responsible for significant mortality. In a review study Arvaniti *et al*[11] evaluated 178 studies with more than 11000 patients with cirrhosis and found that infections increase mortality four-fold. In these patients delayed antibiotic treatment and inadequate empirical therapy are independently associated

**Table 1** Prevalence and prognosis of multidrug-resistant organisms infections in cirrhosis

with mortality[20,21].

As stated before, recent studies suggest that about 34% of cirrhotic patients with bacterial infections are infected with MDRO[7]. Infections by MDRO have a worse prognosis because they are associated with lower rate of infection resolution with traditional empirical antibiotic treatment. In the first series (2005-2007) of a Spanish study, failure to antibiotic treatment was higher (30% *vs* 8%) in MDR infections than in susceptible bacterial infections. In addition, this study found a higher frequency of septic shock (26% *vs* 10%) and higher hospital mortality rate (25% *vs* 12%) in MDR infections compared to infections by non-resistant bacteria. An important finding of the second series (2010-2011) of this study was the higher prevalence of MDRO in nosocomial infections (39%) compared to HCA (a type of infection that occurs in patients with a previous contact with a healthcare environment, *e.g.*, hospitalization or short-term admission for at least 2 d in the previous 90 d, residence in a nursing home or a long-term care facility, or chronic hemodialysis) and community-acquired infections (20% and 0%, respectively)[22]. Similarly, an intercontinental study evaluated 1302 infected cirrhotic patients and confirmed that infections caused by MDRO were associated with a lower efficacy (40% *vs* 68%) and a longer duration (12 d[7-18] *vs* 10 d[7-15]) of empirical antibiotic treatment. Furthermore, patients with bacterial infections by multi-resistant strains had a higher incidence of septic shock (27% *vs* 13%) and higher in-hospital and 28-d mortality rate (31% *vs* 21% and 34% *vs* 22%, respectively)[7]. Finally, a meta-analysis on the impact of infections by MDRO on mortality in cirrhosis found a four times increased risk of mortality associated with bacterial resistance compared to non-resistant bacterial infections[11].

## RISK FACTORS FOR MULTIDRUG RESISTANT BACTERIAL INFECTIONS

MDR infection results from an interaction of different risk factors that act synergistically. Although some risk factors have been identified, we still far from completely understand all the mechanisms involved, and there is still much to research in this field. Identifying risk factors for multidrug resistance is essential to define the best antibiotic treatment strategy in each case[21].

Previous use of antibiotics is a well-known driver for multidrug resistant infection in different clinical settings. A strong association of MDRO with previous antibiotic therapy was also observed in cirrhotic patients. Extended use of broad-spectrum antibiotics[23] and exposure to systemic antibiotics treatment for at least five days, especially in the previous three months, were highlighted as risk factors[7,24]. Prior use of beta-lactam antibiotics is especially important and has been identified as an independent predictor in the multivariate analysis[22,25]. These findings reinforce the importance of the judicious use of antibiotics in preventing MDRO emergence, with avoidance of overuse and early de-escalation strategies.

Another important risk factor for MDR infections is the previous occurrence of infections by resistant bacteria. In the multivariate analysis, infection caused by MDR bacteria in the last 6 mo increases the risk by 2.45 times[22].

Current or recent contact with the healthcare system is another important risk factor for MDR infections. A strong association between MDR infections and hospital admission has been shown in several studies[10,26,27]. Patients with nosocomial infection, hospitalization for more than 48 h, and those discharged in the last 30 d are at increased risk for MDR infections. In addition, an increased risk has been reported in patients admitted to the intensive care unit. The risk of MDR infections is also related to the duration of hospitalization and the invasiveness of the procedures performed.

Non-hospitalized patients with healthcare-associated (HCA) infections have an intermediate rate (14%-41%) of infections caused by MDRO, which is lower than in nosocomial infections (23%-39%) but higher than that observed in community-acquired infections (0%-16%). Therefore, the risk of MDR infection is directly related to where the infection was acquired (nosocomial or community-acquired)[22,26,28].

Although the association of quinolone prophylaxis with MDR infection was not identified with the use of norfloxacin for six months in a placebo-controlled trial[29] and in an epidemiological study[7], the prophylactic use of antibiotics has been pointed out as a risk factor for MDR infections in other studies [22,25,30].

The bacteriological profile of antibiotic resistance in each geographic region also influences the risk of multidrug resistance. Patients from India, other Asian centers, and South America had an increased risk of MDR bacteria[7]. The bacteriological profile of antibiotic resistance at each health care unit is also an important point, and this local antibiotic resistance profile should be considered in the estimation of the MDR risk of each patient[7,31].

MDR risk is also related to the site of the infection. For example, MDR infections were more commonly observed in patients with pneumonia, skin and soft tissue infections than in those with SBP or spontaneous bacteremia[7,27].

A higher prevalence of proton pump inhibitors (PPI) use among patients with MDR infection has been reported[24], suggesting that PPI could be a risk factor for infections caused by MDRO. However, this association still needs to be better explored in further studies.

MDR infections are more commonly observed in patients with worse liver function, however it is difficult to establish whether liver function is an independent risk factor for MDR because patients with more severe liver disease have more frequent hospitalizations and are more exposed to the use of antibiotics. In the study of Piano *et al*[7], liver function was not independently associated with MDR infections in the multivariate analysis although patients with MDR infections presented higher Child and MELD-Na scores. Therefore, even if it is not an independent risk factor, MDR infection is often associated with more severe liver disease.

Table 2 shows the main risk factors for MDR infections.

## MANAGEMENT

### Empirical antibiotic therapy

In the early phases of bacterial infections in patients with cirrhosis, typical signs of infection (like fever) may not be present. Bacterial infections can precipitate and/or constitute part of the process of acute decompensation of cirrhosis, and an appropriate work-up for infections (*e.g.*, diagnostic paracentesis; chest X-ray; urinalysis; blood, ascites and urine cultures) should be made in all patients hospitalized for decompensated liver disease[32].

Optimizing the prescription of antibiotics is cardinal to effectively treat infections, protect patients from harms caused by unnecessary antibiotic use, and combat antibiotic resistance. As the prevalence of MDRO differs throughout the world, the choice of an empirical antibiotic therapy should be tailored to the local microbiological epidemiology, and it should also be influenced by the type of infection (*e.g.*, SBP, urinary tract infection, pneumonia, soft tissue infection), the severity of infection, and the potential risk factors for infections caused by MDRO[32,33] (Table 1).

Effective antibiotics need to be administered as early as possible. In a retrospective cohort study of 126 cirrhotic patients with SBP-associated septic shock, each hour of delay in the appropriate antimicrobial therapy was associated with 1.86 times increase in hospital mortality[34]. In a worldwide study of hospitalized patients with cirrhosis, the administration of adequate empirical antibiotic treatment was found to be an independent and the only potentially modifiable predictor of in-hospital and 28-d mortality[7].

In the whole Canonic series, MDROs were more prevalent in infections causing severe sepsis/septic shock and/or ACLF and associated to lower resolution rate and higher mortality at 28 d, especially if treated with inadequate empirical antibiotic strategies[10]. A multicenter retrospective study of 865 consecutive patients with a first presentation of SBP in Korea pointed that empirical carbapenem treatment was significantly associated to lower in-hospital mortality than third-generation cephalosporins of among 314 critically ill patients (CLIF-SOFA scores  $\geq 7$ ; 23.1% *vs* 38.8%; aOR, 0.84;

**Table 2 Risk factors for multidrug-resistant infection in cirrhosis**

No.	Risk factors for MDR infection in cirrhosis
1	Prior (3 mo) use of broad-spectrum antibiotics
2	Prior infection by MDROs (6 mo)
3	Nosocomial infection
4	Recent contact with the healthcare system
5	Site of infection (pneumonia, skin, and soft tissue infections)
6	Geographic region
7	Prophylactic use of antibiotics (?)/proton pump inhibitors use?

MDR: Multi-drug resistant; MDRO: Multi drug resistant organism.

95%CI, 0.75-0.94;  $P = 0.002$ )[35].

In the treatment of HCA infections in an Italian population of cirrhotic patients, with a prevalence of MDRO of 40%-46%, empirical broad-spectrum therapy (imipenem/cilastatin  $\pm$  vancomycin) significantly reduced in-hospital mortality when compared to third generation cephalosporins, particularly in patients with sepsis. It also reduced the rate of treatment failure and length of stay[36]. In a prospective randomized controlled trial (RCT) that enrolled 32 patients with nosocomial SBP, the broad-spectrum antibiotic therapy (meropenem plus daptomycin) was more effective than ceftazidime (86.7% vs 25%,  $P < 0.001$ ). Furthermore, meropenem plus daptomycin was effective in 90% of nonresponders to ceftazidime. The response to first-line treatment was an independent predictor of survival[37].

The isolation of MDRO in rectal and nasal swabs could also guide empirical antibiotic strategies in cirrhotic patients. In a study of two European cohorts comprising a total of 907 critically ill patients, including 550 patients with cirrhosis, rectal colonization by MDRO was highly prevalent in cirrhotic patients, ranging from 28.7% to 31.1% in intensive care unit admissions, and MDRO carriage increased the short-term risk of subsequent infection by the colonizing organism[38].

Patients with cirrhosis and severe infections may benefit from therapeutic strategies aimed at optimizing the antibiotics' pharmacokinetic/pharmacodynamic target. The use of high antibiotic doses within the first 48-72 h after the diagnosis of infection and the continuous or extended infusions of beta-lactams are more likely to achieve and to maintain serum drug levels above the minimum inhibitory concentration compared to standard bolus administration. In a secondary analysis of a European prospective multicenter study of patients with cirrhosis and bloodstream infection, the empirical continuous/extended infusion of piperacillin-tazobactam or carbapenems was associated with lower mortality compared to traditional dosing schedules (adjusted hazard ratio, 0.41; 95%CI, 0.110-0.936;  $P = 0.04$ ), and it was particularly useful in those patients who were critically ill[39].

After completing 48-72 h of antibiotic therapy, early de-escalation can be considered based on clinical evolution and available antibiotic susceptibility tests. Short-term treatment is another key measure to prevent antibiotic resistance[7,40,41]. In the 1990s, a randomized controlled trial of 100 patients with SBP showed that a short-course (5-d) treatment is as effective as long-course (10-d) therapy and significantly less expensive[42]. In non-SBP infections, the optimal duration of antibiotic therapy has not been established, but data from the general population suggests that a 7-d course is adequate for most infections[32].

Figure 1 and Table 3 summarizes the management of patients with cirrhosis and bacterial infection.

### Non-antibiotic approach

The emergence and spread of MDRO in cirrhosis require the implementation of measures aimed to prevent its complications. Pharmacological and non-pharmacological strategies are needed, including hand hygiene and barrier precaution, restriction of antibiotic use to high-risk populations, de-escalating antibiotic therapy based on rapid microbiological tests, study of non-antibiotic prophylaxis measures, broad and strict infection control policies, and programs of epidemiological surveillance[25].

**Non-antibiotic drugs with potential benefit on infections in cirrhosis:** Although antibiotic treatment is the most effective measure for controlling established MDR infection, other drugs have shown potential benefits in preventing infections in cirrhosis. A lower occurrence of SBP has been demonstrated in patients using non-selective beta-blockers (NSBB)[43]. This benefit of NSBB has been related to its potential effect in improving intestinal motility, improving intestinal permeability, and reducing bacterial translocation[44,45]. Statins also seem to have a beneficial effect against bacterial infection[46] that is attributed to its anti-inflammatory and immunomodulatory properties.

**Table 3 Recommended empirical antibiotic treatment for bacterial infection in cirrhosis**

Type of infection	Community-acquired infection	Nosocomial and HCA infection or sepsis
SBP, spontaneous bacterial empyema and spontaneous bacteremia	Cefotaxime or Amoxicillin/clavulanic acid	Piperacillin/tazobactam or Meropenem ± Vancomycin or Daptomycin or Linezolid <sup>1</sup>
UTI	Fosfomycin or cotrimoxazole	Uncomplicated: Nitrofurantoin or Fosfomycin; if sepsis: Piperacillin/tazobactam or Meropenem ± Glycopeptide
Pneumonia	Amoxicillin/clavulanic acid; Ceftriaxone + Macrolide; Levofloxacin; Moxifloxacin	Piperacillin/tazobactam or Meropenem or Ceftazidime + Ciprofloxacin; Glycopeptides or Linezolid <sup>1</sup> should be added in patients with risk factors for MRSA <sup>2</sup>
Skin and soft tissue infections	Amoxicillin/clavulanic acid or ± Clindamycin	Meropenem or Piperacillin/tazobactam + Glycopeptide or Daptomycin or Linezolid <sup>1</sup> ± Clindamycin; if necrotizing fascitis: Meropenem + Daptomycin + Clindamycin

<sup>1</sup>Vancomycin, teicoplanin or daptomycin in areas with a high prevalence Methicillin-resistant *Staphylococcus aureus* and vancomycin-susceptible enterococci. Vancomycin must be replaced by linezolid in areas with a high prevalence of vancomycin-resistant enterococci.

<sup>2</sup>Ventilator-associated pneumonia, previous antibiotic therapy, nasal Methicillin-resistant *Staphylococcus aureus* carriage.

HCA: Health care associated; MRSA: Methicillin-resistant *Staphylococcus aureus*; SBP: Spontaneous bacterial peritonitis; UTI: Urinary tract infection.

**Figure 1 Suggested algorithm for the management of patients with cirrhosis and bacterial infections.** MDR: Multidrug-resistant.

**Non-pharmacological measures:** Non-pharmacological measures are based on preventive strategies and procedures focusing on intestinal colonization with MDRO. The most important preventive measure is the restrictive and judicious antibiotic use since the main driver for the emergence of MDR infections is the widespread use of antibiotics.

The main non-pharmacological measures focus on gut microbiota[27]. A healthy microbiome is essential to prevent colonization and infection by MDRO[25]. Different approaches focusing on the modulation of the intestinal microbiome were studied, such as probiotics, prebiotics/synbiotics dietary regimens, and fecal microbiota transplant (FMT)[45].

Although some studies have shown favorable results with probiotics, there are also negative studies. This controversy is probably related to different probiotics used and the different number and concentration of the species. Further studies are necessary to define the ideal combination, dose, and duration of administration.

FMT involves the safe transfer of exogenous bacterial flora from a healthy donor to another patient, in capsule or liquid formulations. The rationale for using this technique is the central role of the gastrointestinal colonization in the development of MDR infections. It has been demonstrated that colonization by MDRO is associated with increased risk of infection by the colonizing bacteria in the

short-term[38]. FMT has the potential effect of promoting MDRO decolonization.

A systematic review with meta-analysis[47] of five studies, with a total number of 52 patients, evaluated whether FMT decolonizes antibiotic-resistant bacteria from the gut of colonized adults. Evidence from this meta-analysis indicates a potential benefit of FMT as a decolonization intervention, with few adverse effects. Despite the low quality of evidence appointed by this meta-analysis, these preliminary results suggest that FMT is a promising approach that deserves further analysis in RCTs.

In cirrhotic patients, a preliminary study of FMT in patients with advanced cirrhosis on lactulose and rifaximin demonstrated that FMT restored antibiotic-associated disruption in microbial diversity and function[48]. The impact of FMT in the reduction of gut microbial antibiotic resistance genes was later reported in two trials: a capsule FMT trial and an enema FMT trial with 20 patients each. This study demonstrated that, despite differences in routes of administration, antibiotic resistance gene abundance was reduced after FMT compared to pre-FMT baseline and non-FMT groups in decompensated cirrhosis[49].

Another possible approach, although still requiring further studies, is phage therapy. This technique is based on the use of bacteriophages which are viruses that infect bacteria[50]. The bacteriophages replicate inside the bacteria leading to their destruction. It is an old technique that was left aside with the advent of antibiotics, but nowadays it has been considered again as a therapeutic option to face the serious problem of antibiotic multidrug resistance[51,52]. Although specific studies in cirrhotic patients are not available, phage therapy represents a possible future alternative therapy for controlling MDRO [53].

## CONCLUSION

In this review, we describe the epidemiology, clinical settings and the current evidence-based strategies for early recognition and treatment alternatives for MDR infection in cirrhotic patients.

### Abstract

The term "periodontal disease" refers to a group of chronic inflammatory illnesses caused by specific microorganisms from subgingival biofilm, that affect the tooth-supporting tissues. Recent research has also shown that periodontal infection plays a role in aggravating systemic disease states at distal sites, reinforcing the significance of the oral cavity for general health. Additionally, it has been suggested that gastroenterological malignancies may be promoted by hematogenous, enteral or lymphatic translocation of periopathogens. In the past 25 years, the global burden of pancreatic cancer (PC) has more than doubled, making it one of the major causes of cancer-related mortality. Periodontitis has been linked to at least 50% increased risk of PC and it could be considered a risk factor for this malignancy. A recent study performed on 59000 African American women with a follow up of 21 years showed that participants who had poor dental health had higher chances of PC. The findings, according to researchers, might be related to the inflammation that some oral bacteria trigger. Regarding the mortality of PC, periodontitis considerably raises the chance of dying from PC. Microbiome

alterations in the gut, oral cavity and pancreatic tissues of PC patients occur when compared to healthy flora, demonstrating a link between PC and microecology. Inflammation may also contribute to PC development, although the underlying pathway is not yet known. The function of the microbiome in PC risk has drawn more focus over the last decade. Future risk of PC has been linked to the oral microbiome, specifically increased levels of *Porphyromonas gingivalis* and *Aggregatibacter actinomycetemcomitans* and decreased relative abundance of *Leptotrichia* and *Fusobacteria*, suggesting that it may have an impact on the inflammatory condition by expanding, altering, and regulating the commensal microbiome. Patients who received periodontal treatment had significantly decreased incidence rate ratios for PC. By analyzing patterns in the microbiome composition throughout PC development and establishing strategies to enhance the cancer-associated microbial system, we can increase the efficacy of therapy and eventually find an application for the microbial system. The development of immunogenomics and gut micro-genomics in the life sciences will result in a significant advancement in our understanding of how microbial systems and immunotherapy interact, and it may also have intriguing therapeutic implications for extending the lifetime of PC patients.

## INTRODUCTION

The term "periodontal disease" refers to a group of inflammatory illnesses that affect the tooth-supporting tissues, ultimately leading to tooth loss and even resulting in systemic inflammation. Up to 90% of people worldwide are affected by the two most common periodontal disorders, gingivitis and periodontitis[1]. The cornerstone of avoiding periodontitis is the treatment of gingivitis, a reversible inflammation of the gingiva that takes place before periodontitis. By gradually destroying the alveolar bone and periodontal ligament, periodontitis-which is typically caused by Gram-negative bacteria-can result in recession, increased probing depth, or both[1].

Periodontal disease is initiated and progresses due to a dysbiosis of the commensal oral microbiota, which subsequently interacts with the host's immune system[2,3]. Diverse bacteria (or certain gene combinations within the community) may be capable of having various functions within the periodontal ecosystem that collaborate to generate and establish a microbiota that promotes disease. Numerous microbial species were found in the oral cavity, but most of them are commensal bacteria such as *Streptococcus*, *Capnocytophaga*, *Eikenella corrodens* and *Veillonella parvula*; nevertheless, in condition of some imbalances, they could also become pathogens for the tooth supporting tissues[4]. One of the crucial requirements for the development of a potentially pathogenic community is the ability of certain species to modify host responses in ways that compromise immune surveillance and tip the balance from homeostasis to dysbiosis[5]. *Porphyromonas gingivalis* (*P. gingivalis*), *Treponema denticola* and *Tannerella forsythia*, Gram-negative and anaerobic bacteria, possess a higher virulence and aggressiveness and are also involved in periopathogenesis[4].

Numerous mechanisms, including the systemic dissemination of periodontal pathogens and the systemic leakage of local inflammatory mediators, have been involved in the strong association between periodontitis and a number of systemic disorders[6]. Periodontal and systemic diseases have a two-way relationship; periodontal disease can have negative effects on the overall systemic health, and some systemic conditions increase the risk of periodontal disease onset[6,7]. Recent research has also shown that periodontal infection plays a role in aggravating systemic disease states at distal sites, including cardiovascular disease, adverse pregnancy outcomes, diabetes mellitus, Alzheimer's disease, inflammatory bowel diseases, and various cancer types, reinforcing the significance of the oral cavity for general health[6-9]. Additionally, it has been suggested that gastroenterological malignancies may be promoted by hematogenous (oral-blood axis *via* the perturbed periodontal tissues), enteral (oral-gut axis *via* saliva) or lymphatic (*via* the lymphatic drainage system) translocation of periopathogens[10-12].

In the past 25 years, the global burden of pancreatic cancer (PC) has more than doubled, making it one of the major causes of cancer-related mortality[13]. It comprises for almost 2% of all malignancies and is linked to 5% of deaths caused by cancer[14]. North America, Europe, and Australia have the highest incidence rates of PC[14,15]. While the ageing process of the global population could increase the incidence, other major risk factor, specifically smoking, obesity, diabetes and drinking alcohol should be considered for their modifiable nature[13,15].

Only around 20% of patients are initially diagnosed with early-stage PC, which is surgically resectable, thus explaining the low survival rates[13]. Even after a potentially radical treatment, the majority of patients eventually relapse, and their 5-year survival rate is only 2%-9%[14]. During the initial stages of the disease and its progression to advanced pancreatic metastasis, when tumor cells are very invasive, the majority of patients don't exhibit any apparent symptoms. Considering that it is one of the life-threatening malignant tumors, early diagnosis is imperative[13-15]. Pancreatic ductal adenocarcinomas account for over 90% of pancreatic malignancies[13].

Viral infections have been shown to express a strong relationship with cancer, but also certain bacteria can stimulate or trigger uncontrolled cell development by escaping the immune system or preventing apoptosis. Since periodontitis is a chronic oral bacterial infection, a potential link between periodontitis and PC has been proposed[9].

## AIM

The purpose of this current review is to update and organize the most recent data on periodontal disease and its implications in PC in order to highlight the fact that there is sufficient evidence to establish a connection between them, through the action of periodontal pathogens, taking into account that periopathogens are essential for the onset and progression of periodontal disease, and their involvement in various systemic disorders has already been proven. This would encourage more exploration into the negative impact of periodontal disease on the development of PC in individuals with both disorders. The findings of future studies may have significant implications for periodontal and gastroenterological practice. For instance, periodontal screening for patients with this type of cancer and periodontal therapy, when necessary, may help lower the risk of PC's adverse evolution while also improving the quality of life for these patients.

## PERIODONTAL DISEASE AND PC: EPIDEMIOLOGIC DATA

Periodontitis has been linked to various malignancies, with risk ranging between 14% and 20%[16,17]. Periodontitis has been linked to at least 50% increased risk of PC and it could be considered a risk factor for this malignancy[1,16,17], whereas other studies reported no significant association between periodontal disease and PC[1,18]. Periodontal disease risk is linked to a number of variables that are known to increase the risk of PC, such as smoking, alcohol drinking, and diabetes. The oral microbiome is thus affected by these exposures and circumstances, leading to dysbiosis and a relative increase in the amount of oral pathogenic microorganisms[19,20].

A 10 years follow-up study showed that the risk of all or specific gastro-intestinal malignancies, including PC, was not significantly associated with the severity of chronic periodontitis. After sex and age stratification, this null connection remained consistent[21]. No associations were found between the risk of PC and the eight single nucleotide polymorphisms, which provide the strongest explanation for a genetic predisposition to developing chronic or aggressive periodontitis[22].

Patients with PC may exhibit increased bleeding on probing when exposed to minimal amounts of dental plaque, which could point to periodontitis' excessive activity, often known as a hyperactive phenotype. Although dysfunctions of the CD14 axis receptor, nuclear factor kappa B (NF- $\kappa$ B) factors, and NOTCH pathway proteins are hypothesized, the source of high bleeding on probing index values at a relatively low plaque index rate is unknown at this time[23].

A cohort study that followed 5889441 individuals for a median of 7.2 years discovered that, compared to those with a healthy dental status, people with root canal infections, mild inflammation, and periodontitis in the under-50 age group had a 58% higher risk of developing PC, while those with periodontitis had a 56% higher risk. Only the subgroup of those with periodontitis exhibited a 20% elevated risk in the 50–70 age range. In all age categories, people with fewer teeth seemed to be at a higher risk[12]. Another study found that having periodontal disease was linked to a higher risk of developing PC in people 65 years of age or older, but not in people under 65[24].

A recent study performed on 59000 African American women with a follow up of 21 years showed that participants who had poor dental health had higher chances of PC[25]. Participants who reported both gum disease and tooth loss had a 58% higher chance of receiving a PC diagnosis[25]. Furthermore, compared to women who had neither periodontal disease nor tooth loss, those who reported periodontal gum disease but no tooth loss had a 77% higher chance of being diagnosed with PC[25]. Their research revealed that PC diagnoses were twice as likely to occur in women without periodontal disease but with absent teeth. Furthermore, the risk was significantly increased among patients who had at least 5 extracted teeth[25]. The findings, according to researchers, might be related to the inflammation that some oral bacteria trigger[25]. In an older research paper, when periodontal disease and recent tooth loss were evaluated together, the risk of PC significantly rose, with a risk ratio of 2.71 compared to people who had neither periodontal disease nor recent tooth loss. These findings imply that recent tooth loss may be a sign of severe periodontal disease[26].

Compared to the link between tooth loss and PC, the relationship between periodontal disease and PC has showed more consistent evidence[16,24,27,28]. According to a meta-analysis, the summary relative risk for periodontitis and PC was 1.74, while the risk for edentulism was 1.54[18]. Nevertheless, data is inconsistent as other research reported no associations between tooth loss and PC[27,28].

So far, research indicates that, independently of other recognized risk factors, like smoking, periodontal disease may contribute to the development of PC[26,29]. A prospective research of 48375 male health professionals revealed that those who had a history of periodontal disease at baseline had a 64% higher risk of PC[26,27,30]. In people who had never smoked, there was a stronger correlation between periodontal disease and PC[26,27,30]. Smoking is also linked to a two-fold increase in the risk of PC[26].

In a research with a long follow-up (10 years) and a substantial population-based cohort (568273 participants), there was a strong positive association between periodontitis and cancer mortality, particularly PC mortality[31]. After adjusting for age, sex, and additional controls for smoking, education, race/ethnicity, and body mass index (BMI), orodigestive cancer mortality was higher in patients with periodontal disease. Furthermore, the severity of periodontal disease enhanced the risks for orodigestive cancer mortality[32]. With age, sex, smoking, education, race/ethnicity and BMI adjustments, the mortality for PC in periodontal patients increased by nearly four times[32].

Regarding the mortality of PC, periodontitis considerably raises the chance of dying from PC[1].

## HUMAN MICROBIOME AND PC

Multiple diverse organisms, such as bacteria, viruses, fungus, and protozoa, compose the human microbiota, as the presence of certain microorganisms was reported even before birth, in the human placenta[14,33,34]. They are essential for maintaining human health and preventing illnesses. Bacteria's ability to cause cancer is linked to both individual species and dysbiotic ecosystems[11]. Some hepatitis viruses, particular oral, gastrointestinal, and pancreatic microorganisms may have an etiological role in PC development[14,33,35].

Microbial diversity in the colon and other internal organs is decreased as a result of human microbial system dysregulation and, in PC patients, the imbalance of the intestinal microbiota is common[14,33,35]. Regardless of the severity of PC, the bacterial DNA patterns in the pancreatic and duodenal tissue of the same participants were comparable, indicating that bacteria may be traveling from the gut to the pancreas[36]. Microbiome alterations in the gut, oral cavity and pancreatic tissues of PC patients occur when compared to healthy flora, demonstrating a link between PC and microecology (Table 1). Inflammation may also contribute to PC development, although the underlying pathway is not yet known[37].

According to scientific research, the human microbiota has a key contribution to the onset, progression, and prognosis of PC[14,33,35,38]. The NYU Langone study found that, in contrast to other research linking poor oral health to PC, oral microbiome dysbiosis actually occurred before the malignancy took hold[30].

The function of the microbiome in PC risk has drawn more focus over the last decade. Using 16S rRNA fluorescent probes and quantitative real-time polymerase chain reaction, it was discovered that PC patients had an intrapancreatic bacterial load that was 1000 times higher than that of normal pancreatic tissue. The mean relative proportions of certain taxa varied between the healthy cohort, pancreatic benign neoplasm, and PC[35]. A recent case-control study found that there were discrepancies in the overall bacterial communities between those with PC and controls. While the presence of *Enterobacteriaceae*, *Lachnospiraceae* G7, *Bacteroidaceae*, or *Staphylococcaceae* was linked to an increased risk

Table 1 Selected studies assessing various methods for detecting bacteria in different types of gastroenterological cancers

Ref.	Types of samples and methods used	Bacteria detected in patients with PC	Types of digestive cancers
Del Castillo <i>et al</i> [36], 2019	16S rRNA gene sequencing was performed on tissue samples (pancreatic duct, duodenum, pancreas), swabs (bile duct, jejunum, stomach), and stool samples	<i>Lactobacillus</i> , <i>Porphyromonas</i> , <i>Fusobacterium</i> , <i>Prevotella</i>	Pancreatic cancer
Torres <i>et al</i> [37], 2015	16S rRNA gene sequencing was performed on saliva samples	<i>Leptotrichia</i> , <i>Porphyromonas</i>	Pancreatic cancer
Vogtmann <i>et al</i> [39], 2020	16S rRNA gene sequencing was performed on saliva samples		Pancreatic adenocarcinoma
Fan <i>et al</i> [43], 2018	16S rRNA gene sequencing was performed on pre-diagnostic oral wash samples	<i>Porphyromonas gingivalis</i> , <i>Aggregatibacter actinomycetemcomitans</i>	Pancreatic adenocarcinoma
Farrell <i>et al</i> [47], 2012	16S rRNA gene sequencing was performed on saliva samples	<i>Streptococcus mitis</i> , <i>Granulicatella adiacens</i> , <i>Neisseria elongata</i>	Pancreatic cancer
Tan <i>et al</i> [48], 2022	16S rRNA gene sequencing was performed on oral wash samples, resected cancer tissue and matched normal adjacent tissues	<i>Porphyromonas gingivalis</i> , <i>Firmicutes</i> , <i>Proteobacteria</i> , <i>Neisseria</i> , <i>Haemophilus</i> , <i>Aggregatibacter</i> , <i>Pseudomonas</i> , <i>Sphingomonas</i> <i>Bacteroidota</i>	Pancreatic cancer
Mitsuhashi <i>et al</i> [52], 2015	Genomic DNA was extracted from pancreatic tissues specimens	<i>Fusobacterium</i>	Pancreatic ductal adenocarcinoma
Yamamura <i>et al</i> [53], 2017	Genomic DNA was obtained using a cotton swab in the oral cavity and from cancerous tissues	<i>Fusobacterium</i>	Esophageal, gastric, colorectal, liver and pancreatic cancer
Gaiser <i>et al</i> [58], 2019	Microbial DNA was isolated from cyst fluid and plasma	<i>Fusobacterium nucleatum</i> , <i>Granulicatella adiacens</i>	Pancreatic cystic neoplasms

PC: Pancreatic cancer.

of PC, increased relative levels of *Haemophilus* were linked to a lower risk[39]. Currently, *Neisseria elongata*, *P. gingivalis*, *Streptococcus mitis* and *Fusobacterium* are the key pathogens implicated in PC and it was postulated that *Fusobacterium* can significantly decrease a patient's survival time when it comes to the prognostic evaluation of PC[11,14].

By causing DNA damage, epigenetic alterations of phagocytosis-related genes, immunological response, chromatin organization, cellular proliferation, and higher DNA mutation rates, the microbiome can influence cancer's development. The microbiome can also potentially cause signaling pathway disruption, enhanced local inflammation, and impaired epithelial barrier function[11]. According to one study, the point mutations in the PC patient's p53 tumor suppressor gene may be caused by the peptidyl arginine deaminase enzymes that are specific to oral periopathogen *P. gingivalis* [40].

According to one study, periodontitis, PC and chronic pancreatitis may all share the excessive inflammatory response brought on by the mutations of certain genes, *Q705K* and *F359L*, which are amino acids in *NLRP2* and *NLRP3*. It has been shown that rs35829419 (*Q705K*, *NLRP3*) polymorphism is more common in people with PC, while rs17699678 (*F359L*, *NLRP2*) polymorphism is more common in people with chronic pancreatitis[41].

By triggering systemic inflammation or, alternatively, by increasing the synthesis of bacterial metabolites, such as nitrosamines, reactive oxygen species sulfides, butyrate or acetaldehydes, chronic periodontitis through periopathogens may facilitate pancreatic carcinogenesis[9-11,18]. According to various theories, nitrosamines, acetaldehyde and gastric acidity play a significant role in the development of PC[9,18,27,42], as they can cause DNA alkylation, mutations, damage or impaired repair, which can result in inflammation or tumorigenesis[11].

Although the underlying mechanism connecting periodontitis to gastrointestinal cancers is not fully understood, and it is still uncertain which stage of periodontitis may affect cancer risk, gastroenterological malignancies have a high biological plausibility in relation to oral infections and inflammation[1, 19]. Blood antibodies to certain oral pathogens and poor oral health status were linked to an elevated risk of PC[19,43]. A person's chance of developing PC was increased by 70% and 80%, respectively, whether they had oral mucosal lesions, or tongue lesions caused by *Candida*[1]. PC development was positively associated with tooth loss, although seropositivity to *Helicobacter pylori* was not significantly correlated with tooth loss[44]. Recent research could not establish a link between *Helicobacter pylori* and a higher risk of PC[45].

Future risk of PC has been linked to the oral microbiome, specifically increased levels of *P. gingivalis* and *Aggregatibacter actinomycetemcomitans* (*A. actinomycetemcomitans*) and decreased relative abundance of *Leptotrichia* and *Fusobacteria*, suggesting that it may have an impact on the inflammatory condition by

expanding, altering, and regulating the commensal microbiome[11-13,29]. It's noteworthy that *Leptotrichia* species, which are opportunistic pathogenic bacteria, are also frequently discovered in immunosuppressed individuals[46]. Using direct bacterial DNA analysis from samples of people's saliva taken years before diagnosis, a cohort research found strong associations between two periodontogens, *P. gingivalis* and *A. actinomycetemcomitans*, and PC[1,10,43]. This connection is also confirmed by a research which found that pre-diagnostic blood samples from those diagnosed with PC had more antigens to *P. gingivalis* than samples from controls[13]; in contrast, phylum *Fusobacteria* appeared to be linked with a reduced chance of developing PC[10,33]. There are still unanswered doubts regarding the mechanism underlying this connection and whether there is a direct causal correlation[13].

Oral microbiome profiles in patients with PC and controls significantly differ, according to scientific research[47]. Combining immunological dysregulation, genomic damage, and microbial variations between PC cases, early PC cases, and healthy controls, these factors point to a mechanistic role for oral microbiome components in PC development[11].

Bacteria can have a significant impact on carcinogenesis' mechanisms[43,45]. The bacterial "driver-passenger model" best describes this method of collaboration, in which the "driver" pathogen, such as *A. actinomycetemcomitans*, causes DNA damage in the host cells. A more stable ecosystem results from the modifications this driving pathogen makes to the microenvironment around the host cell. These changes make it easier for other germs to proliferate and survive. Once the cancer cells have been located, the "passenger" bacteria, such as *F. nucleatum*, will operate as a connecting organism between the early colonization microorganisms (*A. actinomycetemcomitans*) and the late colonizing microbes (*P. gingivalis*). *P. gingivalis* has the ability to block cancer cell death and encourage tumor growth[43,45]. The three microorganisms could have a significant synergistic impact on the onset and progression of cancer. This means that a diversified microbial environment is both more stable and harmful than a single species of bacterium, which may be a key element in the development of cancer[45].

### ***Porphyromonas gingivalis***

A recent study revealed that numerous bacterial taxa which were often detected in the tumoral milieu were also discovered in the oral microbiome, raising the possibility of bacterial translocation from the mouth to the pancreas. Unexpectedly, *P. gingivalis*, one major periodontal pathogen, which usually colonizes the oral cavity, was found in the saliva samples, normal surrounding tissues and the malignant tissues of PC patients in the same report[42,48]. The oral-derived migration of *P. gingivalis* into the pancreas as well as its capacity to cause PC were further shown. The explanation is that *P. gingivalis* induces the aggregation of neutrophils and the release of neutrophil elastase, which eventually promotes pancreatic neoplasms[48].

There is growing evidence that PC and periodontal infections are closely related[12] as *Leptotrichia* and *Porphyromonas* were more prevalent in PC patients' saliva than in healthy controls' saliva[37].

A 1.6-fold higher risk of PC was found in one of the biggest prospective cohort analyses to date when *P. gingivalis* taxa were directly detected in saliva using 16S RNA genes[43]. Unlike past studies assessing bacterial DNA in cancer patients' saliva, this cohort study was distinctive in that saliva samples were taken up to 10 years before a cancer diagnosis[28,43].

Participants who had *P. gingivalis* in their oral microbiome were shown to have a 59% higher chance of developing PC than those who did not[32]. In a European cohort research, those with high levels of antibodies to *P. gingivalis* (> 200 ng/mL) had a twofold increased probability of developing PC[1,10,30,33].

Although the dose-response was not linear and tended to flatten at higher immunoglobulin G (IgG) levels, a cohort research demonstrated a threefold increase in orodigestive cancer mortality, including pancreatic tumors, with rising *P. gingivalis* IgG levels[28,30,32].

Periodontal disease, oral pathogenic microorganisms, and PC have all been linked in a direct manner *via* biological pathways that have been hypothesized. One theory proposes a novel apoptosis-resistant mechanism that promotes immunosuppression and oncogenesis, with *P. gingivalis* serving as the common link[1]. Inhibiting epithelial cells' ability to undergo apoptosis, which has an essential function in defending malignant cells, is one of *P. gingivalis*' major carcinogenic effects. Some signaling pathways that *P. gingivalis* activates are implicated in immune evasion, tumorigenesis, cell invasion of tumor cells, and induction of apoptosis[49].

The bacteria *P. gingivalis* was discovered to be enriched in the abundant intratumor microbiota composition in human PC tissue. *P. gingivalis* may create a tumor microenvironment that is pro-inflammatory and elevate neutrophil elastase levels, eventually promoting the development of PC[42,48]. It was discovered that *P. gingivalis* survives inside PC cells, a property that can be improved *in vitro* and is amplified by hypoxia, a key aspect of PC[50]. The capacity of the bacteria to survive intracellularly and to increase Akt signaling and cyclin D1 expression, two essential pathways associated with PC development, are connected to the enhancement of proliferation. *P. gingivalis* infection of tumor cells led to enhanced growth *in vivo*. The scientists concluded that *P. gingivalis* directly influences PC cells in a pro-tumorigenic manner[50]. PC cell proliferation was considerably increased by live *P. gingivalis*, but surprisingly, this effect was not mediated by Toll-like receptor 2, an innate immune receptor that is activated in response to *P. gingivalis* on immune and cancer cells and is necessary for the bacterium to

cause alveolar bone resorption[50].

Another link between *P. gingivalis* and tumors is the metabolism of possibly carcinogenic compounds produced by this bacteria[49]. Following the administration of lipopolysaccharide from *P. gingivalis*, increased expressions of certain genes (*Reg3A* and *G*) were reported, thus the authors suggested that it could play an important role in *P. gingivalis*-lipopolysaccharide-related PC in mice[51].

*P. gingivalis* was definitely able to influence the host immunological responses, according to RNA sequencing. After *P. gingivalis* infection, neutrophil chemokines (*Cxcl1*, *Cxcl2*, *Cxcr2*, *etc.*) were discovered to be strongly elevated, but genes linked to gram-negative bacterial defense and antitumor-origenic activities, such as lymphocyte chemotaxis and cell cytolysis, were significantly suppressed. In PC mouse models, *P. gingivalis* specifically bypasses the host immune system and severely reduces the host's ability to fight tumors[48].

High frequencies of mutations in the tumor suppressor gene *p53* were found in PC patients, leading researchers to draw the conclusion that alteration of the *p53* gene is a crucial event in the development of human pancreatic tumors[49]. Furthermore, *P. gingivalis* decreases *p53* levels while increasing the cell cycle's S-phase advancement[11].

Both *F. nucleatum* and *P. gingivalis* possess strong antiapoptotic properties as well as capabilities of immune evasion and disruption[11].

### ***Fusobacterium nucleatum***

*Fusobacterium* species were examined by Mitsuhashi *et al*[52] in 283 PC patients and their results found a detection rate of 8.8% in tumor tissue and 28% in normal adjacent tissues. When using multivariate Cox regression analysis, it was shown that the presence of these bacteria is associated with a greater mortality, in comparison with *Fusobacterium*-negative group[52]. Conversely, a recent study did not detect *F. nucleatum* DNA in PC tissues. They hypothesized that *F. nucleatum* would contribute to the development of gastroenterological tract cancer but not pancreatic or liver cancer[53], although Mitsuhashi *et al*[52] stated that the bacterium could be considered a prognostic marker of PC[52].

Moreover, greater abundance of *Fusobacteria* and its genus *Leptotrichia* was linked to a lower risk of PC, according to a cohort study that used direct bacterial DNA sequencing from samples of people's saliva obtained years before diagnosis[42,43]. In contrast, *F. nucleatum*-positive pancreatic ductal adenocarcinomas were linked to elevated cancer-specific mortality rates[11,46].

*Fusobacterium* species were more frequently discovered in pancreatic tail cancer than in head or body cancer, despite the lack of a significant association. Uncertainty surrounds the high incidence of *Fusobacterium* species in pancreatic tail tumors. The difference in vascular supply between the pancreas tail and head or body could represent one possibility for this observation[52].

### ***Aggregatibacter actinomycetemcomitans***

Moreover, although the connection was not as strong as for *P. gingivalis*, people who exhibited *A. actinomycetemcomitans* in their oral microbiome also had at least a 50% higher relative chance of developing PC[32]. When *A. actinomycetemcomitans* taxa were directly detected in saliva using 16S RNA genes, one of the biggest cohort analyses to date found a 2-fold increased risk of PC[43]. In contrast to past studies measuring bacterial DNA in cancer patients' saliva, the samples used in this cohort study were taken up to 10 years before the cancer diagnosis[28].

Through the insertion of DNA double-strand breaks *via* CDT activity, *A. actinomycetemcomitans* Y4 can cause genomic instability, a significant phase in the tumorigenesis[11].

Bacterial toxins, such as the cytolethal distending toxin released by *A. actinomycetemcomitans*, can disrupt the balance of the host's immune system, harm antigen-presenting cells, and prevent lymphocyte proliferation[11]. Moreover, their lipopolysaccharide may help accelerate carcinogenesis through NF- $\kappa$ B signaling and TLR4 binding, both of which are elevated in the tumor microenvironment[11].

## **THERAPEUTIC APPROACHES**

Previous research has demonstrated a connection between microbes and the development and spread of PC. The development of biomarkers that may control how responsive cancers are to therapeutic drugs may be regulated by the human microbial system, which is particularly advantageous for enhancing PC's clinical efficiency. Chemotherapy and immunotherapy can be paired with microbial systems, which may provide PC patients a significant amount of hope. But there is still a lot of disagreement in this area[14].

### **Early detection**

It has been established that intestinal microbiota contributes to PC by producing tumor-specific immunity and systemic immunity, although the mechanism is yet unknown. In an effort to develop new therapeutic approaches, future research will concentrate on how microbiota influences the development and maintenance of immunological tolerance. In order to create more targeted techniques of response modulation, a thorough investigation of the PC-associated microflora can be performed to pinpoint

particular communities that contribute either positively or negatively to the onset and progression of PC [14]. The biggest chance of increasing survival rates would arise from early identification of PC. A particular oral microbiota analysis might be developed to enable the early diagnosis of cancer since mouth dysbiosis appears to be more pronounced in individuals with gastrointestinal tumors [29].

To determine if the presence of specific microbial species may be used as a biomarker for the early diagnosis of PC, the salivary bacterial profiles of 108 people were examined; 8 of them received a PC diagnosis, 22 were healthy controls and the other had other diseases. When compared to healthy participants or patients with other disorders, the ratio of *Leptotrichia* and *Porphyromonas* was considerably greater in the saliva of subjects with a future PC diagnosis [20,37]. *P. gingivalis* may serve as a biomarker for the emergence and progression of PC [49].

Similar shifts may be observed in individuals with preneoplastic lesions, such as intraductal papillary mucinous neoplasms, if alterations in the oral microbiota are connected to the probability of developing PC [20].

Saliva is a biofluid that is simple to acquire, making it perfect for the early identification of a variety of illnesses, including bacterial and viral infections, cardiovascular, renal, autoimmune disorders and, especially, malignancies [54-56]. Eight metabolites (leucine with isoleucine, tryptophan, valine, glutamic acid, phenylalanine, glutamine, and aspartic acid) were found in a research that thoroughly investigated salivary metabolites and identified metabolic patterns unique to several types of malignancies, including PCs. According to this, salivary metabolites could be considered cancer-specific markers [55].

### Gut microbiome modulation

The identification of biomarkers for predicting future PC risk and prognosis is made possible by microbiota research, which offers the chance to fully explain the underlying processes. According to prior research, PC is linked to bacteria that may alter a tumor's susceptibility to therapeutic medicines. Through appropriate adjustment, the effectiveness of this deadly disease's therapy can be greatly improved. The development and application of novel antibiotics, prebiotics, probiotics or microbial transplantation in conjunction with chemotherapy and immunotherapy may hold considerable potential for PC patients [35,46,57].

Reducing the pancreatic inflammatory microbiome may be a viable treatment option for individuals with an early precursor of PC, like pancreatic cysts-intraductal papillary mucinous neoplasms-, because of the demonstrated co-occurrence and enrichment of oral bacterial species in their microbiome [58].

Pushalkar *et al* [59] showed that intestinal bacteria may invade the pancreas, and that in PC tissue, both in animal models and in people, there is an increased abundance of bacteria compared with control cases with a different microbiome community in PC samples compared to controls. Furthermore, compared to healthy animals, PC mouse models have a higher capacity for the gut microbiota to translocate to the pancreas [20,59]. In one investigation, the significance of the *P. gingivalis*-inflammatory system-pancreas axis in the progression of PC was clarified, and it was suggested that lowering *P. gingivalis* infections or inflammatory state would help with PC prevention and therapy [48].

Additionally, PC developed more slowly in germ-free mutated animals. Oral antibiotic therapy also showed a protective effect against tumor growth, while gut microbiome repopulation with PC mouse feces increased cancer progression [20].

It was discovered that microbe-free mice did not respond to immunotherapeutic medications, but mice that were administered *Bacteroides fragilis* responded positively. According to Sivan *et al* [60], *Bifidobacterium* increased the effectiveness of cancer immunotherapy in mice, which suggested that microbes, particularly gut bacteria, may be triggering the immune response by causing enterocytes to produce specific message molecules or send signals to immune cells, which enhances their capacity to fight tumors [35,60]. Due primarily to its poor response to chemotherapy, PC is often a fatal disease. Recent research suggests that the tumor microenvironment may be a significant factor in developing gemcitabine chemoresistance [57].

By analyzing patterns in the microbiome composition throughout PC development and establishing strategies to enhance the cancer-associated microbial system, we can increase the efficacy of therapy and eventually find an application for the microbial system. The development of immunogenomics and gut micro-genomics in the life sciences will result in a significant advancement in our understanding of how microbial systems and immunotherapy interact, and it may also have intriguing therapeutic implications for extending the lifetime of PC patients [14].

### Periodontal treatment

Enhancing our knowledge of the connection between periodontal disease and other risk factors and how they affect cancer risk, as well as identifying potential bacteria that may be involved in carcinogenesis, may also open up new opportunities for early cancer detection (through the discovery of biomarkers), and provide information on whether active treatment for periodontal disease will lessen the burden of cancer [28,46]. It is uncertain to say at this point if the burden of cancer would decrease with the treatment of periodontitis [28].

Using the Taiwanese NHIRD, a research project investigated the link between periodontal disease and cancer, particularly PC, and the impact of periodontal disease therapy, which was defined as at least 10 procedures like scaling and periodontal flap surgery. Patients who received treatment had

significantly decreased incidence rate ratios for PC and adjusted hazard ratios. The modified model did not, however, take smoking into account[19,61].

## CONCLUSION

These researches support the hypothesis that certain characteristics of the human microbiome play a significant role in shaping the immune response in a manner that facilitates tumor development. Given the growing epidemiological data linking periodontal disease to PC and the rapid unraveling of new molecular links between periopathogens and cancer development, the impact of bacterial infection on pancreatic carcinogenesis has to be given more consideration. More research in this field is expected to improve our knowledge of this aggressive malignancy and provide us with new chances for early identification and/or the development of treatments.

## Abstract

### BACKGROUND

Stroke is a common and frequently occurring disease of the nervous system and one of the three major diseases leading to human death. The incidence and mortality of stroke in China increase with age. Overall, 70 % of patients with stroke have serious disability, which results in heavy burden to their families and the society.

### AIM

To analyze the effects of Qixue Shuangbu decoction and acupuncture combined with Western medicine on immune indexes and digestive tract function in patients with acute severe stroke.

### METHODS

A total of 68 patients with acute severe stroke admitted to Lanzhou Second People's Hospital between March 2018 and September 2021 were selected and divided into the control and observation groups according to a random number table method. The control group was administered routine Western medicine treatment, such as dehydration, lowering intracranial pressure, anticoagulation, improving cerebral blood circulation and cerebral nerve protection according to the "Guidelines for the Diagnosis and Treatment of Acute Ischemic Stroke in China." The observation group was administered Qixue Shuangbu decoction *via* nasal feeding tube on the basis of the routine Western medicine treatment with simultaneous acupuncture. The two groups were compared.

### RESULTS

The acute physiology and chronic health evaluation II, organ dysfunction syndrome score, National Institutes of Health Stroke Scale, and traditional Chinese medicine syndrome scores of the two groups were significantly decreased compared with those measured before treatment, and the complements C3 and C4, and immunoglobulins (Ig) M and G were significantly increased

compared with those observed before treatment ( $P < 0.05$ ). After treatment, the scores of the observation group were lower than those of the control group, and the complement and Ig levels were higher than those of the control group ( $P < 0.05$ ). The levels of diamine oxidase (DAO), D-lactic acid (D-LA), and calcitonin gene-related peptide (CGRP) in the two groups were significantly higher than those before treatment, while the levels of lipopolysaccharide, ubiquitin carboxyl-terminal hydrolase 1 (UCH-L1), tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukin (IL) -2, and IL-8 were significantly lower than those before treatment ( $P < 0.05$ ). After treatment, DAO, D-LA, and CGRP were higher in the observation group than in the control group, while lipopolysaccharide, UCH-L1, TNF- $\alpha$ , IL-2, and IL-8 were lower than in the control group ( $P < 0.05$ ). The hospitalization time of individuals in the observation group was shorter than that of the control group ( $P < 0.05$ ).

## CONCLUSION

Qixue Shuangbu decoction and acupuncture combined with Western medicine for the treatment of acute severe stroke can regulate intestinal flora, reduce inflammation, improve intestinal mucosal barrier function and immune function related indicators, and promote recovery.

**Key Words:** Qixue Shuangbu Decoction; Acupuncture; Western medicine; Acute severe stroke; Intestinal flora; Degree of inflammation; Immune function

**Core Tip:** Severe stroke is an acute and critical disease of the nervous system, which is a group of diseases that cause brain tissue damage due to the sudden rupture of brain vessels or the failure of blood to flow into the brain due to vascular obstruction. Traditional Chinese medicine believes that the disease belongs to the category of "stroke." There is evidence that lack of multi-factor endowment, aging, and yang hyperactivity wind, or drinking of syrup, overeating fat, climate change and other incentives result in viscera dysfunction, qi and blood disturbance, disturbing the brain orifices, and channeling the meridians for stroke.

## INTRODUCTION

Severe stroke is a common disease of the nervous system with high mortality. Due to the most common sensory and motor dysfunction caused by neurological impairment, patients cannot eat independently; therefore, they require nutritional support treatment. However, long-term nutritional support treatment leads to abnormal intestinal flora, imbalance of gastrointestinal hormone secretion, and eventually systemic inflammatory response and even flora disorder[1]. The disease belongs to "apoplexy" category of traditional Chinese medicine. Because the brain is the capital of the gods, the disorder of qi and blood leads to the occurrence of apoplexy and the imbalance of qi movement in spleen and stomach. Additionally, the stagnation of intestinal dross leads to the accumulation of blood stasis and heat, which disturbs the gods. Both form a vicious circle. Therefore, traditional Chinese medicine (TCM) advocates the principle of promoting qi and activating blood, dredging the fu organs and reducing turbidity. Qi and blood Shuangbu decoction is mainly used to supplement qi and blood deficiency in patients with stroke, and acupuncture treatment focuses on regulating gastrointestinal function[2]. In this study, the effects of Qixue Shuangbu decoction and acupuncture combined with Western medicine on patients with acute severe stroke were assessed. The immune function and digestive tract function indexes were selected as the observation objects to analyze the therapeutic effect of integrated traditional Chinese and Western medicine to provide the corresponding basis for clinical practice.

## MATERIALS AND METHODS

### General information

A total of 68 patients with acute severe stroke admitted to Lanzhou Second People's Hospital between March 2018 and September 2021 were selected and divided into two groups according to the random number table method. A total of 34 cases were included in the control group, of whom 19 and 15 were men and women, respectively, and were aged 42–75 years (average,  $60.84 \pm 5.32$  years). The time from onset to treatment was 0.5–6 h, with an average of  $2.74 \pm 0.46$  h. The locations of lesions were the basal ganglia, lobe, and brainstem in 19, 10, and 5 cases, respectively. The Glasgow coma scale (GCS) was  $6.25 \pm 1.04$ . A total of 34 cases were included in the observation group, of whom 17 were men and 17 were women, aged 41–75 years (average,  $61.01 \pm 5.05$  years). The time from onset to treatment was 0.5–6 h, with an average of  $2.69 \pm 0.47$  h, and the locations of lesions were the basal ganglia, brain lobe, and brain stem for 17, 12, 5 cases, respectively. The gCS score was  $6.22 \pm 1.01$  points. General data were balanced between the two groups, with no statistical significance being observed ( $P > 0.05$ ).

The inclusion criteria were as follows: (1) Stroke defined in line with the “Chinese guidelines for the diagnosis and treatment of acute ischemic stroke 2014” criteria for ischemic stroke[3]: (a) acute onset; (b) focal neurological deficit; (c) unlimited duration of symptoms or signs; (d) excluding non-vascular causes; and (e) excluding cerebral hemorrhage; (2) stroke defined in line with the “common diagnostic criteria of traditional Chinese medicine” in the Qixue deficiency syndrome standard[4], including dizziness, fatigue, insomnia, amnesia, shortness of breath, pale lips, pale tongue, weak pulse, and other syndromes; (3)  $\geq 40$  years of age,  $\leq 75$  years of age; (4) GCS score of  $\leq 8$  and National Institutes of Health Stroke Scale (NIHSS) score of  $\geq 17$ ; and (5) family members sign informed consent.

The exclusion criteria were as follows: (1) A history of mental illness; (2) a history of serious underlying digestive diseases or abdominal surgery; (3) complicated with severe visceral lesions; and (4) thyroid dysfunction, coagulation dysfunction, malignant tumors, or severe malnutrition.

### Methods

In the control group, routine Western medicine treatment, including dehydration and intracranial pressure reduction, anticoagulation, improvement of cerebral blood circulation, and cerebral nerve protection, was adopted. Patients were administered enteral nutrition support treatment. Enteral nutrition suspension (commodity name: Nengquanli, Newdihya Pharmaceutical Co., Ltd., Batch No. 20180318) was administered 1500–2500 mL/day with 50–100 mL/h dripping speed using a gastric tube.

In the observation group, the patients were administered with Qixue Shuangbu decoction using a nasal feeding tube and simultaneous acupuncture treatment was performed. Prescriptions of Qixue Shuangbu decoction included *Codonopsis* (15 g), *Atractylodes* (15 g), *Poria* (12 g), *Angelica* (12 g), *Paoniae Alba* (12 g), *Rehmannia glutinosa* (15 g), *Chuanxiong* (9 g), and *Radix Glycyrrhizae* (6 g). The above drugs were decocted for 150 mL and administered using a nasal feeding tube daily for 14 d. The acupuncture points were Neiguan, Zusanli, Guanyuan, Qihai, Shangjuxu, Zhongwan, and Xiawan. One-time acupuncture was performed using the twirling small lifting insertion technique, following the use of a gas needle for 20 min. Acupuncture was performed twice a day as a continuous treatment of 14 d.

### Observation indicators

Acute physiology and chronic health evaluation II (APACHE II)[5] and organ dysfunction syndrome (MODS)[6] scores were used to evaluate the overall severity of the disease and severity of organ failure. The two scores were proportional to the overall severity of the disease and severity of organ failure, respectively. NIHSS[7] was used to evaluate the degree of neurological deficit, and it was proportional to the degree of neurological deficit. TCM syndrome score was estimated based on symptoms, including dizziness, laziness, amnesia, fatigue, insomnia, dreaminess, blurred vision, palpitations, shortness of breath, loss of appetite, slim body, and luxuriant face. The above symptoms were categorized from light to heavy using the Likert 4 grade scoring method, ranging from 0–3 points.

The incidence of gastrointestinal complications (diarrhea, constipation, gastrointestinal bleeding, vomiting), pressure sores, ventilator-associated pneumonia (VAP), offline success rate, hospitalization time, and 28-d mortality in the two groups were recorded[8].

### Detection method

Fasting venous blood (3 mL) was extracted from patients and centrifuged at 2000 r/min for 30 min. Hitachi 7600i automatic biochemical analyzer was used for determination of biochemical parameters. The kit was provided by Nanjing Jiancheng Biological Products Co., Ltd. The calcitonin gene-related peptide (CGRP), ubiquitin carboxyl-terminal hydrolase 1 (UCH-L1), tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukin (IL)-2, IL-8, diamine oxidase (DAO), and D-lactic acid (D-LA) were estimated using enzyme-linked immunosorbent assay. The changes of the lipopolysaccharide concentration were determined using a radioimmunoassay. The changes of complement C3, complement C4, immunoglobulin (Ig) M, and IgG were detected by flow cytometry.

The patient's feces weighing 1 g were diluted with 5 mL of distilled water and inoculated in appropriate culture medium to determine the number of *Bifidobacterium*, *Lactobacillus*, *Enterococcus*, and *Enterobacter*.

### Statistical analysis

The data were processed using the SPSS19.0 software. The data were assessed for normal distribution and uniform variance was described using mean  $\pm$  SD. The *t* test was used for comparison, and the number of cases (%) for enumeration data were used for description. The  $\chi^2$  test was used for comparison, and statistical significance was set at  $P < 0.05$ .

## RESULTS

### Comparison of scores between and within groups

Before treatment, APACHE II, MODS, NIHSS, and TCM syndrome scores were not significantly different between the groups ( $P > 0.05$ ). Table 1 shows that APACHE II, MODS, NIHSS, and TCM syndrome scores were significantly lower than those before treatment for both groups ( $P < 0.05$ ). After treatment, the scores of the observation group were lower than those of the control group ( $P < 0.05$ ).

### Comparison of complement and Ig system indexes between and within groups

Complement (complement C3, complement C4) and Ig system (IgM, IgG) indexes were not significantly different before treatment ( $P > 0.05$ ). Table 2 shows that the complement and Ig system indexes were significantly higher than those before treatment in both groups ( $P < 0.05$ ). After treatment, complement C3, complement C4, IgM, and IgG were higher in the observation group than in the control group ( $P < 0.05$ ).

### Comparison of intestinal mucosal barrier function indexes between groups and within groups

Before treatment, the intestinal mucosal barrier function indexes were not significantly different between the groups ( $P > 0.05$ ). Table 3 shows that DAO and D-LA were significantly increased ( $P < 0.05$ ), while lipopolysaccharide was significantly decreased ( $P < 0.05$ ) in the two groups. After treatment, DAO and D-LA were higher in the observation group than in the control group, while lipopolysaccharide was lower than that in the control group ( $P < 0.05$ ).

### Comparison of CGRP, UCH-L1, TNF- $\alpha$ , IL-2, IL-8 between and within groups

Before treatment, CGRP, UCH-L1, TNF- $\alpha$ , IL-2 and IL-8 were not significantly different ( $P > 0.05$ ). Table 4 shows that CGRP was significantly increased ( $P < 0.05$ ), and UCH-L1, TNF- $\alpha$ , IL-2 and IL-8 were significantly decreased ( $P < 0.05$ ) in the two groups. After treatment, CGRP was higher, while UCH-L1, TNF- $\alpha$ , IL-2 and IL-8 were lower in the observation group than in the control group ( $P < 0.05$ ).

### Comparison of intestinal flora between groups and within groups

The number of intestinal flora before treatment were not significantly different between the groups ( $P > 0.05$ ). As shown in Table 5, *Bifidobacterium*, *Lactobacillus*, and *Enterococcus* numbers were significantly higher in the two groups than those before treatment ( $P < 0.05$ ), while the number of *Bacteroides* was significantly lower than that before treatment ( $P < 0.05$ ). After treatment, *Bifidobacterium*, *Lactobacillus*, and *Enterococcus* numbers were higher in the observation group than in the control group, while the number of *Bacteroides* was lower than in the control group ( $P < 0.05$ ).

### Comparison of the incidence of gastrointestinal complications and pressure ulcers between groups

There were seven cases of gastrointestinal complications and one case of pressure sore in the control group. The overall complication rate was 23.53%, which was higher than that of the observation group (8.82%); however, no statistical significance was reached ( $P > 0.05$ ) (Table 6).

### Comparison of VAP incidence, weaning success rate, hospital stay, and 28-d mortality between groups

The incidence of VAP and the success rate of weaning were higher in the observation group than those in the control group, while the 28-d mortality rate was lower than that in the control group; however, no statistical significance was reached ( $P > 0.05$ ). The hospitalization time of the observation group was significantly shorter than that of the control group ( $P < 0.05$ ) (Table 7).

## DISCUSSION

Severe stroke refers to the brain tissue necrosis or softening caused by hypoxia and ischemia due to cerebral blood circulation disorder, which is a common cerebrovascular disease in clinic. The occurrence of patients with stroke is generally developed on the basis of atherosclerosis changes. Inflammatory reaction is one of the reasons for cell loss, which has a serious impact on life safety and physical and

mental health of patients[9]. Most critically ill patients experience disturbance of consciousness, swallowing dysfunction, and metabolic exuberance; therefore, they have higher nutritional needs. However, limited intake leads to high stress response, resulting in malnutrition and reduced immune function[10]. Western medicine mainly relies on intestinal nutrition support in the aspect of supplemental nutrition; however, it can cause reproduction of pathogenic bacteria and formation of flora disorder, which would eventually lead to excessive activation of systemic inflammatory response. At the same time, the loss of neurological function in patients with stroke would lead to the inactivation of gastrointestinal hormones and change in neurotransmitter secretion, affecting the function of human

VAP: Ventilator-associated pneumonia.

intestinal mucosa and causing intestinal flora disorder.

TCM believes that stroke belongs to the category of stroke. In early stages of the disease, wind, fire, phlegm, and silt are the main factors, while in late stages, deficiency and silt are the main factors. TCM theory believes that qi is the handsome of blood, blood is the mother of qi, qi is the blood, qi is the vitality and movement, and qi deficiency is unable to promote the operation of blood, which will lead to blood stasis. This study adopts the TCM treatment method of Qixue Shuangbu decoction combined with acupuncture treatment. Qixue Shuangbu decoction consists of Sijunzi decoction and Siwu decoction. Reinforcing qi by *Dangshen*, strengthening healthy qi and expelling pathogenic factors, reinforcing qi by *Shaoyao Ganhuayin*, replenishing blood by *Danggui Shudihuang* and activating blood by *Chuanxiong*. *Rhizoma Atractylodis Macrocephalae* and *Poria* can nourish qi and blood by invigorating spleen, while stir-fried licorice can reconcile various drugs. Ginger and jujube can support spleen and stomach, give consideration to tonifying qi and blood, play the role of nourishing blood, invigorating spleen and kidney, tonifying qi and blood, and harmonizing qi and blood[11-14].

Acupuncture treatment is the external treatment of TCM. This study selected acupoints that are commonly used in the treatment of gastrointestinal diseases. Zusanli is a strong point, can strengthen the body, spleen and stomach, while Shangjuxushichangchangchangxiahe point can reconcile gastrointestinal function. Guanyuan and Qihai can strengthen the spleen and kidney, while Buyuanqi and Zhongwan can reduce adverse stomach. Xiawan is Tongzhi and Neiguan and can open the orifices to wake up the min. Therefore, the acupuncture treatment of the above acupoints helps regulate the intestinal function of patients and improve the imbalance of flora. This study found that DAO and D-LA were higher, while lipopolysaccharide was lower in the observation group than in the control group after treatment, indicating that the regulation of TCM combined therapy on intestinal flora was significant. The above indicators are commonly used for the observation of intestinal mucosal loss. There is a bidirectional regulation between the human intestinal tract and the brain. Reducing intestinal loss through combined treatment can be administered back to the brain, thereby reducing the neurological deficit symptoms of patients[15,16].

In this study, the APACHE II, MODS, NIHSS and TCM syndrome scores were significantly decreased in the two groups compared with those before treatment, and the scores in the observation group were lower than those in the control group after treatment, indicating that the combined treatment of TCM had good effects on improving the symptoms of neurological deficit and reducing the severity of patients. Chinese medicine prescriptions can improve blood flow, improve vascular reserve capacity of patients, and alleviate the corresponding clinical signs caused by stroke. In this study, the complement and Ig system indexes of the two groups were significantly improved compared with those before treatment. The complement C3, complement C4, IgM and IgG were higher in the observation group than those in the control group after treatment, indicating that the immune function of the patients was significantly improved after TCM combined treatment. TCM and acupuncture treatment can promote the secretion of IL-2, thereby promoting lymphocyte proliferation and differentiation, as well as antibody formation, and playing an important role in human immune response. In this study, the changes of inflammatory factors in patients were also analyzed. TNF- $\alpha$ , IL-2, and IL-8 are the commonly used cellular inflammatory factors in clinic. The increase in their concentration suggested that the inflammatory response in patients was aggravated, and it could mediate the cascade activation process of inflammatory response. UCH-L1 was mainly expressed in the brain, testis, or ovary tissue, belonging to neuron-specific protein, which was of great significance to maintain the normal function of the nervous system. CGRP was a vasodilator polypeptide substance in the peripheral and central nervous system, which could form a strong antagonistic effect on cardiovascular and cerebrovascular contraction. Therefore, the severe response of patients in this study was reduced. The decrease of vasoconstrictive substance concentration suggests the possible mechanism of TCM combined therapy [17,18].

This study also analyzed the complications. The two main complications were gastrointestinal complications and pressure sores, which could be alleviated through active treatment. In contrast, the observation group showed significantly shortened hospitalization time, indicating that the combined

treatment of TCM used multiple ways to regulate the clinical signs and symptoms of patients helping reduce the hospitalization time of patients. In terms of the changes of bacterial flora in patients after treatment, *Bifidobacterium*, *Lactobacillus*, and *Enterococcus* numbers were higher in the observation group than in the control group, and the number of *Bacteroides* was lower than in the control group. Under normal conditions, beneficial and harmful bacteria in the human body were inhibited and reached a balance. The balance of bacterial flora is helpful for the digestion and absorption in the human body. Through the combined treatment of TCM, the beneficial bacteria in patients with severe stroke were increased, and the reproduction of harmful bacteria was inhibited, so as to protect the gastrointestinal function and promote the absorption of nutrients, which played an important role in maintaining the balance of bacterial flora in the human body[19,20].

In this study, patients with severe stroke were selected as the research objects, and the improvement effect of the combined treatment of TCM on patients was emphatically analyzed. At the same time, a variety of observation indexes were selected, including inflammatory factors, immune factors, intestinal flora, and other factors, which further confirmed the effect of the combined treatment of TCM and Western medicine, and could provide certain basis for the clinical comprehensive treatment of severe stroke. However, the number of cases included in this study is limited, and the cases derived from the same hospital, which may introduce a bias in case selection, and the follow-up time was relatively short. Follow-up studies should have been further confirmed by increasing the quality of life and living ability of patients outside the hospital.

## CONCLUSION

In summary, Qixue Shuangbu decoction and acupuncture combined with Western medicine in the treatment of acute severe stroke can regulate intestinal flora, reduce inflammation, improve intestinal mucosal barrier function and immune function related indicators, and promote recovery.

## ARTICLE HIGHLIGHTS

### Research background

Stroke is a common and frequently occurring disease of the nervous system and one of the three major diseases leading to human death.

### Research motivation

The effects of Qixue Shuangbu decoction and acupuncture combined with Western medicine on immune indexes and digestive tract function in patients with acute severe stroke were analyzed.

### Research objectives

This study aimed to observe the curative effect of Qixue Shuangbu Decoction and acupuncture combined with Western medicine on acute severe stroke, with the purpose of improving the clinical therapeutic effect.

### Research methods

The observation group was administered Qixue Shuangbu decoction *via* nasal feeding tube on the basis of the routine Western medicine treatment with simultaneous acupuncture. The two groups were compared.

### Research results

After treatment, the scores of the observation group were lower than those of the control group, and the complement and Ig levels were higher than those of the control group. The levels of diamine oxidase, D-lactic acid, and calcitonin gene-related peptide in the two groups were significantly higher than those before treatment, while the levels of lipopolysaccharide, ubiquitin carboxyl-terminal hydrolase 1, tumor necrosis factor- $\alpha$ , interleukin (IL) -2, and IL-8 were significantly lower than those before treatment.

### Research conclusions

Qixue Shuangbu decoction and acupuncture combined with Western medicine for the treatment of acute severe stroke can regulate intestinal flora.

### Research perspectives

The immune function and digestive tract function indexes were selected as the observation objects to analyze the therapeutic effect of integrated traditional Chinese and Western medicine to provide the corresponding basis for clinical practice.

## Abstract

### BACKGROUND

The recognition of idiopathic membranous nephropathy (IMN) as an autoimmune disease has paved the way for the use of B-cell-depleting agents, such as Rituximab (RTX), which is now a first-line drug for treating IMN with proven safety and efficacy. Nevertheless, the usage of RTX for the treatment of refractory IMN remains controversial and challenging.

### AIM

To evaluate the efficacy and safety of a new low-dose RTX regimen for the treatment of patients with refractory IMN.

### METHODS

A retrospective study was performed on refractory IMN patients that accepted a low-dose RTX regimen (RTX, 200 mg, once a month for five months) in the Xiyuan Hospital of Chinese Academy of Chinese Medical Sciences' Department of Nephrology from October 2019 to December 2021. To assess the clinical and immune remission data, we performed a 24 h urinary protein quantification (UTP) test and measured the serum albumin (ALB) and serum creatinine (SCr) levels, phospholipase A2 receptor (PLA2R) antibody titer, and CD19<sup>+</sup> B-cell count every three months.

### RESULTS

A total of nine refractory IMN patients were analyzed. During follow-up conducted twelve months later, the results from the 24 h UTP decreased from baseline [ $8.14 \pm 6.05$  g/d to  $1.24 \pm 1.34$  g/d ( $P < 0.05$ )] and the ALB levels increased from baseline [ $28.06 \pm 8.42$  g/L to  $40.93 \pm 5.85$  g/L ( $P < 0.01$ )]. Notably, after administering RTX for six months, the SCr decreased from  $78.13 \pm 16.49$   $\mu$ mol/L to  $109.67 \pm 40.87$   $\mu$ mol/L ( $P < 0.05$ ). All of the nine patients were positive

for serum anti-PLA2R at the beginning, and four patients had normal anti-PLA2R titer levels at six months. The level of CD19<sup>+</sup>B-cells decreased to 0 at three months, and CD19<sup>+</sup>B-cell count remained at 0 up until six months of follow-up.

## CONCLUSION

Our low-dose RTX regimen appears to be a promising treatment strategy for refractory IMN.

**Key Words:** Refractory nephrotic syndrome; Idiopathic membranous nephropathy; Low-dose rituximab

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core Tip:** According to the Kidney Disease Improving Global Outcomes 2021 guidelines, Rituximab (RTX) is now the first-line therapy for patients with idiopathic membranous nephropathy (IMN). However, the use of RTX for the treatment of patients with refractory IMN remains challenging. We conducted a retrospective study on nine patients with refractory IMN to explore the efficacy and safety of a new low-dose RTX regimen (RTX, 200 mg, once a month for five months), and conclude that our low-dose RTX regimen is a promising treatment strategy for refractory IMN.

## INTRODUCTION

Idiopathic membranous nephropathy (IMN) is a common pathological type of glomerular disease, and its incidence rate has been continuously increasing yearly[1]. In the past 10 years, the proportion of adult patients with IMN with renal puncture has risen from 12.2%–24.9%, ranking second among those with primary glomerular diseases[2]. Currently, IMN is considered to be an autoimmune disease[3]. The M-type phospholipase A2 receptor (PLA2R) on the cell surface of podocytes is the major target antigen in IMN and can be found in 70%–80% of IMN patients[4]. Additionally, new antigens. Such as thrombospondin type-1 domain-containing 7A, neural epidermal growth factor-like 1 protein, and semaphorin 3b have also been recently discovered[5,6], further rationalizing the use of B-cell-depleting agents.

Rituximab (RTX) is an anti-CD20 monoclonal antibody that is used to treat several autoimmune disorders[7]. Since 2004, some reports have explored the use of RTX in patients with refractory nephrotic syndrome, and the preliminary results showed that RTX may lead to remission and reduce immunosuppressive drug use[8,9]. According to the Kidney Disease Improving Global Outcomes 2021 guidelines, RTX is now the first-line therapy for patients with IMN, and the remission rate can reach 60%–80% at 12 mo[10]. However, 35%–40% of IMN patients still show no response to RTX. Refractory IMN is characterized by recurrence or resistance to RTX-based and other traditional immunosuppressive therapies, including prednisone (Pre), cyclophosphamide (CTX), and calcineurin inhibitors (CNIs)[11]. In Asia, 5%–14% of refractory patients progress to end-stage renal disease (ESRD) within 10–15 years[12]. Therefore, new therapies are urgently needed to treat IMN.

When introduced to IMN treatment, standard doses for RTX (375 mg/m<sup>2</sup> every week for four weeks or 1 g fixed-dose with a repeat dose in two weeks) were drawn from the preexisting dosages for treating other autoimmune diseases, such as anti-neutrophil cytoplasmic antibody-associated vasculitis, rheumatoid arthritis (RA), autoimmune cytopenia, and focal segmental glomerulosclerosis[13]. Recently, few case series studies have proven the effectiveness of low-dose RTX regimens with repeated injections in treating patients with refractory IMN and showed that low-dose RTX could effectively improve the remission rate and peripheral blood B-cell elimination[14]. Currently, for the treatment of RA, a low-dose RTX regimen (500 mg twice daily) has replaced the original dose (1000 mg twice daily) and become the new standard. Kurosu *et al*[15] reported a case of steroid-resistant Nephrotic syndrome, where the kidney pathology showed minimal changes in glomerulopathy. The patient achieved complete remission (CR) with a single dose of RTX of 375 mg/m<sup>2</sup>. Wang *et al*[16] reported the case of a 51-year-old man diagnosed with refractory IMN. The patient received a single dose of 100 mg RTX, after which the B-cells declined rapidly, and a gradual reduction in proteinuria was also observed. Katsuno *et al*[17] reported three patients with refractory IMN who were treated with single-dose RTX (500–600 mg) where two of the patients achieved complete and incomplete remission.

Based on previous studies, we evaluated the efficacy and safety of low-dose RTX in patients with refractory IMN. The regimen included 200 mg RTX once a month for five months. Compared to traditional regimens, our regimen appears to be a promising treatment strategy for refractory IMN.

## MATERIALS AND METHODS

### *Patients*

This was a retrospective case series study that included patients with refractory IMN who were admitted at the Xiyuan Hospital of the Chinese Academy of Chinese Medical Science Department of Nephrology from October 2019 to December 2021 ( $n = 9$ ).

### *Acceptance and discharge standards*

The inclusion criteria were as follows: (1) Patients with histologically proven IMN and a PLA2R antibody-positive status (Anti-PLA2R titer  $> 20$  RU/mL); (2) Patients diagnosed with refractory IMN, broadly defined, who still presented with the nephrotic syndrome after six months of regular corticosteroid and immunosuppressive therapies, including those with Pre, CTX, cyclosporine, tacrolimus, mycophenolate mofetil, and RTX[10]; (3) Patients who signed the informed consent form for the low-dose RTX regimen and fully understood the risks of treatment; and (4) Patients with a follow-up period of  $> 1$  year with an interval of  $< 3$  months or  $> 4$  visits between visits *per* year. The patients had complete clinical data, including routine blood test results, liver and kidney function test results, 24 h urinary protein quantitation (UTP) test results, serum anti-PLA2R antibody titer, and CD19<sup>+</sup> B-cell counts. The exclusion criteria were as follows: (1) Presence of secondary membranous nephropathy, such as lupus nephritis, hepatitis B virus, hepatitis C, and tumors; (2) Glomerular diseases combined with other types; (3) Severe infections; and (4) Allergic reactions constitution.

### *Intervention*

The low-dose RTX regimen was administered with a dose of 200 mg once a month for five months. Notably, after the patients were treated with RTX, the dosage of the primary therapeutic immunosuppressant was gradually decreased in all patients. If the patient's blood pressure remained  $> 130/80$  mmHg, an appropriate angiotensin receptor blocker was added to the regime to stabilize blood pressure.

Every three months, clinical data such as 24 h UTP, serum ALB and serum creatinine (SCr) levels, PLA2R antibody titer, and CD19<sup>+</sup> B-cell count were evaluated.

### *Efficacy evaluation criteria*

The primary outcome was complete clinical remission. A composite remission was defined either as a complete response (CR) or partial response (PR). Proteinuria of  $< 0.3$  g/d is defined as CR, while PR is defined as a 24 h UTP of 0.3 g-3.5 g/d, or 24 h UTP decreased by more than 50% compared to baseline. No reaction was defined as a decrease in proteinuria of less than 30% or renal function deterioration.

The secondary outcomes were 24 h UTP, ALB and SCr levels, Anti-PLA2R titer, CD19<sup>+</sup> B-cell count, adverse events, and a composite endpoint of 40% reduction in estimated glomerular filtration rate, doubling of SCr, ESRD, and death.

### *Statistical methods*

Statistical analyses were performed using IBM SPSS Statistics for Windows, version 23.0 (IBM Corp., Armonk, N.Y., United States). Data is presented as the mean  $\pm$  SD unless otherwise indicated. The comparison of each indicator before and after treatment was performed using a paired sample t-test, and unsatisfactory results were expressed as the median. The paired rank-sum test was used to compare before and after the treatment. Qualitative data was expressed as percentages (%). Comparisons between the groups were performed using the chi-square test, and the test level was set to 0.05.

## RESULTS

### *Baseline characteristics*

Nine patients with refractory IMN were treated with low-dose RTX at our center between October 2019 and December 2021. The baseline features of the patients are listed in Table 1. There were five men and four women, with an average age of  $44.0 \pm 11.7$  years. Of these, six patients were diagnosed with IMN by kidney biopsy, and the other three patients were diagnosed with a serum anti-PLA2R titer  $> 100$  RU/mL. Furthermore, all nine (100%) patients tested positive for serum anti-PLA2R at the beginning of the trial. Before the administration of RTX, all nine patients had received regular corticosteroid and immunosuppressive therapy for at least six months prior and still presented with the nephrotic

Table 1 Baseline characteristics

Patient No.	Age (yr)	Sex	PLA2R	Duration (mo)	Previous treatment	Effect	Side effect	Current treatment
1	57	M	+	12	(1) RTX 500 mg iv twice in two months; and (2) Pre 40 mg/d + CSA 150 mg/d	SR	Serum glucose up	Pre + TAC
2	28	M	+	54	(1) Pre 20 mg/d + TAC 2 mg/d; and (2) Pre 24 mg/d + TAC 2 mg/d	SR	Cushing's syndrome	Pre + TAC
3	40	M	+	21	(1) CSA 150 mg/d; (2) Pre 20 mg/d + CTX 100 mg/d; and (3) Pre 30 mg + TAC 2 mg/d	SR	Hypertension	Pre + TAC
4	60	F	+	51	(1) TAC 2 mg/d; and (2) Pre 20 mg + CSA 150 mg/d	SR	Steroid-induced diabetes	Non
5	31	M	+	9	(1) CsA 150 mg/d; (2) Pre 48 mg/d + TAC 2 mg/d; and (3) Pre 48 mg/d + CTX 100 mg/d	SD	Steroid-induced diabetes; liver damage; Hypertension	Pre + TAC
6	29	F	+	31	(1) Pre 15 mg/d + CSA 150 mg/d; (2) Pre 40 mg/d + LEF 30 mg/d; and (3) Pre 25 mg/d + TAC 2 mg/d	SD	Cushing's syndrome; Hypertension	Pre
7	49	M	+	44	(1) Pre 40 mg/d + CSA 150 mg/d; and (2) Pre 24 mg/d + TAC 2 mg/d	SD	Cushing's syndrome; Steroid-induced diabetes	Pre + TAC
8	49	F	+	35	(1) Pre 50 mg/d + CTX 1000 mg iv; (2) Pre 30 mg/d + CSA 150 mg/d; and (3) TAC 3 mg/d	SR	Cushing's syndrome; Liver damage; Steroid-induced diabetes	Non
9	36	F	+	18	(1) Pre 24 mg/d + CSA 100 mg/d; and (2) TAC 2 mg/d	SR	Non	Non

M: Male; F: Female; PLA2R: Phospholipase A2 receptor; RTX: Rituximab; Pre: Prednisone; CAS: Cyclosporine; TAC: Tacrolimus; LEF: Leflunomide; SR: Steroid-resistant; SD: Steroid-dependent.

syndrome; therefore, they were diagnosed with refractory IMN. Of these, six patients were steroid-resistant and three patients were steroid-dependent.

Furthermore, at baseline, all nine patients experienced adverse reactions triggered by the above treatment, including two with elevated serum glucose levels, one with hypertension, one with Cushing syndrome; one combined with steroid-induced diabetes, hypertension, and an abnormal liver function; one combined with hypertension and Cushing syndrome; one combined with steroid-induced diabetes and Cushing syndrome; and one combined with steroid-induced diabetes, an abnormal liver function, and an abnormal liver function.

### Clinical outcomes during follow-up

The clinical outcomes of the nine patients during the twelve months of follow-up are listed in Table 2 and Supplementary Table 1. The proportion of patients who achieved CR or PR over time, as well as the trends of the remission rate, 24 h UTP, ALB, and SCr levels are shown in Figure 1. The PR and CR rates gradually increased with a lengthened treatment time. The remission rates were 56% (5/9; PR 5) at three months, 67% at six months (6/9; PR 6), 89% at nine and twelve months (8/9; CR 3 and PR 5). One patient did not complete the course of treatment due to adverse infusion reactions.

The comparison of the clinical outcomes at twelve months of follow-up is shown in Table 3. In the eight patients treated with a low dose of RTX for six months, the 24 h UTP and ALB levels showed no significant changes when compared with those before treatment. Nine months later, the 24 h UTP decreased from  $8.14 \pm 6.05$  g/d to  $1.74 \pm 1.81$  g/d ( $P < 0.05$ ), and the ALB level improved from  $28.06 \pm 8.42$  g/L to  $36.84 \pm 6.74$  g/L ( $P < 0.05$ ). At the end of the twelve-month follow-up, 24 h UTP decreased to  $1.24 \pm 1.34$ , and ALB improved to  $40.93 \pm 5.85$  g/L, which are significant differences compared with those before treatment ( $P < 0.05$  and  $P < 0.01$ , respectively). This means that the longer the follow-up period, the higher the remission rate. Notably, after administering RTX, there was a significant difference in the SCr levels when compared with those before treatment ( $P < 0.05$ ).

### Immunologic remission during follow-up

We used serum PLA2R antibodies and CD19<sup>+</sup> B-cells to assess immune remission. As shown in Table 4, all nine patients had elevated serum PLA2R antibody titers at the beginning of the trial. Concerning the anti-PLA2R titers before RTX administration, three patients had low titers of anti-PLA2R ( $\leq 50$  IU/L), two patients had medium titers of anti-PLA2R (50–150 IU/L), and four patients had a high titer of anti-PLA2R ( $> 150$  IU/L). Of them, eight patients were followed up for six months, and the titers of anti-PLA2R decreased after administering RTX. Furthermore, at the three-month follow-up, one patient (No. 6) tested negative for the PLA2R antibody; at the six-month follow-up, four patients (No. 1, 6, 8, and 9)

Table 2 Clinical outcomes

Scr (μmol/L)	109.67 ± 40.87	97.38 ± 27.34	78.13 ± 16.49 <sup>a</sup>	84.5 ± 16.96	90.5 ± 19.81
Remission rate (%)	—	56% (5/9)	67% (6/9)	89% (8/9)	89% (8/9)

<sup>a</sup>*P* < 0.05 vs 0 mo.

<sup>b</sup>*P* < 0.01 vs 0 mo.

<sup>c</sup>*P* < 0.05 vs 3 mo.

Data were analysed by one-way ANOVA followed by post hoc LSD test (albumin and serum creatinine) and presented as the mean ± SD. Data were analysed by Kruskal Wallis H test (24 h urinary protein quantitation).

UTP: Urinary protein quantitation; ALB: Albumin; Scr: Serum creatinine.

were negative for the PLA2R antibody. The level of CD19<sup>+</sup> B-cells decreased to 0 at three months, and remained the same until six months of follow-up.

### Adverse events

During the median (8.7 ± 3.7 mo) period of follow-up, among the nine patients who experienced adverse reactions, one patient presented with shivering. Shivering occurred during the first infusion of RTX, but no dyspnea or fever occurred simultaneously. Symptoms were relieved 10 min after terminating the RTX treatment, and no RTX was infused afterwards; the patient did not complete the treatment. Two patients had a fever, which occurred within 24 h of RTX infusion. The body temperature was 37.5–38.5 °C, but returned to normal within 48 h without administering antibiotics. The fever did not recur.

## DISCUSSION

IMN is the most common cause of primary nephrotic syndrome in adults. The prognosis of patients with IMN varies greatly, with around 1/3 of the patients progressing to ESRD within 10–15 years, and another 1/3 being relieved of symptoms[3]. To date, alkylating agents are the only drugs with a proven efficacy in preventing the development of ESRD[18]. Therefore, corticosteroid therapy combined with alkylating agents has been recognized as the treatment of choice for decades. Other immunosuppressive agents[19], such as CNIs, have been tested only in trials using proteinuria reduction as an alternative

RTX: Rituximab; PLA2R: Phospholipase A2 receptor.

**Figure 1 Clinical outcomes.** A: Kaplan-Meier curve for complete or partial remission; B: 24 h urinary protein quantification trend after Rituximab (RTX) in 9 patients with refractory idiopathic membranous nephropathy (IMN); C: Albumin trend after RTX in 9 patients with refractory IMN; D: Serum creatinine trend after RTX in 9 patients with refractory IMN. UTP: Urinary protein quantification; ALB: Albumin; SCr: Serum creatinine.

endpoint.

Although an effective immunosuppressive treatment scheme for IMN has been established clinically, 20%–30% of IMN patients are resistant to standard immunosuppressive therapy or often relapse[20]; these patients were diagnosed with refractory IMN. In Asia, 5%–14% of refractory IMN patients will progress to ESRD. Therefore, effective and safe therapeutic strategies for refractory IMN must be explored. In the past decade, significant advances in understanding of IMN have established that it is an autoantibody-driven disease[21,22]. As a result, there is a clear choice for treating B-cell depletion. Currently, RTX is the most important immunosuppressive treatment for IMN. The results of the MENTOR trial provide the basis for RTX being the first-line treatment in patients with IMN[23].

Although the results of RTX are promising, it should be noted that approximately 30%–40% of cases experience treatment failure, which means that other treatment regimens are needed. Currently, some studies have focused on the paradigm shift from RTX to new alternatives or combined drugs in treating patients with refractory IMN to overcome drug resistance. However, the second course of RTX may achieve remission even in the setting of resistant RTX after the first course[24].

The natural course of IMN varies greatly; thus, it is not suitable for all patients to receive a unified treatment and the optimal RTX dose for the treatment of IMN remains controversial. Different RTX application regimens were used across various studies, ranging from a single dose of 375 mg/m<sup>2</sup> to a repeated dose of 375 mg/m<sup>2</sup> for four weeks after six months. A prospective clinical study evaluated the low-dose RTX regimen (375 mg/m<sup>2</sup>, once) compared with the standard RTX regimen (375 mg/m<sup>2</sup>, four times)[25]. If the consumption of B-cells is insufficient, the same dose can be used in the low-dose RTX group. The results showed that among the twelve patients who were administered with low-dose RTX, only one needed a second dose to achieve complete B-cell depletion, and at 1 year, the remission rate of the two groups was the same. They also concluded that a single-dose RTX regimen was extremely cost-effective and may limit the production of antichimeric antibodies, lowering the risk of adverse reactions. Similarly, another retrospective study compared forty-two patients administered low-dose RTX (375 mg/m<sup>2</sup>)[26]. The control group was treated with steroid hormones combined with alkylating agents or a standard RTX regimen (375 mg/m<sup>2</sup>, four times). At twenty-four months, there was no significant difference in clinical outcomes between the two groups. All patients treated with RTX showed complete B-cell depletion in the first month, but B-cell recovery occurred earlier in the low-dose group than in the standard group. Recently, some case reports and case series studies have proven the effectiveness of low dose but RTX regimens with repeated injections in treating patients with refractory IMN. These regimens seem to extend the inhibition of B-cells. We explored a new RTX regimen (200 mg once a month for five months) for treating patients with refractory IMN in our hospital.

Nine patients with refractory PLA2R-associated MN were included in this analysis. In the data provided twelve months after baseline, the remission rate was 56% (5/9; PR 5) at three months, 67% at six months (6/9; PR 6), and 89% at nine and twelve months (8/9; CR 3 and PR 5). Another patient did not complete the treatment because of infusion reactions. In a review of currently available studies, the overall remission rates (complete and partial) of RTX at twelve months of treatment for patients with IMN consistently ranged from 44%–85%. Few studies have reported that among patients with refractory IMN, the efficacy rate of RTX can only reach 40%. The remission rate of the low-dose RTX regimen at our center was significantly higher than that reported in previous studies.

In addition, we observed that clinical remission in patients with refractory IMN was slower than in patients with immune remission. We used serum PLA2R antibody titer and CD19<sup>+</sup> B-cell counts to assess immune remission. The level of CD19<sup>+</sup> B-cells decreased to 0 at three months, which was maintained until six months of follow-up. At the beginning of the trial, all nine patients were positive for the PLA2R antibody. The titers of anti-PLA2R decreased after administering low-dose RTX, and one patient (No. 6) had a normal anti-PLA2R titer after three months, while four patients (No. 1, 6, 8, and 9) had a normal anti-PLA2R titer after six months. However, when compared with the previous situation, the 24 h UTP and ALB levels showed no significant changes at six months. Until nine months post-treatment, 24 h UTP decreased from  $8.14 \pm 6.05$  g/d to  $1.74 \pm 1.81$  g/d ( $P < 0.05$ ), while ALB has increased from  $28.06 \pm 8.42$  g/L to  $36.84 \pm 6.74$  g/L ( $P < 0.05$ ). At the end of the twelve-month follow-up period, the clinical outcomes were significantly enhanced when compared to those before treatment. This means that the longer the follow-up time, the higher the remission rate that was observed. Notably, none of the eight patients had a recurrence until the date.

Compared with the standardized dose (375 mg/m<sup>2</sup> every week for four weeks, or 1 g fixed-dose with a repeat dose in two weeks), our low-dose RTX regimen lasted for a longer time (*i.e.*, B-cell levels remained low for a longer period of time), which meant that the disease was less likely to relapse. Furthermore, when compared to the high-dose RTX and traditional immunosuppressive regimens, our low-dose RTX regimen also has advantages in terms of security. Although effective immunosuppressive regimens for IMN have been established clinically, the preceding therapeutic options have significant disadvantages, which limit their application, especially in patients with renal insufficiency. At the beginning of the trial, eight patients had a side reaction associated with previous immunosuppressive treatment. During the twelve-month follow-up that tracked adverse reactions, there was only one case of shivering. Notably, after administering RTX for six months, the SCr level decreased from  $78.13 \pm 16.49$  μmol/L to  $109.67 \pm 40.87$  μmol/L ( $P < 0.05$ ). In this study, we found that our low-dose RTX regimen for the treatment of refractory IMN significantly improved the clinical outcomes and further increased the remission rate. Moreover, treatment with our low-dose RTX regimen is more cost-effective than that with high-dose RTX.

However, it is worth noting that this research also has few limitations that must be considered. First of all, since our study was retrospective in nature and the sample size was small ( $n = 9$ ), the statistical analysis of data may have biases and inadequacies in terms of generalization. Second, the clinical outcomes were monitored after 1 year; however, the data on immunological indicators, including serum anti-PLA2R titer and CD19<sup>+</sup> B-cell count, were monitored only after six months. The long-term prognosis of our low-dose RTX regimen in treating refractory IMN patients is still yet to be explored. To confirm these results and deepen our understanding about this treatment option, we need to conduct

large-scale clinical trials and further clarify the mechanism of action of RTX in refractory IMN.

## CONCLUSION

The treatment of patients with refractory IMN using RTX remains controversial and challenging. Conventional immunosuppressive treatment strategies have been applied for several years and have clinically established therapeutic efficacy. In conclusion, we found that our low-dose RTX regimen significantly improved clinical outcomes and further increased the remission rate of patients with IMN. Moreover, treatment with our low-dose RTX regimen is more cost-effective than that with high-dose RTX.

## ARTICLE HIGHLIGHTS

### Research background

The recognition of idiopathic membranous nephropathy (IMN) as an autoimmune disease has paved the way for the use of B-cell depleting agents such as Rituximab (RTX), which is now a first-line drug for IMN patients with proven safety and efficacy.

### Research motivation

RTX for the treatment of refractory IMN patients remains controversial and challenging.

### Research objectives

To evaluate the efficacy and safety of a new low-dose RTX regimen for the treatment of refractory IMN patients.

### Research methods

A retrospective study was performed on refractory IMN patients that accepted Low-dose RTX regimen (RTX, 200 mg, once a month for five months).

### Research results

A total of 9 refractory IMN patients were analyzed. At 12 mo of follow-up data from baseline, the 24 h urinary protein quantification was decreased from  $8.14 \pm 6.05$  g/d to  $1.24 \pm 1.34$  g/d ( $P < 0.05$ ), and the albumin was improved from  $28.06 \pm 8.42$  g/L to  $40.93 \pm 5.85$  g/L ( $P < 0.01$ ). Notably, after administering RTX for 6 mo, the serum creatinine decreased from  $78.13 \pm 16.49$   $\mu$ mol/L to  $109.67 \pm 40.87$   $\mu$ mol/L ( $P < 0.05$ ). All of the 9 patients were serum anti-phospholipase A2 receptor (PLA2R) positive at the beginning, and 4 patients had a normal anti-PLA2R titer at six months. The level of CD19<sup>+</sup> B-cells decreased to 0 at three months, and the count of CD19<sup>+</sup> B-cells lasted to 0 until six months of follow-up.

### Research conclusions

We found that our low-dose RTX regimen for the treatment of refractory IMN significantly improved clinical outcomes and further increased the remission rate.

### Research perspectives

Treatment with our low-dose RTX regimen is more cost-effective than high-dose RTX.

## Abstract

### BACKGROUND

Patients with severe aplastic anemia (SAA) frequently present with inflammatory episodes, and during flared inflammatory episodes, hematopoietic function is further exacerbated. The gastrointestinal tract is the most common site for infectious and inflammatory diseases, and its structural and functional features confer on it the most potent capacity to affect hematopoietic and immune functions. Computed tomography (CT) is a readily accessible approach to provide highly useful information in detecting morphological changes and guiding further work-ups.

### AIM

To explore CT imaging presentations of gut inflammatory damage in adult SAA patients during inflammatory episodes.

### METHODS

We retrospectively evaluated the abdominal CT imaging presentations of 17

hospitalized adult patients with SAA in search of the inflammatory niche when they presented with systemic inflammatory stress and exacerbated hematopoietic function. In this descriptive manuscript, the characteristic images that suggested the presence of gastrointestinal inflammatory damage and related imaging presentations of individual patients were enumerated, analyzed and described.

## RESULTS

All eligible patients with SAA had CT imaging abnormalities that suggested the presence of an impaired intestinal barrier and increased epithelial permeability. The inflammatory damages were concurrently present in the small intestine, the ileocecal region and the large intestines. Some readily identified imaging signs, such as bowel wall thickening with mural stratification (“water holo sign”, “fat holo sign”, intramural gas and subserosal pneumatosis) and mesenteric fat proliferation (fat stranding and “creeping fat sign”), fibrotic bowel wall thickening, “balloon sign”, rugged colonic configuration, heterogeneity in the bowel wall texture, and adhered and clustered small bowel loop (including various patterns of “abdominal cocoon”), occurred at a high incidence, which suggested that the damaged gastrointestinal tract is a common inflammatory niche responsible for the systemic inflammatory stresses and the exacerbated hematopoietic failure in patients with SAA. Particularly, the “fat holo sign” was present in 7 patients, a rugged colonic configuration was present in 10 patients, the adhesive bowel loop was present in 15 patients, and extraintestinal manifestations suggestive of tuberculosis infections were present in 5 patients. According to the imaging features, a suggestive diagnosis of Crohn’s disease was made in 5 patients, ulcerative colitis in 1 patient, chronic periappendiceal abscess in 1 patient, and tuberculosis infection in 5 patients. Other patients were diagnosed with chronic enterocolitis with acutely aggravated inflammatory damage.

## CONCLUSION

Patients with SAA had CT imaging patterns that suggested the presence of active chronic inflammatory conditions and aggravated inflammatory damage during flared inflammatory episodes.

**Key Words:** Aplastic anemia; Computed tomography; Bowel inflammatory damage; Fat holo sign; Balloon sign; Abdominal cocoon

**Core Tip:** Patients with severe aplastic anemia frequently present with inflammatory episodes. The gastrointestinal tract is the most common site for infectious and inflammatory diseases, and its structural and functional features confer on it the most potent capacity to affect hematopoietic and immune functions. We retrospectively reviewed the bowel morphological changes on computed tomography in seventeen patients with severe aplastic anemia during flared inflammatory episodes. All patients demonstrated imaging abnormalities that suggested the presence of active chronic inflammatory conditions and aggravated inflammatory damage in the gastrointestinal tract. These inflammatory conditions likely contributed to their systemic inflammatory stresses and exacerbated hematopoietic failure.

## INTRODUCTION

Aplastic anemia (AA) is the paradigm of hematopoietic failure resulting from the immune-mediated destruction of hematopoietic progenitor cells, leading to heavily suppressed blood cell productivity and peripheral cytopenia. In patients with severe AA (SAA), fulminant infections, frequently in the absence of localized symptoms and signs, and refractory to broad-spectrum antibiotics, are the most common complications and the main causes of death. Infections in SAA are usually attributed to severely impaired granulopoiesis, and it frequently has a poor response to recombinant human granulocyte colony-stimulating factor (rhG-CSF) treatment[1-3]. However, successful treatment of the underlying

infections can significantly improve the hematological profile and even achieve a complete hematological remission in some patients, providing strong evidence that aggravated inflammatory reactions are responsible, at least in a fraction of patients, for the exacerbated hematopoietic suppression[4-6]. Very recently, initiation and perpetuation of AA pathogenesis has been found to be associated with gut inflammatory disorders (GIDs)[7,8]. However, the role of GIDs in AA pathogenesis is overlooked likely due to the high prevalence and good tolerance of GIDs and the low incidence of AA.

The gastrointestinal tract hosts the most enriched and complex microbial community in the human body. Not only pathogenic microbes but also dysbiotic commensal bacteria and various chemical components can compromise the intestinal barrier[9,10]. In the setting of impaired intestinal barrier structure and function, antigens from commensal microbes and undigested food as a source of continuous antigen supply can translocate to the lamina propria, blood, and remote organs and come into intimate contact with host immune cells, thereby initiating and perpetuating autoimmunity[11,12] and amplifying aberrant immune responses[13]. The gastrointestinal tract also hosts the most enriched lymphoid tissues and hence can provide sufficient activated immune cells to sustain exaggerated immune responses. Because the body is constantly confronted with various harmful environmental factors, the gastrointestinal tract is the most common site for infectious and inflammatory diseases[9,10].

Active GIDs, whether as a consequence or as an incentive factor in the process of gut dysbiosis and epithelial damage, can lead to morphological manifestations that can be detected by various imaging modalities. The imaging presentations are usually nonspecific, and arriving at an etiopathological diagnosis usually necessitates the comprehensive analysis of data from clinical, endoscopic, pathological and laboratory investigations, and is frequently dependent on the results of specific laboratory tests and the responses to specific treatments. However, computed tomography (CT) is a readily accessible approach able to provide highly useful information not only in detecting the distribution, extent, degree, and patterns of the gastrointestinal lesions and the adjacent inflammatory changes that prompt a radiological diagnosis but also in guiding further work-ups for pathognomonic diagnosis, identifying complications, evaluating treatment responses and monitoring disease activities in the subsequent follow-ups[14-16]. In this study, we explored the CT imaging manifestations of the gastrointestinal tract in adult patients with SAA during flared inflammatory episodes and showed that all patients had imaging abnormalities suggesting the presence of active chronic gut inflammatory conditions and acutely aggravated inflammatory damages.

## MATERIALS AND METHODS

### Participants

In this retrospective study, we reviewed the abdominal CT images in 17 hospitalized adult SAA patients who were treated at our center from October 2019 to March 2022, including 8 males and 9 females, with a median age of 55 years (ranging from 34 to 78 years). They were hospitalized due to rapidly exacerbated cytopenia, aggravated fatigue, varying degrees of febrile episodes and elevated inflammatory indices, indicating the presence of systemic inflammatory responses[1-3]. Each patient was definitively diagnosed with SAA for more than 2 years, and the SAA progressed from non-SAA (NSAA) after the patients experienced various accelerating episodes. In addition to supportive care, they were routinely treated with cyclosporine (3-4 mg/kg/d), stanozolol (6-8 mg/d) and eltrombopag (50 mg/d) in the SAA stage, in the absence of any therapeutic responses. In the patients with very SAA (VSAA), recombinant human granulocyte colony-stimulating factor (rhG-CSF, 100-200 µg/d) was added, without an evident increase in granulocytes. Patients who had diseases of portal hypertension, hepatic disease, pancreatic disease, cardiopulmonary disease, heart failure, severe hypoalbuminemia and ischemic enteropathy were excluded, because these diseases can cause stratified bowel wall thickening by blood congestion in the gastrointestinal tract, which may confound the imaging presentations of inflammatory lesions[16-18]. Abdominal CT was performed to search for the inflammatory niche before antibiotic and other treatments.

The modified Camitta criteria were used to assess severity of AA[3]: The diagnostic criteria for SAA were absolute neutrophil count (ANC)  $< 0.5 \times 10^9/L$ , platelets (PLTs)  $< 20 \times 10^9/L$ , and absolute reticulocyte count (Ret)  $< 20 \times 10^9/L$ . The diagnostic criteria for VSAA were ANC  $< 0.2 \times 10^9/L$  in addition to the above hematological presentations.

### Study procedure

**CT imaging modalities:** Conventional CT was performed for all patients in the search of the inflammatory niche during flared inflammatory episodes. If the conventional CT was sufficient to determine the radiological changes, contrast-enhanced CT was waived in order to reduce the radiation exposure. If the conventional CT was unable to determine the imaging abnormalities due to the difficulty in the discrimination of a massive lesion from contents in the intestinal lumen or due to the suspicion of a massive lesion being malignant, contrast-enhanced CT was performed. Meanwhile, endoscopic examination of the large intestine and ileocecal region was performed. Contrast-enhanced CT was performed in 1 patient in this study. Multiplanar reconstruction was performed for the assessment and

expression of the radiological manifestations.

**CT image reviewing process:** Each patient's CT images were reviewed, and the imaging abnormalities were collected independently by each of the six authors: Xi-Chen Zhao, Cheng-Jiang Xue, Hui Song, Bin-Han Gao, Fu-Sen Han, and Shu-Xin Xiao. After several rounds of extensive consultation, the imaging abnormalities suggesting the presence of GIDs were decided by the first and corresponding author. In patients with evident chest CT presentations that likely had pathogenic relationships with the bowel inflammatory damages; those chest CT abnormalities were also enumerated and described.

**Radiological manifestations suggesting the gut involvement of inflammatory disorders:** After careful assessment of the radiographs and after extensive consultations within our research group with reference to the patients' symptoms and signs, the following imaging presentations were considered to have abnormalities suggestive of the presence of GIDs.

First, the criteria for the diagnosis of bowel wall thickening met one of the following criteria[17-21]: (1) Bowel wall thickness greater than 3 mm in adequately distended intestinal segments; (2) bowel wall thickness greater than 4 mm in underdistended intestinal segments; (3) cross-sectional diameter greater than 6 mm in collapsed small intestines; and (4) cross-sectional diameter greater than 5 mm in collapsed large intestines.

The bowel wall thickening may be focal or segmental, symmetrical or asymmetrical, concentric or eccentric, homogeneous or heterogeneous. The following signs were helpful in the identification of the location and extent of the diseased bowel segments: (1) Mesenteric inflammatory changes indicative of transmural inflammation: "fat stranding"[22,23], "creeping fat sign"[24-26] and "comb sign"[27,28]; (2) mural stratification indicative of edematous bowel wall (water halo sign) and submucosal fat deposition (fat halo sign)[17-21]; (3) intramural gas and/or subserosal pneumatosis indicative of aerogenous bacterial proliferation in the bowel wall[14-16]; (4) gas-liquid levels in the intestinal lumen indicative of intestinal dynamical abnormalities; (5) heterogeneity in the bowel wall texture especially with segmentally gas-filled and segmentally liquid-filled intestinal lumen; (6) inflamed diverticulitis; (7) epiploic appendagitis; (8) "empty colon sign" or narrowed bowel lumen[15,16]; (9) adhesive bowel loop, especially with mesenteric inflammatory changes and/or adjacent peritoneal fibrotic thickening ("abdominal cocoon")[29-32]; and (10) rugged colonic configuration, especially with mesenteric inflammatory changes and/or adjacent peritoneal fibrotic thickening.

Second, the "balloon sign" refers to a segment of a paper-thin bowel wall (a highly dilated and thinned bowel segment filled with gas) wrapped by a large cluster of circumferentially distributed hypervascular mesenteric fat stranding[33-36]. The hypervascular mesenteric fat deposition suggests the presence of active chronic transmural inflammatory damage in the diseased intestinal segments[22-26].

Third, peritoneal involvement: Including peritoneal thickening, ascites particularly loculated ascites and peritoneal nodularity.

In the evaluation of bowel inflammatory damage, particular attention was given to imaging abnormalities in the large intestines and ileocecal region, since in these sites, the lymphoid tissues are the most enriched and the microbial community is the most abundant; therefore, inflammatory damage and compromised epithelial integrity in these intestinal segments has the most potent capability to supply sufficient intestine-derived antigens and to activate sufficient immune cells and hence has the most potent capability to affect hematopoietic and immune functions[9,10].

This study was approved by the Institutional Review Board of The Central Hospital of Qingdao West Coast New Area and followed the Declaration of Helsinki (No. 2022-10-08). The requirement for written informed consent was waived by the Review Board since this was a retrospective study, and no information about patient identification was revealed in the manuscript.

### Statistical analysis

Categorical data are presented as numbers with percentages, and continuous data are presented as medians with interquartile ranges.

## RESULTS

### General characteristics of patients

General information, severity of AA, disease duration, complete blood cell count (CBC) results when abdominal CT was performed, major gastrointestinal presentations and suggested radiological diagnosis are listed in Table 1. Seventeen patients (8 men and 9 women) with a median age of 55 years, ranging from 34 years to 78 years were enrolled. The total AA duration ranged from 8 years to 23 years, with a median duration of 13 years, and the total SAA duration ranged from 2 years to 9 years, with a median duration of 5 years. Among all patients, 5 had VSAA. Abdominal tenderness was present in all patients, but abdominal pain was present in only 8 patients, in accordance with the good tolerance of GIDs. Abnormalities in the frequency and property of the feces were present in 11 patients.

M: Male; F: Female; SAA: Severe aplastic anemia; VSAA: Very-severe aplastic anemia; WBC: White blood cells ( $\times 10^9/L$ ); CBC: Complete blood cell count; WBC: White blood cell count; ANC: Absolute neutrophil count ( $\times 10^9/L$ ); Hb: Hemoglobin (g/L); Plt: Platelets ( $\times 10^9/L$ ); Ret: Absolute reticulocyte count ( $\times 10^9/L$ ); AP: Abdominal pain; AT: Abdominal tenderness; CAA: Chronic appendiceal abscess; CEC: Chronic enterocolitis; ATB: Abdominal tuberculosis; CD: Crohn's disease; UC: Ulcerative colitis.

### ***CT imaging abnormalities reflecting gut involvement of inflammatory conditions***

Characteristic images are enumerated, analyzed and described in the Discussion section. All patients recruited in this study presented with evident imaging abnormalities that suggested the presence of inflammatory damages in the gastrointestinal tract. Noticeably, inflammatory involvement of the large intestine and the ileocecal region was present in all patients. Inflammatory lesions were also present in the small intestine in all patients, suggesting that the inflammatory pathogenesis was most likely initiated at the proximal gastrointestinal tract. According to the imaging features, a suggestive diagnosis

of Crohn's disease was made in 5 patients, ulcerative colitis in 1 patient, chronic periappendiceal abscess in 1 patient, and tuberculosis infection in 5 patients. Other patients were diagnosed with chronic enterocolitis with acutely aggravated inflammatory damage. The suggested radiological diagnosis is listed in Table 1.

## DISCUSSION

The severity of cellular immune-mediated hematopoietic suppression in patients with AA commonly fluctuates in parallel with the waxing and waning of physical and mental stresses, and these stresses are obviously driven by active chronic inflammatory conditions and their recurrently aggravated episodes. In flared inflammatory episodes, blood cell production is heavily suppressed, and cytopenia worsens. With effective treatment of the inflammatory episodes, blood cell productivity can be significantly improved. Along with the increased frequency of and decreased intervals between these inflammatory episodes, patients eventually enter into an advanced stage, in which immune-mediated hematological damage is exacerbated and the sensitivity to previous effective treatments is lost[1,2,37,38].

This is not surprising because the blood cells themselves are immune cells, and their production is regulated largely in response to a variety of microbial attacks. When confronting an acute and limited infection, host hematopoiesis skews its proliferation and differentiation toward the production of innate immune cells to fight against the invading microbes at the expense of reduced self-renewal capacity[39,40]. After the infected pathogens are cleared out, the activated host immune system quickly returns to the homeostatic state, and the skewed blood cell production ends. However, in the setting of active chronic inflammatory conditions or overwhelming infections, host hematopoiesis can be heavily suppressed and exhausted due to prolonged and exaggerated immune responses and the subsequently overproduced proinflammatory mediators[41-43], resulting in heavily decreased marrow cellularity and increased peripheral cytopenia in genetically susceptible subjects, which are the characteristic morphological and immunological changes seen in AA[1-3]. The sustenance of an active inflammatory condition in which the degree and duration of immune responses are sufficient to induce severe aplastic cytopenia critically necessitates sufficient activated immune cells and a continuous antigen supply.

The gastrointestinal tract provides the largest interface bridging the host neuro-endocrine-immune system with environmental factors and is constantly confronted with a variety of environmental challenges. The gastrointestinal tract also hosts the body's most abundant gut-associated lymphoid tissues and microbial community[9,10]. These structural and functional characteristics make the gastrointestinal tract the most vulnerable site for pathogen invasion and chemical injuries and the most common source of a continuous antigen supply. Therefore, the gastrointestinal tract becomes the most important site for pathological interactions between host immune cells and pathogenic antigens.

The gastrointestinal tract is the most common site for chronic and active inflammatory niches not only due to various pathogenic microbial attacks and chemical injuries but also due to dysbiotic commensal microbes and autoimmunity. Such abundant lymphoid tissues and microbial communities confer on the gastrointestinal tract the ability to provide sufficient activated immune cells and a continuous antigen supply and thereby have the most potent capacity to continuously release excessive proinflammatory cytokines.

Under chronic and active inflammatory conditions, upregulated human leukocyte antigen and pattern recognition receptors on hematopoietic progenitors enhance their responsiveness to pathogenic stimulation[44-46], and upregulated Fas molecules accelerate their apoptotic cell death[45], eventually resulting in the exhaustion of hematopoietic progenitor cells. The severity of GIDs is largely affected by changes in a variety of environmental factors, such as food supplements[47-49], antibiotic abuse[50,51], mental stresses[52,53] and pathogen invasion, leading to the fluctuant property of GIDs, in accordance with the fluctuant property of AA.

AA has been reported to be associated with gut inflammatory diseases, including inflammatory bowel disease, celiac disease and neutropenic enterocolitis[8]. In our previously reported case, intermittent treatments with a gut-cleansing preparation achieved reproducible hematological remissions, providing direct evidence for the role of GIDs in the initiation and perpetuation of AA pathophysiology[4]. Merely gluten-free diets[5] or resection of diseased intestinal segments[6] can achieve excellent hematological improvement, providing convincing evidence that GIDs play an indispensable role in the sustenance of AA pathophysiology.

In this pathogenic process, impaired intestinal integrity and increased epithelial permeability play pivotal roles[11,12]. These GID-associated morphological changes could be detected by various imaging modalities. Abdominal CT is a readily accessible and highly efficient imaging modality for detecting morphological changes in the gastrointestinal tract[14-16,19,20]. In this study, we explored the abdominal imaging presentations in patients with SAA in search of the inflammatory niche when the patients presented with systemic inflammatory stresses. We selected patients with SAA experiencing flared episodes because during this stage, morphological changes due to the gut inflammation are probably more serious and hence more easily identified by radiological examination.

**Figure 1** Characteristic images of case 4. A-C: Characteristic images of the ileocecal region. The ileocecal valve (yellow arrows), the proximal ascending colon (orange arrows) and the terminal ileum (purple arrows) were significantly thickened and stratified by submucosal fat deposition, forming the so-called “fat halo sign”. From the distal ascending colon to the sigmoid colon (red arrows), the wall was thickened and stratified with “water halo sign”. The small intestine was heterogeneous in bowel wall texture, and gas-filled in some segments and liquid-filled in other segments, and a segment of adhesive bowel loop was found in the middle jejunum (blue arrows); D-F: Characteristic images of the ascending colon. The irregular contour and the fibrotic thickening of the mucosal folds made the colonic configuration rugged. The mucosa of the cecum and the appendiceal root was fibrously thickened (green arrows), and the appendix was gas-filled. Thickened omentum surrounded the ileocecal region and the ascending colon. A segment of adhesive bowel loop was found in the proximal ileum (a white arrow). The mucosa of the proximal ileum in the adhered bowel loop was fibrotically thickened, with mesenteric fat deposition and adjacent peritoneal thickening forming the so-called “abdominal cocoon”; G and H: Typical fat halo sign in the ascending colon. The “fat halo sign” was more typical in the middle ascending colon; I: Thickened and stratified larger intestine. From the distal ascending colon to the sigmoid colon (red arrows), the wall was thickened and stratified by edematous submucosal tissues, forming the so-called “water halo sign”. In some segments, the colon was emptied. Paracolic fat stranding was present from the cecum to the sigmoid colon. The disproportionately less severe paracolic fat stranding suggested that the edematous colon most likely occurred during an acute episode.

In the evaluation of abdominal CT imaging abnormalities, particular attention has been given to inflammatory abnormalities in the ileocecal region and the colonic segments because they host the most enriched microbial community and lymphoid tissues[9,10,19]; therefore, inflammatory diseases and compromised intestinal barriers in these bowel segments have the most potent capacity to provide sufficient intestine-derived antigens and activated immune cells to affect hematopoietic and immune functions irrespective of whether they are primary damage or secondary to dysbiotic gut microbiota. As demonstrated by this study, all patients with SAA during flared inflammatory episodes had evident morphological abnormalities that could reflect the presence of a severely damaged intestinal structure and function in the ileocecal region and the colonic segments. All patients also presented with inflammatory damages in the proximal small intestine, suggesting that inflammatory damages in the upper gastrointestinal tract led to the inflammatory damages in the downstream intestinal segments, probably by altering the gut microbial composition[54-56]. In the following sections, we described the characteristic CT imaging findings in each patient in the category of readily identified morphological presentations.

All patients demonstrated CT imaging abnormalities that suggested the presence of gut inflammatory damage in the large intestine. Colonic wall thickening with mural stratification, intramural gas and paracolic fat stranding is the common presentation of colonic involvement of inflammatory damage. A stratified bowel wall can be caused by submucosal fat deposition (fat halo sign) or submucosal edematous tissues (water halo sign)[17-19]. The water halo sign was present in 8 patients [Figure 1 (case 4), Figure 2 (case 3), Figure 3 (case 6), Figure 4 (case 9), Figure 5 (case 15), Figure 6 (case 2), Figure 7 (case 1), and Figure 8 (case 12)], commonly accompanying intramural gas and subserosal pneumatosis, which indicated the presence of aerogenous bacterial proliferation in the colonic wall irrespective of primary

**Figure 2 Characteristic images of case 3.** A-C: Characteristic images of the thickened transverse colon. The segmentally thickened, stratified (water holo sign) and emptied colon with paracolic fat stranding was present in the hepatic flexure (yellow arrows) in which an inflamed polypoid lesion was found on endoscopic examination, followed by the asymmetrically thickened wall and gas-filled lumen of the transverse colon (red arrows) in which the colonic villi were absent; D-F: Characteristic images of the thickened descending colon. The wall of the descending and sigmoid colon was thickened and stratified with mesenteric fat stranding (orange arrows), with the most striking segment being in the splenic flexure; G and H: Characteristic images of an adhesive bowel loop. While the ileum was gas-filled and distended (green arrows), the adhesive jejunal loop (white arrows) was heterogeneous in bowel wall texture and liquid-filled with multiple gas-liquid levels and accrescent plica. Increased mesenteric fat and vasculature were adjacent to the adhered jejunal loop; I: Characteristic image of a balloon sign. Clustering and hypervascular mesenteric fat proliferation wrapped a segment of paper-thin ileum, forming the so-called “balloon sign”. Balloon sign was also present in the hepatic flexure.

**Figure 3 Characteristic images of case 6.** A and B: Characteristic images of the upper abdomen. Several inflamed diverticula (orange arrows) were present in the colonic segments. In the duodenum-jejunum junction (a blue arrow), the bowel wall was fibrotically thickened and the lumen was gas-filled. In the bulb part of the duodenum, a polypoid mass (a black arrow) protruded into the lumen. A segment of adhesive jejunal loop was present in the proximal jejunum (white arrows); C and D: Characteristic images of the thickened colon. The wall from the cecum to the descending colon was significantly thickened with mural stratification, intramural gas and pericolic fat stranding. A segment of adhesive bowel loop was present in the middle jejunum (a purple arrow) in which the bowel wall was asymmetrically thickened and the lumen was gas-filled with particularly prominent mesenteric fat stranding; E: Characteristic images of the ileocecal region. Stratified thickening of the ileocecal valve and the terminal ileum was gas-filled (yellow arrows). The third segments of adhesive bowel loop were present in the distal jejunum (a green arrow); F: Characteristic image of a balloon sign. The sigmoid colon was dilated and the wall was paper-thin (navy blue arrows), with clustering pericolic fat stranding forming the so-called “balloon sign”.

infection or infection secondary to dysbiotic microbiota, acute episodes or chronic damage[22,23]. The fat holo sign which suggested the existence of active chronic gut inflammation was detected in 7 patients [Figure 1 (case 4), Figure 9 (case 13), Figure 4 (case 9), Figure 10 (case 11), Figure 11 (case 17), Figure 7 (case 1), and Figure 12 (case 16)]. In these 7 patients, the fat holo sign was located in the

DOI: 10.12998/wjcc.v11.i3.576 Copyright ©The Author(s) 2023.

**Figure 4 Characteristic images of case 9.** A-C: Characteristic images of an empty colon sign. The segmentally wall-thickened, stratified and emptied colon in the hepatic flexure (purple arrows) followed by the collapsed transverse (adjacent to the dilated ileum in which gas-liquid levels could be recognized) and descending colon (orange arrows), forming the so-called “empty colon sign”. A short segment of asymmetrically thickened wall was present in the proximal ileum (a white arrow), around which the hypervascular fat stranding was especially prominent, distal to which the ileal lumen was gas-filled, and proximal to which the ileal lumen was liquid-filled; D-F: Characteristic images of the ileocecal region. The ileocecal valve and the terminal ileum were thickened and stratified by submucosal fat deposition (red arrows). Omental thickening was especially prominent in the ileocecal region. The wall of the ascending colon was thickened and, in some segments, stratified with submucosal fat deposition, and in other segments, stratified with submucosal edematous tissue (yellow arrows). Several inflamed diverticula (green arrows) were present in the cecum and ascending colon. The distal ileum was strictured (blue arrows), proximal to which the ileal lumen was liquid-filled; G-I: Characteristic images of adhesive bowel loops. The fibrotic mucosa and liquid-filled lumen of the adhesive bowel loops were present in the proximal ileum (powder blue arrows) and distal ileum (jade-green arrows); J: Characteristic image of a balloon sign. A large cluster of circumferentially distributed hypervascular fat stranding wrapped a segment of the dilated lumen and paper-thin bowel wall of the sigmoid colon, forming the so-called “balloon sign”. An inflamed diverticula was present in the cecum, with strikingly thickened omentum (a green arrow); K: Characteristic image of an adhesive bowel loop in the proximal ileum. A segment of adhesive bowel loop in the proximal ileum, together with the fibrotically thickened peritoneum, formed the so-called “abdominal cocoon”; L: Characteristic image of esophagus. Hypertrophic lesions presented in two segments of the esophagus, together with the inflammatory lesions in the jejunum suggesting that the initiating factor in the upper gastrointestinal tract affected the functions of the downstream intestinal segments.

ileocecal region and proximal ascending colon.

The “balloon sign” is characterized by circumferentially distributed clustering of hypervascular mesenteric fat proliferation wrapping a short segment of highly distended paper-thin bowel wall[33, 34]. The “balloon sign” can also be seen in a large subserosal pneumatosis[35,36]. The circumferentially distributed clustering of hypervascular fat proliferation suggests the presence of an active chronic inflammatory condition in diseased intestinal segments. The balloon sign was present in 7 patients. The paper-thin bowel wall can be the wall of either the small or large intestine. In Figure 2 (case 3), the paper-thin bowel wall was present in the proximal ileum. In Figure 13 (case 14), the paper-thin bowel wall was present in the ascending colon. In Figure 11 (case 17), the paper-thin bowel wall was present in the hepatic flexure. In Figure 3 (case 6), Figure 4 (case 9), Figure 8 (case 7) and Figure 14 (case 8), the paper-thin bowel wall was present in the sigmoid colon.

DOI: 10.12998/wjcc.v11.i3.576 Copyright ©The Author(s) 2023.

**Figure 5 Characteristic images of case 15.** A-C: Characteristic images of the ascending colon. The ascending colon was rugged with omental thickening and paracolic fat stranding, and the colonic wall was thickened with mural stratification and intramural gas (white arrows). From the hepatic flexure to the sigmoid colon (red arrows), the bowel wall was thickened and stratified with several inflamed diverticula (green arrows) in these colonic segments. Three segments of adhesive bowel loops were visualized: one in the distal ileum (blue arrows), the other two in the middle ileum (orange arrows) and the jejunum (purple arrows); D-F: Characteristic images of the ileocecal region. The ileocecal valve and the terminal ileal wall were fibrotically thickened (yellow arrows), proximal to which the ileal lumen was liquid-filled; G-I: Characteristic images of the adhesive bowel loops in the middle and distal ileum. The bowel loop in the middle ileum was adhered and clustered (orange arrows), with the bowel wall being highly heterogeneous in texture and the mucosa being hyperdense. The bowel loop in the distal ileum was adhered, the lumen was liquid-filled, and the bowel wall was fibrotically thickened, together with the fibrotically thickened peritoneum forming the so-called “abdominal cocoon” (blue arrows).

DOI: 10.12998/wjcc.v11.i3.576 Copyright ©The Author(s) 2023.

**Figure 6 Characteristic images of case 2.** A-C: Characteristic images of the ileocecal region. The ileocecal valve and the terminal ileal wall were thickened and stratified (white arrows), the ileal mucosa was hyperdense and the ileal lumen was liquid-filled. The adhered and clustered distal ileum and cecum with the fibrotically thickened peritoneum (a purple arrow) formed the so-called “abdominal cocoon”; D and E: Characteristic images of the ascending colon and the adhesive bowel loops. In the ascending colon (green arrows), the wall was thickened and stratified with “water halo sign”, the mucosa was hyperdense and the configuration was rugged, with paracolic fat stranding, omental thickening and subserosal pneumatosis. The wall of the descending and sigmoid colon (red arrows) was also thickened and stratified. In two segments of the adhesive bowel loop (blue arrows and yellow arrows), the bowel wall was heterogeneously thickened and the lumen was gas-filled, suggesting the presence of heterogeneity in small bowel wall texture; F: A particularly striking edematous segment was present in the rectum.

DOI: 10.12998/wjcc.v11.i3.576 Copyright ©The Author(s) 2023.

**Figure 7 Characteristic images of case 1.** A-C: Characteristic images of the ileocecal region. A massive cluster of fat stranding that was wrapped by the strikingly thickened omentum (purple arrows) was centered on the homogeneously wall-thickened and gas-filled appendix (orange arrows), leading to the diagnosis of a chronic periappendiceal abscess. The periappendiceal inflammatory changes extended to the scrotum along the inguinal canal (red arrows). In the adjacent sigmoid colon, the wall was thickened and stratified with the water halo sign, and the lumen was gas-filled (blue arrows); D-F: Characteristic images of the ascending colon. The ileocecal valve was thickened and strictured (green arrows), proximal to which the ileal lumen was liquid-filled. Bowel wall thickening with irregular mucosal folds, emptied lumen, mural stratification (fat halo sign) and paracolic fat stranding that was disproportionately less severe than the severity of the colonic wall thickening was present in the ascending colon (yellow arrows). In the descending colon, the wall was also fibrotically thickened; G-I: Characteristic images of an adhesive bowel segment. A segment of adhesive bowel loop with fibrotic bowel wall thickening, peritoneal thickening and hypervascular mesenteric fat stranding was present in the jejunum (white arrows), together with the segmentally gas-filled, segmentally liquid-filled jejunal lumen, suggesting the inflammatory involvement of the upper gastrointestinal tract; J: Characteristic image of the thickened transverse colon. Bowel wall thickening with emptied lumen, mural stratification (water halo sign) and paracolic fat stranding that was disproportionately less severe than the severity of the colonic wall thickening was present in the transverse colon, suggesting the involvement of a transmural inflammatory condition; K and L: The thickened and stratified sigmoid colon. Of the sigmoid colon adjacent to the massive inflammatory lesion, the wall was thickened and stratified with the water halo sign, and the lumen was gas-filled.

The “empty colon sign” refers to a colonic segment in which any contents are absent, usually in a segmentally wall-thickened colon or following a focally wall-thickened colon. Malignant masses are the most common cause. However, inflammatory diseases can also cause empty colon signs, especially in segmental thickening of the colonic wall with edematous submucosal tissues and prominent mesenteric fat stranding[15-18]. In this study, 6 patients presented with an empty colon sign. In **Figure 9** (case 13), the empty colon sign was exhibited a thickened, stratified and emptied colonic segment in the hepatic flexure, followed by the collapsed proximal transverse colon. In **Figure 4** (case 9), the collapsed transverse and descending colon followed the segmentally wall-thickened colon in the hepatic flexure, and endoscopic examination later demonstrated a polypoid lesion in the diseased colonic segment. In **Figure 7** (case 1), the empty colon sign was exhibited as a long segment of the thickened, stratified and emptied ascending and proximal transverse colon. In **Figure 1** (case 4), **Figure 2** (case 3) and **Figure 5** (case 15), the empty colon sign was exhibited a segmentally thickened, stratified and emptied colon in the hepatic flexure.

**Figure 8 Characteristic images of case 7.** A-F: Characteristic images of the ileocecal region and the large colon. The ileocecal valve was thickened and stratified (yellow arrow). The distal ileum was thickened and strictured (green arrows) with a large cluster of misty exudative lesions surrounding the cecum and distal ileum, and the proximal small intestine was liquid-filled with multiple gas-liquid levels. From the cecum to the distal descending colon, the mucosa and the villi were hyperdense, with several focally wall-thickened and stratified colonic segments (red arrows) and several inflamed diverticula (blue arrows). An obstructively thickened segment of the sigmoid colon (orange arrows) with prominent paracolonial hypervascular fat stranding was distal to the remarkably distended lumen and paper-thin bowel wall of the sigmoid colon (white arrows); G-I: Reconstructed images of the obstructively thickened sigmoid colon. From the reconstructed images, the obstructively thickened segment of the sigmoid colon (orange arrows) and the proximal distended sigmoid colon (white arrows) were better visualized. The misty exudative lesions and the surrounded cecum and distal ileum were also better visualized (green arrows).

The “creeping fat sign” represents an imaging presentation in which proliferated fat deposition leads to the widening of the bowel loop[24]. The appearance of the creeping fat sign signifies the presence of chronic transmural inflammation in diseased intestinal segments[16,18,24,25]. In Figure 15 (case 10), the silt-like fat deposition led to the widening of the small bowel loop. In the ileal segment, the wall was thickened, and the lumen was dilated. In Figure 14 (case 8), similar imaging features were shared with those in Figure 15 (case 10). However, Figure 14 (case 8) presented concomitantly with infectious lesions in the pleura, indicative of the reactivation of old tuberculosis.

Diffused bowel inflammatory damage in Crohn’s disease predominantly affects the small intestine, and the ileocecal valve and large intestine are commonly involved. The “creeping fat sign” is the characteristic imaging presentation in the diagnosis of Crohn’s disease[24,25]. In Figure 15 (case 10), the “creeping fat” manifested as silt-like fat deposition. However, most patients manifested perienteric hypervascular fat proliferation wrapping the fibrotically thickened wall and dilated lumen of the ileal segment. Four patients (cases 8, 9, 12, and 14) were found to have this radiological feature. In Figure 14 (case 8), this form of creeping fat was present in the distal jejunum, whereas in the other 3 patients [Figure 15 (case 9), Figure 16 (case 12) and Figure 13 (case 14)], creeping fat was present in the ileum. They also presented with other forms of inflammatory changes in the small and large intestines.

While the diffuse bowel inflammatory lesions of Crohn’s disease predominate in the small intestine, the bowel inflammatory lesions of ulcerative colitis predominate in the colon. Fibrotic thickening of the colonic wall is a common imaging presentation, usually with striking paracolonial hypervascular mesenteric fat proliferation, indicating chronic lesions in nature, different from those of acute colonic infectious diseases[15-19]. The ileocecal region and small intestine are commonly involved in various forms of inflammatory damages. These imaging features were present in Figure 17 (case 5). In addition to fibrotic thickening of the colonic wall and the dilated colonic lumen, peritoneal thickening and loculated ascites in the iliac fossa and pelvic cavity indicated peritoneal involvement of inflammatory lesions. The hypertrophic lesion in the pleura with pleural effusion suggested the presence of tuberculosis infection. These imaging features indicated that tuberculosis infection likely initiated the gut inflammatory condition in this case.

**Figure 9 Characteristic images of case 13.** A-C: Characteristic images of the ileocecal valve and ascending colon. There was edematous fat deposition around the ileocecal valve and the terminal ileum, forming the so-called “fat halo sign”. A massive necrotic lesion in the colonic wall was adjacent to the edematous fat deposition, and the serosal colonic wall was hypertrophically thickened (orange arrows). The adjacent parietal peritoneum (purple arrows) and the left parietal peritoneum (navy blue arrows) were also hypertrophically thickened. The mucosa of the cecum was fibrotically thickened (blue arrow); D-F: Characteristic images of the distal ileum. Strictured thickening of the ileocecal valve and terminal ileum (red arrows) led to the distal ileum being liquid-filled. Proximal to the liquid-filled distal ileum (yellow arrows) was the asymmetrically wall-thickened and gas-filled ileum (green arrows). Heterogeneity of the small bowel wall was observed; G-I: Characteristic images of an “abdominal cocoon”. A segment of adhesive bowel loop was present in the middle jejunum, together with the fibrotically thickened bowel and peritoneal involvement forming the so-called “cauliflower sign”. Edematously thickened colonic wall and emptied colonic lumen were present from the proximal ascending colon to the hepatic flexure, followed by a segment of the collapsed transverse colon (white arrows), forming the so-called “empty colon sign”.

Marked irregular mucosal contour and fibrotically thickened mucosal folds of the large intestine, commonly with colonic wall thickening and subserosal pneumatosis, makes the colonic configuration rugged. This rugged colonic configuration especially with peritoneal thickening could suggest an existence of active and chronic inflammatory conditions in diseased colonic segment. It commonly occurs in the ascending colon and coexists omental involvement and pronounced paracolic fat stranding. This easily recognized imaging presentation is highly useful in the identification of colonic inflammatory damages which is distinguishable from edematous thickening of the colonic wall with disproportionately less severe paracolic fat stranding in acute enterocolitis[14-18]. In patients presented with this imaging presentation, inflammatory lesions also involved other colonic segments, the ileocecal region and small intestine. The rugged configuration of the ascending colon presented in 10 patients [Figure 1 (case 4), Figure 2 (case 3), Figure 4 (case 9), Figure 5 (case 15), Figure 10 (case 11), Figure 6 (case 2), Figure 11 (case 17), Figure 7 (case 1), Figure 14 (case 8) and Figure 12 (case 16)], suggesting that it is common imaging presentations in patients with SAA, in accordance with the high prevalence of inflammatory and infectious diseases in the ileocecal region and the proximal ascending colon.

The “adhesive bowel loop” refers to a segment of small bowel that was adhered and clustered. Various bowel wall abnormalities could be present in the adhered and clustered small bowel segments. Heterogeneity in the bowel wall texture was commonly striking in the adhered small bowel segment. The lumen could be either gas-filled or liquid-filled and frequently alternated. Gas-liquid levels are frequently present in the lumen of the small bowel, indicating the presence of dynamical abnormalities. Bowel wall thickening and transmural inflammatory changes, such as mesenteric fat deposition, increased vasculature and fibrotic peritoneal thickening, were usually particularly striking in the adhered bowel segments. A segment of adhesive bowel loop with peritoneal involvement forms the so-called “abdominal cocoon”[29-32]. In this study, various abdominal cocoons, such as the “accordion sign”, “cauliflower sign” and “bottle gourd sign”, were found. An adhesive bowel loop was present in 15 patients [Figure 1 (case 4), Figure 9 (case 13), Figure 2 (case 3), Figure 3 (case 6), Figure 4 (case 9), Figure 16 (case 12), Figure 13 (case 14), Figure 5 (case 15), Figure 10 (case 11), Figure 6 (case 2), Figure 11 (case 17), Figure 7 (case 1), Figure 8 (case 7), Figure 14 (case 8), and Figure 17 (case 16)]. The high incidence of an adhesive bowel loop suggested the presence of high prevalence of chronic active bowel inflammatory damage in the small intestine in patients with SAA. In the 2 patients without an adhesive bowel loop, Figure 15 (case 10) and Figure 17 (case 5) presented with striking hypervascular mesenteric fat proliferation and a widened bowel loop (creeping fat sign), also indicating the presence of active

DOI: 10.12998/wjcc.v11.i3.576 Copyright ©The Author(s) 2023.

**Figure 10 Characteristic images in case 11.** A-C: Characteristic images of the ascending colon. The ascending colon was rugged with fibrotically and irregularly thickened colonic mucosa, circumferentially distributed omental thickening and paracolic fat stranding (yellow arrows), and other colonic segments were thickened and stratified with water halo sign (red arrows); D-F: Characteristic images of the ileocecal region. The ileocecal valve and the terminal ileal wall were strikingly thickened and stratified (orange arrows). Bowel wall thickening, mural stratification, heterogeneity in bowel wall texture and gas-liquid levels (purple arrows) were found in the small intestine; G-I: Stratified thickening of the large intestine. From the hepatic flexure to the sigmoid colon, the colonic wall was thickened and stratified with water halo sign (red arrows). Several inflamed diverticula was present in the colonic segments (white arrows). A segment of adhesive bowel loop was present in the middle jejunum (blue arrows), together with the peritoneal involvement forming the so-called “cauliflower sign”.

chronic inflammatory involvement of the small intestine[24-26]. Although these inflammatory lesions in the small bowel might not serve as the major factors in the regulation of hematopoietic and immune functions, they exert an important role that affects the downstream gut microbial community and thereby affects downstream intestinal barrier function[54-56].

The ileocecal region is the most common site for various infectious and inflammatory diseases[9,10,14,16]. In this study, all patients with SAA presented with inflammatory involvement of the ileocecal region. Among them, 2 patients presented with inflammatory lesions in the ileocecal region as the predominant imaging presentation. In Figure 7 (case 1), the prominent inflammatory lesion was a large omentum-encapsulated inflammatory mass centered on the homogeneously wall-thickened appendix and extending to the scrotum along the inguinal canal. In Figure 8 (case 7), the particularly prominent inflammatory lesion was a cluster of misty fat stranding wrapping the thickened and strictured distal ileum.

Concomitant extraabdominal presentations may confer useful information for a suggestive etiopathological diagnosis. In this study, pleural involvement of hypertrophic lesions was present in 4 patients [Figure 5 (case 5), Figure 11 (case 17), Figure 14 (case 8), and Figure 12 (case 16)], strongly suggestive of tuberculosis infection. However, no tuberculous lesions were present in their lungs. In addition to the pleural involvement, 1 patients [Figure 9 (case 13)] presented with peritoneal involvement of hypertrophic lesions, also suggesting the presence of tuberculosis infection.

Taken together, this radiological study demonstrated the gut involvement of various inflammatory changes in all patients with SAA. The inflammatory lesions concurrently affected the large intestine, ileocaecal region and small intestine. Although compromised intestinal integrity in the ileocecal region and large intestine exerts a major role in the development of hematological and immunological diseases [9-13], inflammatory damage and dysfunction in the upper gastrointestinal tract can affect the pathophysiologies of the downstream intestinal integrity[54-56] and thereby exert an indirect impact on hematological and immunological function. In susceptible individuals, active chronic gut inflammatory conditions may initiate and perpetuate hematological damage, and aggravated gut damages may induce flared episodes[4-8].

During flared episodes, the imaging features suggested the presence of chronic gut inflammatory conditions and acutely aggravated inflammatory damages. Some readily recognized imaging signs, such as bowel wall thickening with mural stratification (“water halo sign”, “fat halo sign”, intramural

DOI: 10.12998/wjcc.v11.i3.576 Copyright ©The Author(s) 2023.

**Figure 11 Characteristic images in case 17.** A-C: Characteristic images of the ileocecal region and the ascending colon. Circumferentially distributed fat deposition wrapped the ileocecal valve (yellow arrows), forming the so-called “fat halo sign”. The terminal ileum was thickened, and the strictured ileocecal valve and terminal ileum led to the small intestines being liquid-filled. Heterogeneity and hypertrophic lesions of the small intestines were easily recognized. The ascending colon was rugged with paracolic fat stranding and peritoneal thickening, and the colonic wall was thickened and stratified with edematous submucosal tissue and intramural gas (orange arrows). From the transverse to the sigmoid colon (red arrows), the colonic wall was fibrotically thickened, with multiple inflamed diverticula in this colonic segment; D-F: Characteristic images of an adhered jejunal segment. A long segment of the adhered jejunal loop was present in the left iliac fossa and pelvic cavity (green arrows). In the adhesive jejunal loop, the lumen was gas-filled in the proximal segment and liquid-filled in the distal segment. Hypervascular mesenteric fat stranding and fibrotic peritoneal thickening were present in this bowel segment, forming the so-called “abdominal cocoon”. Fibrotic wall thickening was present in the entire jejunal segment and accrescent pili were visualized in the adhesive jejunal loop and the proximal jejunum; G-I: Erosive lesions in extraintestinal organs. Erosive lesions on the background of the calcified lesions were found in the esophagus. Hypertrophic lesions and seromembranous effusion were visualized in the pericardium (black arrows) and the pleura (light blue arrows). Exudative lesions were also present in the vertebral column (blue arrows); J-L: Erosive lesions in the stomach. Erosive lesions on the background of the calcified lesions were also found in the stomach; M-O: Exudative lesions in extraintestinal organ. Hypertrophic lesions and seromembranous effusion were visualized in the pericardium (black arrows) and the pleura (light blue arrows). Exudative lesions were also present in the renal pelvis and urinary tract (a purple arrow). These radiological features led to the diagnosis of reactive tuberculosis infections in the gastrointestinal tract, urinary tract, peritoneum, vertebral column, pleura and pericardium.

gas and subserosal pneumatoses) and mesenteric fat proliferation (fat stranding and “creeping fat sign”), “balloon sign”, rugged colonic configuration and adhesive bowel loop (including various patterns of abdominal cocoon), occurred at a high incidence, which suggested that the gastrointestinal

**Figure 12 Characteristic images in case 16.** A-C: Characteristic images of the ileocecal region and the small intestine. The ileocecal valve was fibrotic and thickened with edematous fat deposition, forming the so-called “fat halo sign” (orange arrows), and the distal ileum was adhesive with mesenteric fat stranding and peritoneal thickening (white arrow), forming the so-called “abdominal cocoon”. Intestinal adhesion with bowel wall thickening, peritoneal involvement and mesenteric fat stranding was also found in the jejunum (blue arrow). Heterogeneity in the bowel wall texture was particularly prominent in the adhesive bowel segments; D: Characteristic image of the large intestine. The ascending colon was rugged and the colonic wall was thickened and stratified, with adjacent omental thickening (yellow arrows). The descending colonic wall were significantly thickened and stratified with mucosal hyperdensity and paracolic fat stranding (red arrows); E and F: Characteristic images of the chest computed tomography (CT) scan. Chest CT revealed that the pleural effusion was predominantly in the left cavity and hypertrophic lesions involved both the left pleura and the pericardium (green arrows).

DOI: 10.12998/wjcc.v11.i3.576 Copyright ©The Author(s) 2023.

**Figure 13 Characteristic images of case 14.** A-C: Characteristic images of the bowel inflammatory lesions. The ileocecal valve and the ileal wall were fibrotically thickened and the ileal lumen was gas-filled (yellow arrows), with a large cluster of hypervascular perienteric fat proliferation wrapping the wall-thickened and lumen-dilated ileum. The cecum (blue arrows) and appendix (green arrows) were also fibrotically thickened and stratified, with peripheral fat stranding. Gas-liquid levels were present in the lumen of the proximal ileum and distal jejunum (purple arrows). However, the adhesive jejunal loop was liquid-filled with prominent hypervascular mesenteric fat proliferation. In a segment of the jejunum (white arrows), the bowel wall was thickened, the lumen was gas-filled and the mesenteric fat stranding was especially prominent. Thickened peritoneum was adjacent to the adhesive jejunal loop, forming the so-call “abdominal cocoon” and the enlarged mesenteric vascularity formed the so-called “comb sign”. The ascending colon was dilated with a paper-thin bowel wall (black arrows), forming the so-called “balloon sign”. From the hepatic flexure to the distal descending colon (red arrows), the bowel was thickened and stratified (water halo sign), with paracolic fat stranding and peritoneal thickening being particular prominent in the hepatic flexure. The sigmoid colon was fibrotically thickened and dilated (orange arrows); D and E: Characteristic images in coronally reconstructed images. The coronally reconstructed images better outlined the above-mentioned imaging features; F: Characteristic image of the descending colon in coronally reconstructed section. A coronally reconstructed image better outlined the thickened and stratified descending colon.

tract is common inflammatory niche responsible for the systemic inflammatory stresses in patients with SAA. Successful treatment of their gut inflammatory conditions significantly improves their hematological profile[4-6], providing convincing evidence for a role of gut inflammation in hematopoietic suppression.

**Figure 14 Characteristic images in case 8.** A-C: Characteristic images of the ileocecal region and the small intestine. The ileocecal valve (red arrows) was thickened, strictured and stratified. The distal ileum (yellow arrows) were significantly thickened with intramural gas and wrapped by prominent mesenteric fat stranding, which suggested the presence of aggravated inflammatory damage in the distal ileum and ileocecal region; D-H: Characteristic images of the small intestine. In the ileocecal region, the ileum adhered to the cecum, and the cecum was thickened and stratified. In other colonic segments (orange arrows), the bowel wall was also thickened and stratified, and the lumen was dilated in some segments and collapsed in other segments. From the jejunum to the proximal ileum (green arrows), the wall was fibrotic and thickened and the lumen was gas-filled. Several segments of adhesive bowel loop were present in the small bowel. Noticeably, panabdominal silt-like hypervascular fat deposition wrapped the adhesive and widened small bowel loop (creeping fat sign), which suggested the presence of chronic transmural inflammatory damage and a diagnosis of Crohn's disease; I: Characteristic image of the chest computed tomography (CT) scan. Chest CT showed exudative lesions in the left pleura in the context of calcified lesions, indicating the reactivation of an old tuberculosis infection.

DOI: 10.12998/wjcc.v11.i3.576 Copyright ©The Author(s) 2023.

**Figure 15 Characteristic images of case 10.** A and B: Characteristic images of the fat deposition. The most noticeable radiological finding was the panabdominal silt-like hypervascular fat deposition, leading to the widening of the bowel loop of the jejunum and the proximal ileum, forming the so-called "creeping fat sign". The ileum was fibritically thickened and dilated, and the duodenum and the proximal jejunum were liquid-filled (green arrows); C and D: Characteristic images of the ileocecal region. The ileocecal valve and the terminal ileum were significantly thickened, stratified and strictured (red arrows), and proximal to the thickened terminal ileum, the ileal lumen was dilated and gas-filled and the mucosa was hyperdense (yellow arrows). The ascending colonic wall was also thickened (purple arrows). In a short segment of the descending colon (blue arrows), accrescent villi were especially prominent; E and F: Characteristic images of the small intestine. The proximal ileum and the distal jejunum (orange arrows) were thickened and gas-filled.

**Figure 16 Characteristic images of case 12.** A-D: Characteristic images of the bowel inflammatory lesions. The ileocecal valve and the terminal ileal wall (red arrows) were thickened, stratified and strictured. Proximal to the strictured terminal ileum, the ileal lumen was dilated and gas-filled, and the mucosa was hyperdense. A large cluster of hypervascular mesenteric fat proliferation wrapped the dilated and gas-filled ileum. The jejunum was liquid-filled and the jejunal loop was adhesive. A cluster of hypervascular fat stranding wrapped a short segment of the jejunum (blue arrows), suggesting that the transmural inflammation was more serious in this jejunal segment. The colonic wall was also thickened and stratified, with intramural gas and subserosal pneumatosis (yellow arrows); E: Characteristic image of the pelvic liquid collection. Mild liquid collection was present in the pelvic cavity (a green arrow), together with the thickened peritoneum (a purple arrow) suggesting the presence of peritoneal involvement; F: Characteristic image in coronally reconstructed section. A coronally reconstructed image better outlined the above-mentioned imaging features.

DOI: 10.12998/wjcc.v11.i3.576 Copyright ©The Author(s) 2023.

**Figure 17 Characteristic images of case 5.** A-D: Characteristic images of the bowel inflammatory lesions. From the cecum to the descending colon, the lumen was dilated, the mucosa was hyperdense and the wall was thickened and stratified in some segments (orange arrows), with striking mesenteric fat stranding. There was a hypertrophic lesion (a red arrow) in the terminal descending colon. The mucosa of the proximal sigmoid colon was hyperdense and the lumen was gas-filled (blue arrows), following which was a short segment of strictured sigmoid colon (yellow arrows). The ileocecal valve and the terminal ileum were thickened and strictured but without mural stratification (a purple arrow), proximal to which the small intestine was liquid-filled. In the ileocecal region, the colonic wall was thickened with smudgy peritoneal thickening (white arrows); E: Characteristic image of the pelvic liquid collection. Mild ascites was present in both the right and left iliac fossa (green arrows), together with a thickened peritoneum suggesting the presence of peritoneal involvement; F: Characteristic image of the chest computed tomography (CT) scan. Chest CT showed the presence of pleural effusion in the bilateral cavities and bilateral pleural hypertrophic thickening. Enlarged blood vessels extended to the hypertrophic lesions.

Although not able to provide an etiopathological diagnosis, abdominal CT can provide useful information for exploring gut inflammatory conditions and guiding further work-ups. In this study, a suggestive diagnosis of Crohn's disease was made in 5 patients, ulcerative colitis in 1 patient, chronic periappendiceal abscess in 1 patient, and tuberculosis infection in 5 patients[57-59]. Although the

presence of abdominal cocoons has been reported to have a high probability of tuberculosis infection[31, 32] and there was a high incidence of abdominal cocoons present in this study, it was difficult to make a presumptive diagnosis of tuberculosis infection in patients with abdominal cocoons other than the abovementioned 5 patients.

This study had several limitations. First, although CT has some advantages in the detection of the site, extent, degree and peripheral changes of gut inflammatory damage, the exact pathogenic factors cannot be identified, and arriving at an etiopathological diagnosis frequently requires other laboratory tests. This study lacked the endoscopic, pathological and other definitive diagnostic examinations largely due to the contraindication of invasive operative procedures resulting from the very low platelet count and the platelet transfusion refractoriness of these patients. Second, the number of studied patients was quite small, leading to the incidence of each imaging sign being less representative of the actual incidence. Third, the treatment responses by suggested radiological diagnosis were not summarized.

## CONCLUSION

All patients with SAA during inflammatory episodes demonstrated gut involvement of both active chronic inflammatory conditions and acute inflammatory damage, providing further evidence to demonstrate the role of GIDs in the pathogenesis of immune-mediated hematopoietic failure. Although arriving at an etiopathological diagnosis frequently requires other laboratory tests, abdominal CT imaging can provide highly useful information for the exploration of gut inflammatory damage and is very helpful for the suggestion of an effective treatment modality. In patients with aggravated cytopenia and clinical presentations suggestive of the presence of inflammatory responses, inflammatory diseases in the gastrointestinal tract should be considered, abdominal CT should be performed, and imaging signs that suggest the presence of gut inflammatory lesions should be carefully identified.

## ARTICLE HIGHLIGHTS

### Research background

The gastrointestinal tract hosts the body's most enriched lymphoid tissues and microbial community and therefore can provide sufficient activated immune cells and continuous intestine-derived antigens to influence the host hematopoietic and immune functions. The gastrointestinal tract is the most common site for infectious and inflammatory diseases. Morphological changes on computed tomography (CT) images can provide useful information that reflects the distribution, extent, and severity of the bowel inflammation and even suggests a pathogenic diagnosis.

### Research motivation

Initiation and perpetuation of aplastic anemia (AA) pathogenesis has been found to be associated with gut inflammatory disorders (GIDs). GIDs have a powerful impact on hematopoietic and immune functions. Treatment of GIDs can improve hematological profile and immunological derangement.

### Research objectives

To explore CT imaging presentations of gut inflammatory damage in adult patients with severe AA (SAA) and to provoke awareness of GIDs in the pathogenesis of hematological and autoimmune disorders.

### Research methods

We retrospectively evaluated the abdominal CT imaging presentations of 17 hospitalized adult patients with SAA in search of the inflammatory niche when they presented with systemic inflammatory stress and exacerbated hematopoietic function.

### Research results

All eligible patients with SAA had CT imaging abnormalities that suggested the presence of an impaired intestinal barrier and increased epithelial permeability. The inflammatory damages were concurrently present in the small intestine, the ileocecal region and the large intestines.

### Research conclusions

All patients with SAA had CT imaging patterns that suggested the presence of active chronic inflammatory conditions and aggravated inflammatory damage during flared inflammatory episodes. In patients with aggravated cytopenia and clinical presentations suggestive of the presence of inflammatory responses, inflammatory diseases in the gastrointestinal tract should be considered, abdominal CT should be performed, and imaging signs that suggest the presence of gut inflammatory lesions

should be carefully identified.

### Research perspectives

Abdominal CT imaging presentations in association with hematopoietic failure and autoimmune diseases warrant extensive investigations.

## Abstract

### BACKGROUND

The inferior vena cava filter is utilized worldwide to intercept thrombi and to reduce the risk of fatal pulmonary embolism (PE). However, filter-related thrombosis is a complication of filter implantation. Endovascular methods such as AngioJet rheolytic thrombectomy (ART) and catheter-directed thrombolysis (CDT) can treat filter-related caval thrombosis, but the clinical outcomes of both treatment modalities have not been determined.

### AIM

To compare the treatment outcomes of AngioJet rheolytic thrombectomy *vs* catheter-directed thrombolysis in patients with filter-related caval thrombosis.

### METHODS

In this single-center retrospective study, 65 patients (34 males and 31 females; mean age:  $59.0 \pm 13.43$  years) with intrafilter and inferior vena cava thrombosis were enrolled between January 2021 and August 2022. These patients were assigned to either the AngioJet group ( $n = 44$ ) or the CDT group ( $n = 21$ ). Clinical data and imaging information were collected. Evaluation measures included thrombus clearance rate, periprocedural complications, urokinase dosage, incidence of PE, limb circumference difference, length of stay, and filter removal rate.

### RESULTS

Technical success rates were 100% in the AngioJet and CDT groups. In the AngioJet group, grade II and grade III thrombus clearance was achieved in 26

(59.09%) and 14 (31.82%) patients, respectively. In the CDT group, grade II and grade III thrombus clearance was accomplished in 11 (52.38%) patients and 8 (38.10%) patients, respectively ( $P > 0.05$ ). The peridiameter difference of the thigh was significantly reduced in patients from both groups after treatment ( $P < 0.05$ ). The median dosage of urokinase was 0.08 (0.02, 0.25) million U in the AngioJet group and 1.50 (1.17, 1.83) million U in the CDT group ( $P < 0.05$ ). Minor bleeding was shown in 4 (19.05%) patients in the CDT group, and when it was compared with that in the AngioJet group, the difference was statistically significant ( $P < 0.05$ ). No major bleeding occurred. Seven (15.91%) patients in the AngioJet group had hemoglobinuria and 1 (4.76%) patient in the CDT group had bacteremia. There were 8 (18.18%) patients with PE in the AngioJet group and 4 (19.05%) patients in the CDT group before the intervention ( $P > 0.05$ ). Computed tomography angiopulmonography (CTA) showed that PE was resolved after the intervention. New PE occurred in 4 (9.09%) patients in the AngioJet group and in 2 (9.52%) patients in the CDT group after the intervention ( $P > 0.05$ ). These cases of PE were asymptomatic. The mean length of stay was longer in the CDT group ( $11.67 \pm 5.34$  d) than in the AngioJet group ( $10.64 \pm 3.52$  d) ( $P < 0.05$ ). The filter was successfully retrieved in the first phase in 10 (47.62%) patients in the CDT group and in 15 (34.09%) patients in the AngioJet group ( $P > 0.05$ ). Cumulative removal was accomplished in 17 (80.95%) out of 21 patients in the CDT group and in 42 (95.45%) out of 44 patients in the ART group ( $P > 0.05$ ). The median indwelling time for patients with successful retrieval was 16 (13139) d in the CDT group and 59 (12231) d in the ART group ( $P > 0.05$ ).

### CONCLUSION

Compared with catheter-directed thrombolysis, AngioJet rheolytic thrombectomy can achieve similar thrombus clearance effects, improve the filter retrieval rate, reduce the urokinase dosage and lower the risk of bleeding events in patients with filter-related caval thrombosis.

**Key Words:** Inferior vena cava filter; Thrombosis; AngioJet rheolytic thrombectomy; Catheter-directed thrombolysis; Clinical outcome

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core Tip:** This is a retrospective study. A total of 65 patients were enrolled to evaluate the clinical outcomes of different treatment methods in patients with filter-related caval thrombosis. We compared the data of patients between the AngioJet rheolytic thrombectomy group ( $n = 44$ ) and the catheter-directed thrombolysis group ( $n = 21$ ). The current results showed no difference in thrombus clearance or filter retrieval rate. However, the results showed significant differences in urokinase dosage, peridiameter difference of the thigh, minor bleeding, and length of stay.

### INTRODUCTION

Patients with deep venous thrombosis (DVT) have a high risk of lethal acute pulmonary embolism (PE) if left untreated[1-3]. Anticoagulants are the mainstay of prophylaxis in DVT[4,5]. At present, inferior vena cava (IVC) filters are used to reduce the risk of fatal PE in high-risk patients[6,7]. However, permanent placement of IVC filters may lead to some complications, such as fracture or migration, organ injury, and thrombotic events[8-10]. The incidence of filter-related caval thrombosis ranges from 1% to 30%, depending on the type of filter[11-13]. Filter-related thrombosis can cause caval occlusion associated with some complications, including renal dysfunction and pelvic congestion syndrome[14].

Therefore, early thrombus clearance is essential to restore the patency of the caval outflow. It is difficult to treat filter-related thrombosis because of the large vessel lumen and the large thrombus burden. The methods of thrombus clearance include open surgical thrombectomy, catheter-directed thrombolysis (CDT), and percutaneous mechanical thrombectomy (PMT)[15]. Open surgical thrombectomy ensures satisfactory long-term clinical outcomes for patients who are not eligible for endovascular measures[16]. Although CDT is an effective treatment for filter-related caval thrombosis that can restore blood flow, it increases the risk of bleeding events[13,14,17]. PMT is effective for

resolving filter-related caval thrombosis, reducing the dosage of thrombolytic drugs and the risk of bleeding events[18].

A meta-analysis recently reported the treatment outcomes of AngioJet *vs* CDT for lower extremity deep venous thrombosis (LEDVT)[19]. Based on our clinical experience, PMT can reduce the risk of bleeding and may be a good option. What's more, it is unclear whether CDT and PMT lead to major bleeding or fatal PE in patients with filter-related caval thrombosis. However, the clinical outcomes of both treatment modalities have not been determined in these patients until now. Therefore, we aimed to compare ART with CDT in patients with filter-related thrombosis on treatment outcomes for providing a basis for clinical practice and research.

## MATERIALS AND METHODS

### Patients

This is a single-center retrospective study. Patients with traumatic lower-limb fractures and simultaneous DVT who were admitted to Beijing Jishuitan Hospital between January 2021 and August 2022 were enrolled in the present study. The presence of DVT was confirmed with bilateral color Doppler ultrasound or venography. These patients received an IVC filter before surgical fixation. The IVC filter was deployed in all patients using the standard technique, and the femoral vein of the healthy limb was used as the access site for filter placement. Filter removal was attempted within 2 wk after fracture surgery in all patients, and venography revealed intrafilter and IVC thrombosis. Sixty-five patients (59.0 years  $\pm$  13.43 years) were identified for inclusion in the study. General patient information data, including sex, age, affected limbs, risk factors (fracture types), scope of thrombosis, filter types, and duration of symptoms (defined as the time from detection of lower extremity DVT to thrombus clearance), were collected (Table 1). This study received ethical approval from the Ethics Committee of our hospital.

**The inclusion criteria were as follows:** (1) Unilateral lower extremity fracture and simultaneous DVT (femoral and/or popliteal venous thrombosis) in the acute stage; (2) complete medical records; (4) life expectancy > 1 year; (5) no serious complications of vital organs; (6) no anticoagulant or thrombolysis contraindication after surgical fixation of fractures; and (7) no previous history of thrombosis.

**The exclusion criteria were as follows:** (1) Bilateral lower extremity DVT; (2) thrombosis throughout the iliofemoral vein; (3) history of pregnancy or any hemorrhage; (4) life expectancy < 1 year; and (5) contraindications related therapeutic drugs.

These patients were assigned to either the AngioJet group ( $n = 44$ ) or the CDT group ( $n = 21$ ). The study profile was shown in Figure 1. Evaluation measures included thrombus clearance rate, periprocedural complications, urokinase dosage, incidence of PE, limb circumference difference, length of stay, and filter removal rate. The procedure of intervention was as follows (Table 2).

### AngioJet rheolytic thrombectomy

A 6-Fr AngioJet thrombectomy catheter (Boston Scientific, Natick, MA, United States) was inserted into the IVC thrombus *via* the femoral vein. The power-pulsed spraying thrombolytic mode was used, and saline-containing urokinase (100 mL of normal saline + 200000 U of urokinase) was injected into the IVC thrombus at a speed of 1 mm/s. The dosage of normal saline-containing urokinase depended on the extent of the thrombus. After waiting for 15-20 min, a mechanical rheolytic thrombectomy was performed for aspiration of the thrombus. If the thrombus remained, we repeated the aspiration 2-3 times. If the inferior vena cava angiography showed that the thrombus remained, a 10F guiding catheter (OptEase™ Retrieval Catheter, Cordis Corporation, FL, United States) was used to suck the thrombus out under guidance of an exchange guidewire (Terumo, Japan) *via* femoral vein access. The catheter connected a 20 mL injector, and constant negative pressure of the syringe was maintained for repeated thrombus suction. Finally, inferior vena cava angiography was implemented to assess thrombus clearance (Figure 2).

### CDT

We placed a thrombolytic catheter (UniFuse, AngioDynamics, Latham, NY, United States) in the thrombus *via* the femoral vein. Urokinase was constantly injected through the catheter at a rate of 500000 U/d. Angiography was implemented every 24 h to evaluate the thrombolytic effect (Figure 3). Thrombolysis was terminated when the plasma fibrinogen level was less than 1 g/L, the IVC was unobstructed, or there were serious complications. If the inferior vena cava angiography showed that the thrombus remained, a 10F guiding catheter was used to suck the thrombus out under the guidance of an exchange guidewire (Terumo, Japan) *via* femoral vein access. The catheter connected to a 20 mL injector was maintained for repeated thrombus suction. Eventually, inferior vena cava angiography was performed to evaluate the thrombus clearance effect.

### Filter retrieval

Filter retrieval was performed when the patient was considered low risk for PE. The criteria were as follows: (1) Decreasing trend or normal serum D-dimer levels; (2) IVC thrombus clearance of more than 95% after ART or CDT; and (3) disappearance or organization of the previously visualized lower-limb thrombus. The same placement technique as before was applied for venous access for the filter retrieval procedures. All procedures were performed through the femoral vein. Briefly, after venous access and the introduction of the angiography catheter, initial venography was performed to evaluate the patency of the IVC. The filter was retrieved using the Günther Tulip Retrieval System (William Cook Europe, Denmark). If the above conditions were not met, anticoagulation therapy was continued, ultrasound or venography was further assessed for the associated risks, and filter removal was performed at an optional stage.

**Figure 1 Study profile.** IVC: Inferior vena cava; CDT: Catheter-directed thrombolysis.

### Anticoagulant therapy

During hospitalization, low molecular weight heparin was routinely given after fracture surgery, and anticoagulation therapy with 20 mg rivaroxaban was initiated daily after thrombus clearance. Oral anticoagulant was taken for at least 3 mo after filter removal.

### Observation indicators and evaluation criteria

Technical success is defined as uncomplicated implementation of the AngioJet device or CDT for thrombectomy through femoral vein access. CTA and D-dimer tests were performed before and after the operation within 3 d. D-dimer was analyzed with a Sysmex CS-5100 System. The laboratory reference range was 0 to 0.55 mg/mL. The difference in circumference between the affected and unaffected thighs at 15 cm above the patella was measured before and after treatment. The thrombus clearance effect was assessed according to the outcomes of the first and last venography. The degree of thrombus clearance was divided into three types: Grade I (partial clearance (< 50%)), grade II (most clearance (50%-99%)), and grade III (complete clearance (100%)) [20]. The occurrence of complications was evaluated, including minor bleeding (epistaxis, gum bleeding, and hematoma), major bleeding (retroperitoneal or intracranial bleeding), hemoglobinuria, bacteremia, allergic reaction, serious cardiovascular or respiratory complications, and death. Filter removal of the first phase was defined as immediate retrieval within 3 d after thrombus removal. After anticoagulation and thrombus clearance, all filters were removed, and the cumulative removal rate was calculated by the proportion of successful filter retrieval. The indwelling time of the filter was the time from placement to retrieval. The follow-up time was more than one month, and patients also underwent routine D-dimer tests every month after discharge.

### Statistical analysis

Continuous variables are presented as medians, minimums, and maximums for nonparametric distributions and were compared by using the Mann-Whitney test. Continuous variables are presented as the means and standard deviations for parametric distributions, and comparisons were made using the independent *t* test. Categorical variables are evaluated as frequencies and percentages and compared by using the chi-square test or Fisher's exact test. Statistical significance was defined as  $P < 0.05$ . All statistical analyses were processed with SPSS 23.0 software (SPSS Inc., Chicago, IL, United States).

## RESULTS

### Patients

Sixty-five (65) patients diagnosed with traumatic lower-limb fracture and simultaneous DVT between January 2021 and August 2022 were enrolled in the study. Forty-four patients ( $56.84 \pm 14.19$  years) were included in the AngioJet group, and 21 patients ( $55.24 \pm 11.92$  years) were included in the CDT group. The left lower extremity was affected in 10 patients (47.76%) in the CDT group and in 20 patients (45.54%) in the ART group ( $P > 0.05$ ). Risk factors associated with acute DVT in the two groups were fractures below the knee (28.57% vs 18.18%,  $P > 0.05$ ), fractures of the knee (28.57% vs 31.82%,  $P > 0.05$ ), and fractures above the knee (42.86% vs 50.0%,  $P > 0.05$ ). The scope of thrombosis in both groups included the femoral/popliteal/calf vein (23.81% vs 13.64%,  $P > 0.05$ ) and popliteal/calf vein (76.19% vs 86.36%,  $P > 0.05$ ). Filters of Denali were implanted in 22 patients in the CDT group and 44 in the ART

**Figure 2 Angiography was performed to evaluate the thrombus clearance of AngioJet.** A: A 31-year-old male patient with acute traumatic lower-limb fracture and simultaneous deep venous thrombosis received an inferior vena cava (IVC) filter before surgical fixation; B and C: Filter removal was attempted within 2 weeks after fracture surgery, and angiography showed filter-related IVC-iliac vein thrombosis (white arrow); D and E: A 6-Fr AngioJet thrombectomy catheter was placed for thrombus clearance; F: The 10F guiding catheter was placed and withdrawn, and the thrombus was aspirated under negative pressure until it exited the body, which could be repeated 2-3 times; G and H: The venography showed the complete clearance thrombus of filter-related IVC-iliac vein thrombosis; I: The venography showed that the IVC vein was unobstructed after filter retrieval; J: Computed tomography angiopulmonography did not show pulmonary embolism after intervention.

group (100% *vs* 93.18%,  $P > 0.05$ ). The general information is shown in [Table 1](#).

The scope of thrombosis in both groups included intrafilter thrombosis (85.71% *vs* 86.36%,  $P > 0.05$ ) and intrafilter and IVC thrombosis (14.29% *vs* 13.64%,  $P > 0.05$ ). There were 8 (18.18%) patients with PE in the AngioJet group and 4 (19.05%) patients in the CDT group before the intervention ( $P > 0.05$ ). CTA showed that these cases of PE were resolved after the intervention. The PE was located at the level of segmental or lobar arteries in these patients ( $P > 0.05$ ). The median dosage of urokinase was 0.08 (0.02, 0.25) million U in the AngioJet group and 1.50 (1.17, 1.83) million U in the CDT group ( $P < 0.05$ ). Compared to 33 (75.0%) patients in the AngioJet group, 11 (52.38%) patients in the CDT group were treated with large-lumen catheter suction after thrombus clearance ( $P > 0.05$ ). In the CDT group, the median D-dimer levels were 12.10 (2.29, 30.93) and 8.37 (2.67, 15.98) mg/mL before and after treatment, respectively ( $P < 0.05$ ). In the AngioJet group, the median D-dimer levels were 8.87 (2.01, 18.88) and 7.14 (0.43, 22.05) mg/mL before and after treatment, respectively ( $P < 0.05$ ) ([Table 2](#)).

### Evaluation of clinical outcomes

The technical success rates were 100% in the AngioJet and CDT groups. Thrombus clearance of patients in the CDT and AngioJet groups reached grade I (9.52% *vs* 9.09%), grade II (52.38% *vs* 59.09%), and grade III (38.10% *vs* 31.82%), respectively ( $P > 0.05$ ). In the AngioJet group, the differences in thigh circumference were  $4.76 \pm 0.77$  cm and  $1.58 \pm 0.51$  cm before and after treatment, respectively ( $P < 0.05$ ). In the CDT group, the peridiameter differences of the thigh were  $4.51 \pm 0.65$  cm and  $1.44 \pm 0.36$  cm, respectively ( $P < 0.05$ ).

In the AngioJet group, 7 patients (15.91) developed hemoglobinuria after the procedure, which was relieved after rehydration and hydration, and no hemoglobinuria was found in the CDT group. Bacteremia was found in one patient (4.76%) in the CDT group, which was relieved by anti-infection after catheter removal. In the CDT group, minor bleeding was observed in 4 (19.05%) patients, including

**Figure 3** Angiography was implemented to assess the thrombus clearance of catheter-directed thrombolysis. A: A 36-year-old male patient with acute traumatic lower-limb fracture and simultaneous deep venous thrombosis received an inferior vena cava (IVC) filter before surgical fixation. Filter removal was attempted within 2 wk after fracture surgery, and venography showed IVC-related caval thrombosis; B: A thrombolytic catheter was placed in the thrombosed segment via the right femoral vein, and urokinase was continuously injected; C: The venography showed that the most clearance thrombus of filter-related thrombosis; D: The patient was given anticoagulation therapy with rivaroxaban 20 mg daily after catheter-directed thrombolysis. The venography showed that the complete thrombus clearance of filter-related thrombosis 7 wk later; E: The venography showed that the IVC vein was unobstructed after the filter removal; F: Computed tomography angiopulmonography did not show pulmonary embolism after intervention.

epistaxis in 2 patients, gum bleeding in one patient, and hematoma at the puncture site in one patient, and the difference was significant compared with the AngioJet group ( $P < 0.05$ ). New PE occurred in 4 patients (9.09) in the AngioJet group and in 2 patients (9.52) in the CDT group and was asymptomatic in each case. These PEs were located at the level of segmental arteries in these patients ( $P > 0.05$ ). The mean length of stay was longer in the CDT group ( $11.67 \pm 5.34$  d) than in the AngioJet group ( $10.64 \pm 3.52$  d) ( $P < 0.05$ ).

Immediate filter retrieval was successful in 10 out of 21 patients (47.62% success rate) after the procedure in the CDT group and 15 out of 44 patients (34.09% success rate) in the ART group ( $P > 0.05$ ). Cumulative removal was achieved in 17 (80.95% success rate) out of 21 patients in the CDT group and 42 (95.45% success rate) out of 44 patients in the AngioJet group ( $P > 0.05$ ). Filter retrieval was unsuccessful in one patient due to superior vena cava malformation and was not conducted in 3 CDT patients due to organized thrombus, which prevented the capture of the retrieval hook, and in 2 AngioJet patients because of an organized thrombus on the hook. The median indwelling time for patients in whom retrieval was successful was 16 d (range 13-139 d) in the CDT group and 59 d (range 12-231 d) in the ART group ( $P > 0.05$ ). The therapeutic effects and complications are shown in Table 3.

The median follow-up time was 4(1,10) months. At the 1-mo follow-up, no major bleeding, symptomatic PE, recurrent thrombosis or other serious complications was observed after the procedure in either group. Two (4.5%) patients in the AngioJet group developed recurrent swelling of the affected limb 1 mo after the intervention. The ultrasound showed venous reflux of the lower extremities. There was no skin ulceration or pigmentation in the calf after treatment in either group.

CDT: Catheter-directed thrombolysis; IVCF: Inferior vena cava filter; PE: Pulmonary embolism.

## DISCUSSION

A high incidence of DVT has been reported in trauma patients, especially those with lower-limb fractures. With transient trauma contraindicating anticoagulant use, temporary perioperative IVC filter placement is the best prophylactic option for these patients[12,21]. IVC filter placement, however, may lead to numerous complications[22]. Filter-related thrombosis is one of the complications after implantation, with an incidence of approximately 10% in these patients[12]. Moreover, filter-related thrombosis also causes serious complications, such as caval occlusion or shock[14,23]. Prompt treatment of thrombi and retrieval of IVC filters can reduce the risk of filter-related thrombosis. The more effective methods for treating acute IVC filter-related thrombosis are CDT or ART[18,24]. No relevant literature evaluating the clinical efficacy of the two methods has been found thus far.

In our study, endovascular intervention resulted in good clinical outcomes, with a high incidence of thrombus clearance in patients in both groups. Studies have shown that grade II/III thrombus clearance was achieved in 80%-91% of acute LEDVT patients who underwent ART and in 83%-97% of acute LEDVT patients who underwent CDT[20,25]. The results of this study show that the extent of thrombus clearance in patients with IVC thrombosis is similar to that of patients with LEDVT. However, there have also been studies reporting 100% clearance of grade II/III IVC thrombosis[18,26]. This is somewhat different from our study and may be related to the selection of patients, the time of thrombosis, and the choice of thrombolytic drugs. In our study, manual aspiration thrombectomy (MAT) was performed according to the effect of thrombus removal after the operation. MAT through a large vascular sheath and guiding catheter is an adjunctive procedure for thrombus removal. It is also a necessary and effective means of thrombus clearance because of the large lumen and thrombus burden of the IVC in the treatment of filter-related thrombosis. In one study, the researchers repeated that MAT could achieve more than 95% thrombus clearance, which was shown in venography in patients with acute iliofemoral DVT[27]. However, in another study, the researchers mentioned that MAT had a good thrombusclearance rate but was less effective than ART for the treatment of IVC filter-related

thrombosis ( $74.13 \pm 19.74\%$  vs  $84.58 \pm 11.90\%$ ,  $P < 0.05$ )[18]. ART or CDT combined with MAT can achieve good clinical outcomes, but further studies are needed to confirm this hypothesis in the future.

CDT can rapidly achieve complete thrombolysis without pure anticoagulation but increases the potential risk of bleeding, which may be life-threatening[28]. It has been reported that the incidence of bleeding events in CDT ranges from 9.7% to 21.1% in patients with LEDVT[20,25-26]. Our study showed that the bleeding complication rate was 19.05%, which was similar to that of LEDVT, and no major bleeding events occurred. In addition to bleeding complications, the management of CDT is also a tricky problem, mainly reflected in the restriction of patient movement because of indwelling catheters, bleeding or hematoma, and catheter-related bacteremia. In this study, one patient (4.76%) in the CDT group developed postoperative catheter-related bacteremia, which was cured by antibiotic treatment. When catheter-related infection occurs, it is necessary to remove the catheter, which may affect thrombolytic treatment. Therefore, catheter-related bacteremia should be avoided. ART can quickly reduce the volume of thrombi, which can achieve better clinical outcomes for inferior vena cava-iliac vein thrombosis[29]. Transient hemoglobinuria is one of the common complications of ART, and studies have reported an incidence of 9.1%-19%[18,20]. ART lowers urokinase dosage but causes discomfort, such as chest tightness, during the procedure in patients with IVC thrombosis. If these conditions occur, the procedure should be stopped, and thrombus removal can be resumed when the symptoms are relieved.

Winters *et al*[30] found that the retrieval rate improved from 23% to 45% over the past five years. It was reported in another study that the retrieval rate of the filter increased from 6.9% to 22.1% in the past 5 years[31]. This indicates that the retrievable rate is still low. Because it is difficult to complete DVT treatment within a short retrieval window, one might lose the best chance of filter retrieval. Meanwhile, a large number of retrievable filters were converted to permanent filters due to capturing thrombi or displaced or tilted filters[32]. Therefore, it is very important to perform thrombus clearance for filter-related thrombosis, which can improve the removal rate of the filter. In our study, the cumulative filter removal rate was 80.95% in the CDT group and 95.45% in the ART group. In addition, it is necessary to choose a filter such as Denali with a long indwelling time and a high removal rate as much as possible [33].

Lindsey *et al*[34] reported that the incidence of trapped IVC filter thrombus was 38% in patients with symptomatic lower extremity DVT who underwent endovascular interventions. At present, the occurrence of PE due to thrombus clearance in patients with intrafilter and IVC thrombosis has not been clinically reported. In our study, the incidence of PE was approximately 9% after ART or CDT in these patients. These PEs were asymptomatic, located in the pulmonary segmental or lobar arteries and relieved with conservative anticoagulation. After oral rivaroxaban anticoagulation, the patient's D-dimer level nearly dropped to normal within one month. This suggests that adequate anticoagulation after thrombus clearance is essential.

There are still several limitations in this study. First, it is a single-center retrospective analysis, which makes it prone to patient selection bias and artificial judgment bias for thrombus removal. LEDVT is different from intrafilter and IVC thrombosis. Thrombus clearance assessment for LEDVT may not be appropriate for IVC thrombosis. In the future, it is necessary to explore objective methods for evaluating thrombus clearance. Second, the sample size of the study was limited. Third, due to the short follow-up period, PTS and venous insufficiency were not evaluated. At present, there is a lack of large-scale studies and long-term follow-up on the venous patency rate and incidence of PTS after IVC thrombosis removal.

## CONCLUSION

In summary, we reported the advantages and disadvantages of the two surgical methods in the treatment of patients with filter-related thrombosis. Compared with catheter-directed thrombolysis, ART can attain similar thrombus clearance effects, improve the filter retrieval rate, reduce the dosage of thrombolytic drugs and lower the risk of bleeding. ART and CDT did not cause fatal symptomatic PE in these patients. Because CDT has a greater risk of bleeding, ART may be an alternative treatment for these patients. However, ART, CDT, MAT and conservative treatment with anticoagulants are effective treatments for patients with IVC thrombosis. Which method is more advantageous? Large-sample prospective trials are needed to further confirm the clinical outcome of these treatment modalities.

## ARTICLE HIGHLIGHTS

### Research background

Filter-related thrombosis is a complication of filter implantation. Early thrombus removal is implemented to restore the patency of the caval outflow. AngioJet rheolytic thrombectomy (ART) and catheter-directed thrombolysis (CDT) are endovascular treatment methods for filter-related caval

thrombosis, but the clinical outcomes of both treatment modalities have not been determined.

### Research motivation

We have performed both CDT and ART for filter-related thrombosis at our center. To date, there are few studies comparing the clinical outcomes of the two surgical methods, and the results are expected to be reported.

### Research objectives

The aim of this study is to compare the clinical outcomes of AngioJet rheolytic thrombectomy with those of catheter-directed thrombolysis in patients with filter-related caval thrombosis.

### Research methods

Sixty-five patients (34 males and 31 females; mean age:  $59.0 \pm 13.43$  years) with intrafilter and inferior vena cava thrombosis were enrolled between January 2021 and August 2022. Of these, patients were divided into the AngioJet group ( $n = 44$ ) and the CDT group ( $n = 21$ ). Clinical data and imaging information were collected. Evaluation measures included thrombus clearance rate, periprocedural complications, urokinase dosage, incidence of PE, limb circumference difference, length of stay, and filter removal rate.

### Research results

There was no significant difference in thrombus clearance between the two groups ( $P > 0.05$ ). The peridiameter difference of the thigh was significantly reduced in the patients of both groups after treatment ( $P < 0.05$ ). The median dosage of urokinase was significantly lower in the ART group (0.08 (0.02, 0.25) million U) than in the CDT group (1.50 (1.17, 1.83) million U) ( $P < 0.05$ ). Minor bleeding was shown in 4 (19.05%) patients in the CDT group, and when it was compared with that in the AngioJet group, the difference was statistically significant ( $P < 0.05$ ). There was no case of symptomatic PE after the procedure in either group. The mean length of stay was  $11.67 \pm 5.34$  d in the CDT group and  $10.64 \pm 3.52$  d in the AngioJet group ( $P < 0.05$ ). Cumulative removal was accomplished in 17 (80.95%) out of 21 patients in the CDT group and in 42 (95.45%) out of 44 patients in the AngioJet group ( $P > 0.05$ ).

### Research conclusions

Compared with catheter-directed thrombolysis, AngioJet rheolytic thrombectomy can achieve similar thrombus clearance effects, improve the filter retrieval rate, reduce the urokinase dosage and lower the risk of bleeding events in patients with filter-related caval thrombosis.

### Research perspectives

Further large, prospective clinical studies of the clinical outcomes of CDT and ART are needed.

## Abstract

## BACKGROUND

Propofol is a short-acting, rapid-recovering anesthetic widely used in sedated colonoscopy for the early detection, diagnosis and treatment of colon diseases. However, the use of propofol alone may require high doses to achieve the induction of anesthesia in sedated colonoscopy, which has been associated with anesthesia-related adverse events (AEs), including hypoxemia, sinus bradycardia, and hypotension. Therefore, propofol co-administrated with other anesthetics has been proposed to reduce the required dose of propofol, enhance the efficacy, and improve the satisfaction of patients receiving colonoscopy under sedation.

## AIM

To evaluate the efficacy and safety of propofol target-controlled infusion (TCI) in combination with butorphanol for sedation during colonoscopy.

## METHODS

In this controlled clinical trial, a total of 106 patients, who were scheduled for sedated colonoscopy, were prospectively recruited and assigned into three groups to receive different doses of butorphanol before propofol TCI: Low-dose butorphanol group (5 µg/kg, group B1), high-dose butorphanol group (10 µg/kg, group B2), and control group (normal saline, group C). Anesthesia was achieved by propofol TCI. The primary outcome was the median effective concentration (EC50) of propofol TCI, which was measured using the up-and-down sequential method. The secondary outcomes included AEs in perianesthesia and recovery characteristics.

## RESULTS

The EC<sub>50</sub> of propofol for TCI was 3.03 µg/mL [95% confidence interval (CI): 2.83-3.23 µg/mL] in group B2, 3.41 µg/mL (95% CI: 3.20-3.62 µg/mL) in group B1, and 4.05 µg/mL (95% CI: 3.78-4.34 µg/mL) in group C. The amount of propofol necessary for anesthesia was 132 mg [interquartile range (IQR), 125-144.75 mg] in group B2 and 142 mg (IQR, 135-154 mg) in group B1. Furthermore, the awakening concentration was 1.1 µg/mL (IQR, 0.9-1.2 µg/mL) in group B2 and 1.2 µg/mL (IQR, 1.025-1.5 µg/mL) in group B1. Notably, the propofol TCI plus butorphanol groups (groups B1 and B2) had a lower incidence of anesthesia AEs, when compared to group C. Furthermore, no significant differences were observed in the rates of AEs in perianesthesia, including hypoxemia, sinus bradycardia, hypotension, nausea and vomiting, and vertigo, among group C, group B1 and group B2.

## CONCLUSION

The combined use with butorphanol reduces the EC<sub>50</sub> of propofol TCI for anesthesia. The decrease in propofol might contribute to the reduced anesthesia-related AEs in patients undergoing sedated colonoscopy.

**Key Words:** Colonoscopy; Sedated colonoscopy; Propofol; Butorphanol; Target-controlled infusion; Effective concentration; Adverse event

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core Tip:** Propofol target-controlled infusion co-administrated with butorphanol significantly reduces the dose of propofol required for achieving anesthesia in patients undergoing sedated colonoscopy, leading to the enhancement of efficacy, and reduction in anesthesia-related adverse events when using propofol alone. Therefore, these findings may be beneficial for clinicians in inducing anesthesia, eventually improving the care and satisfaction of patients receiving diagnostic or therapeutic colonoscopic procedures for colorectal diseases.

## INTRODUCTION

Colonoscopy is an essential endoscopic tool for the screening, early diagnosis, and treatment of colorectal diseases, especially colorectal cancer, which is the second most common cause of cancer-related mortality worldwide[1,2]. It has been noted that conventional colonoscopy has a number of limitations, including high degree of patient discomfort during the colonoscopic procedure, prolonged insertion, and difficult or even failed cecal intubation[3,4]. In order to reduce patient discomfort and facilitate cecal intubation, colonoscopy with anesthesia or performed under sedation has gained increasing acceptance and popularity in recent years[4,5]. Indeed, patients under sedation during diagnostic or therapeutic endoscopic procedures generally experience minimal or even no discomfort[4,5]. Numerous studies have evaluated the efficacy and safety of anesthetics for sedation colonoscopy, such as propofol, which is a short-acting rapid-recovering anesthetic[6-12]. The results of previous studies suggest that propofol, particularly delivered by target-controlled infusion (TCI), which is a drug delivery technique applied to achieve the desired anesthetic drug concentration by using a pharmacokinetic model and considering the patient characteristics [*i.e.*, age, gender and body mass index (BMI)], is an effective anesthetic with rapid onset and short recovery[11,13-18]. Compared to conventional methods of administering drugs during anesthesia, such as bolus injection with a syringe and continuous infusion with an infusion pump, TCI provides a relatively constant concentration at the target site, and a more rapid recovery time.

Despite the mentioned advantages, various adverse events (AEs) can occur, including hypoxemia, sinus bradycardia, and hypotension[11,12]. These AEs have been associated with the required high dose of propofol for the induction of anesthesia, when used as the sole anesthetic during colonoscopic procedures[11,12]. Hence, propofol co-administrated with other anesthetics has been sought to reduce the dose of propofol required for anesthesia, enhance the efficacy, and improve the satisfaction of patients undergoing endoscopic procedures[19-24]. For instance, butorphanol, a synthetic opioid, has

higher affinity for opioid receptors, when compared to opioids. Compared to morphine, butorphanol has higher analgesic potency, a similar duration of action, and lower respiratory depression. Furthermore, butorphanol is a mixed opioid agonist/antagonist, which includes an agonistic action on the kappa-opioid receptor and agonistic/antagonistic effects on the mu-opioid receptor. This exerts an analgesic effect mainly by agonizing the kappa-opioid receptor. In addition, butorphanol can be used to mitigate the respiratory depression of mu-opioid agonists. The advantages of butorphanol include low toxicity and low potential for abuse. Previous studies have revealed that compared to other synthetic opioid analgesic drugs (*e.g.*, sufentanil), butorphanol has less anesthesia-related AEs, such as respiratory depression, decreased gastrointestinal activity and smooth muscle spasm, itchy skin, urinary retention, physical and physiological dependence, nausea, and vomiting[25,26]. Furthermore, butorphanol has been widely used in anesthesia for patients undergoing gastrointestinal endoscopy.

The present controlled clinical trial aimed to determine the effects of different doses of butorphanol on the efficacy of propofol TCI based on the median effective concentration (EC<sub>50</sub>) and safety, in terms of anesthesia-related AEs, in patients undergoing colonoscopic procedures under sedation. These results may be beneficial for clinicians in inducing anesthesia, eventually improving the care for patients receiving diagnostic or therapeutic colonoscopic procedures for colorectal diseases.

## MATERIALS AND METHODS

### *Patients and study design*

For the present controlled clinical trial, patients who underwent sedated colonoscopy were prospectively recruited from the First Affiliated Hospital of Dalian Medical University (Dalian, Liaoning Province, China) between December 2020 and March 2021. During the patient enrollment, the following inclusion criteria were used: (1) 18-65 years old; (2) Scheduled to undergo sedated colonoscopy; and (3) American Society of Anesthesiologists (ASA) I-II, graded according to the ASA Physical Status (PS) Classification System. Patients who presented with the following clinical conditions were excluded from the clinical trial: (1) Obstructive sleep apnea hypopnea syndrome; (2) Liver failure, kidney failure, or both; (3) Severe cardio/cerebrovascular diseases categorized as class III or higher, according to the New York Heart Association classification system; (4) Medical history of chronic pain or mental illness; (5) Regular intake of sedatives and painkillers; (6) Medical history of vertigo or motion sickness; (7) BMI of  $\geq 30$  kg/m<sup>2</sup>; (8) Pregnant patients; and (9) Patients who were unwilling to provide a written informed consent. The enrolled patients were assigned to three groups, based on the time sequence: (1) Group B1, received low-dose butorphanol (propofol TCI plus butorphanol, 5 µg/kg); (2) Group B2, received high-dose butorphanol (propofol TCI plus butorphanol, 10 µg/kg); and (3) Group C, the control group [normal saline (NS)]. The Propofol Medium and Long Chain Fat Emulsion Injection (Batch No. J20160089) was obtained from Beijing Fresenius Kabi Pharmaceutical Co. Ltd. (Beijing, China). The Butorphanol Tartrate Injection (Batch no. h20143106) was manufactured by Jiangsu Hengrui Pharmaceutical Co., Ltd. (Nanjing, Jiangsu, China).

The present study was reviewed and approved by the Ethics Committee of the First Affiliated Hospital of Dalian Medical University, with approval no: PJ-KS-KY-2020-144 (X). A written informed consent was obtained from each participant prior to the initiation of the clinical trial. The clinical trial was registered with the Chinese Clinical Trial Registry (ChiCTR 2000034849, 21/07/2020). The present study was conducted in accordance with the guidelines of the Declaration of Helsinki.

### *Anesthesia procedure*

The Propofol Medium and Long Chain Fat Emulsion Injection (Batch no. J20160089) was obtained from Beijing Fresenius Kabi Pharmaceutical Co. Ltd. (Beijing, China). The Butorphanol Tartrate Injection (Trade name: Nuoyang; 2 mL:4 mg; Batch no. h20143106) was manufactured by Jiangsu Hengrui Pharmaceutical Co., Ltd. (Nanjing, Jiangsu, China).

For the anesthesia, at 10 min before the colonoscopy, the patients intravenously received butorphanol at a dose of 5 µg/kg in group B1 and 10 µg/kg in group B2, and patients in group C received NS. Upon arrival in the examination room, an oxygen mask was placed on the patient at a flow rate of 5 L/min. Then, the patient's routine electrocardiogram, heart rate (HR), non-invasive blood pressure and pulse oximetry (SpO<sub>2</sub>) were monitored during the procedure. A computer-controlled TCI pump (Guangxi Weili Fangzhou Technology, Guangxi, China) was initiated. Then, propofol TCI was administered with an initial plasma target concentration of 3.0 µg/mL for the first case in each group. This was used as the first dose of propofol. When the target concentration of propofol was achieved, the colonoscopy was performed. The administration of propofol TCI was stopped when the colonoscope reached the ileocecal region, and colonoscopic withdrawal began.

### *Assessment of primary outcome*

The primary aim of the present study was to determine the EC<sub>50</sub> of propofol for TCI, which is necessary for half maximal effectiveness. The EC<sub>50</sub> of propofol for TCI in each group was measured using the up-and-down sequential method, which has a widely used sequential design for studies on the EC<sub>50</sub> of

anesthesia. The initial plasma target concentration designated for each group was 3.0 µg/mL. Purposeful movements (*e.g.*, the head or limbs) were defined as “responsive”, while no purposeful movements were defined as “non-responsive”. If “responsive” was found in a particular patient, the target plasma concentration of propofol was increased for the next patient by 0.5 µg/mL. In contrast, once “non-responsive” was identified in a particular patient, the target plasma concentration of propofol for the next patient was decreased by 0.5 µg/mL. The process was repeated until eight crossover points were attained. The number of patients needed for the present study could not be calculated beforehand. The target propofol concentration in plasma for consecutive patients in each group and the response to the procedures were determined and used to calculate the EC50 and 95% confidence interval (CI).

### Assessment of secondary outcomes

The secondary outcomes included the following measurements: (1) Amount of propofol used during the colonoscopic procedure; (2) Awakening concentration of propofol, which was referred to as the effect-site concentration of propofol in association with eye opening in response to verbal command; (3) Anesthesia-related AEs in perianesthesia, including hypoxemia, sinus bradycardia, hypotension, nausea and vomiting, and vertigo; and (4) Mean arterial pressure (MAP) and HR at different time points, including prior to anesthesia (T0), immediately after consciousness disappeared in response to the induction of anesthesia (T1), when the colonoscope reached the ileocecal region (T2), and when consciousness was regained (T3).

### Statistical analysis

Statistical analysis was performed using the GraphPad Prism software (San Diego, CA, United States). Quantitative data were expressed as mean ± SD, or median and interquartile range (IQR), as appropriate. Analysis of variance or Kruskal-Wallis test, and post-hoc test with Bonferroni adjustment were performed to compare quantitative data. The numerical data were analyzed by  $\chi^2$  test, while K-test was used to compare the EC50 values of propofol for TCI among the three groups (group C, group B1 and group B2). The logarithm for each target concentration ( $\log x$ ), total number of cases ( $n$ ), effective rate ( $P$ ), and difference between the logarithm of two adjacent target concentrations ( $d$ ) were calculated, as follows: (1) Logarithm of EC50:  $\log EC50 = \sum n \log X / \sum n$ ; (2) Standard error of  $\log EC50$ :  $Slog EC50 = d$

$\sqrt{\sum \frac{p(1-p)}{(n-1)}}$ ; and (3) Logarithm of 95%CI of EC50: ( $\log EC50 - 1.96 \times Slog EC50$ ,  $\log EC50 + 1.96 \times Slog EC50$ ). EC50 and 95%CI were the negative logarithms. A  $P$  value of  $< 0.05$  was considered statistically significant between groups.

## RESULTS

### Demographic and clinical characteristics of patients

A total of 106 patients who underwent sedated colonoscopy were enrolled for the present clinical study. The baseline demographic and clinical characteristics of patients in group C ( $n = 38$ ), group B1 ( $n = 36$ ), and group B2 ( $n = 32$ ) are summarized in Table 1. The mean age of patients was 55.9 years old (SD = 4.3 years old) in group C, 56.9 years old (SD = 4.2 years old) in group B1, and 56.6 years old (SD = 4.8 years old) in group B2. There were no significant differences in baseline demographic characteristics among the groups (all,  $P > 0.05$ ). The mean BMI was 21.8 kg/m<sup>2</sup> (SD = 1.4 kg/m<sup>2</sup>) for patients in group C, 21.3 kg/m<sup>2</sup> (SD = 1.4 kg/m<sup>2</sup>) for patients in group B1, and 21.2 kg/m<sup>2</sup> (SD = 1.3 kg/m<sup>2</sup>) for patients in group B2. No significant difference was observed among the groups (all,  $P > 0.05$ ). In addition, there was no significant difference in the proportion of patients with ASA I or II, based on the ASA PS Classification System and the operation time among groups (all,  $P > 0.05$ ).

### Comparison of primary outcomes

For the EC50 for propofol in TCI, the concentrations needed to achieve half maximal effectiveness were compared among the groups. The target propofol concentrations in the plasma of patients for the calculation of the EC50 are presented in Figure 1. As shown in Table 2, the EC50 for propofol in TCI was 4.05 µg/mL (95%CI: 3.78-4.34 µg/mL) in group C, 3.41 µg/mL (95%CI: 3.20-3.62 µg/mL) in group B1, and 3.03 µg/mL (95%CI: 2.83-3.23 µg/mL) in group B2. The statistical analysis revealed that the EC50 in group B2 was significantly lower, when compared to the EC50 in group B1 and group C ( $P < 0.05$ , Table 2). Furthermore, the amount of propofol necessary for anesthesia was determined as 132 mg (IQR, 125-144.75 mg) in group B2, which was significantly lower, when compared to the amount in group B1 (142 mg; IQR, 135-154 mg) ( $P < 0.05$ , Table 2, Figure 2). These results suggest that the intravenous infusion of 10 µg/kg of butorphanol reduced the need for high-dose propofol for anesthesia, when compared to 5 µg/kg of butorphanol. In addition, the awakening concentration of propofol was 1.1 µg/mL (IQR, 0.9-1.2 µg/mL) in group B2. This concentration was lower than that in group B1 (1.2 µg/mL;

**Table 1** Demographic and clinical characteristics of patients in the different groups

Groups	n	Age (yr)	Gender (M/F)	BMI (kg/m <sup>2</sup> )	ASA (I/II)	Operation time (min)
Group C	38	55.9 ± 4.3	18/20	21.8 ± 1.4	26/12	12 (10-14)
Group B1	36	56.9 ± 4.2	17/19	21.3 ± 1.4	24/12	11 (10-12)
Group B2	32	56.6 ± 4.8	15/17	21.2 ± 1.3	21/11	11 (10-12)

**Figure 1** Target propofol concentrations in plasma for consecutive patients of each group and the response to the procedures. A: Target propofol concentrations in plasma for consecutive patients in the control group (group C); B: Target propofol concentrations in plasma for consecutive patients in group B1; C: Target propofol concentrations in plasma for consecutive patients in group B2. The target propofol concentrations in plasma for consecutive patients in each group and the response to the procedures were used to calculate the median effective concentration (EC50), which is the concentration required to achieve the half maximal effectiveness of propofol. The resulting EC50 for each group and 95% confidence intervals are presented in Table 2.

IQR, 1.025-1.500 µg/mL ( $P < 0.05$ , Figure 2).

### Comparison of secondary outcomes

MAP and HR were compared at different time points (T0, T1, T2 and T3) during the procedure among the groups. As shown in Figure 3 and Table 3, the MAP values at time points T1 and T2 were significantly lower in group C, when compared to groups B1 and B2 ( $P < 0.05$ ). In addition, the HR value at time point T1 was significantly lower in group C, when compared to groups B1 and B2 ( $P < 0.05$ ).

**Table 2 Comparison of median effective concentration, dose for anesthesia, and awakening concentration of propofol among the different groups**

Groups	n	EC <sub>50</sub> (μg/mL)	95%CI (μg/mL)	Amount of propofol necessary for anesthesia (mg)	Awakening concentration of propofol (μg/mL)
Group C	38	4.05	3.78-4.34	151.0 (142.0-160.5)	1.200 (0.975-1.300)
Group B1	36	3.41 <sup>1</sup>	3.20-3.62	142 (135-154) <sup>1,3</sup>	1.200 (1.025-1.500) <sup>3</sup>
Group B2	32	3.03 <sup>1,2</sup>	2.83-3.23	132.00 (125.00-144.75) <sup>1,2</sup>	1.1 (0.9-1.2) <sup>2</sup>

Awakening concentration of propofol was defined as the effect-site concentration of propofol in association with eye opening in response to verbal command. CI: Confidence interval; EC50: Effective concentration

**Figure 2 Bar graphs for the amount of propofol used during the sedated colonoscopy and the awakening concentration of propofol in each group.** A: The amount of propofol used during the sedated colonoscopy in each group; B: The awakening concentration of propofol in each group. The amount of propofol used for the sedated colonoscopic procedure and the awakening concentration of propofol in group C, group B1 and group B2 are illustrated in the bar graphs. The lowest mean amount of propofol used for sedated colonoscopic procedures was observed in group B2, and there was a significant difference among the groups. The waking concentration of propofol was defined as the effect-site concentration of propofol in association with eye opening in response to verbal command. The mean awakening concentration of propofol was lower in group B2, when compared to group B1.

0.05).

Next, a comparison of AEs (*e.g.*, hypoxemia, sinus bradycardia, hypotension, nausea and vomiting, and vertigo) in perianesthesia was performed among the groups, and the resulting data are summarized in Table 4. Overall, the incidence of each AE did not significantly differ among the groups (all, *P* > 0.05). Notably, the incidence of hypoxemia was higher in group C (13.2%), when compared to group B1 (5.6%) and group B2 (9.4%). In addition, one patient (2.6%) had hypotension in group C, while none of the patients had hypotension in groups B1 and B2. The reduction in anesthesia AEs, especially hypoxemia and hypotension, in groups B1 and B2 could have been attributed to the decrease in propofol required for anesthesia, when used in combination with butorphanol, during the colonoscopic procedure.

**Table 3 Comparison of mean arterial pressure and heart rate among the different groups**

	Groups	T0	T1	T2	T3
MAP (mmHg)	Group C	90.4 ± 6.1	73.4 ± 6.1 <sup>1</sup>	77.0 ± 5.8 <sup>1</sup>	88.6 ± 5.4
	Group B1	89.4 ± 5.4	81.7 ± 4.1	85.3 ± 4.0	88.3 ± 3.8
	Group B2	89.5 ± 5.1	78.3 ± 5.0 <sup>2</sup>	82.4 ± 4.2 <sup>2</sup>	88.5 ± 4.1
HR (bpm)	Group C	81.8 ± 8.8	68.8 ± 7.2 <sup>1</sup>	72.1 ± 6.9	79.9 ± 6.0
	Group B1	80.3 ± 9.0	73.2 ± 8.5	74.9 ± 8.0	78.3 ± 6.2
	Group B2	81.9 ± 9.3	74.7 ± 9.8	76.2 ± 8.2	80.1 ± 6.1

<sup>1</sup>*P* < 0.05 *vs* groups B1 and B2.<sup>2</sup>*P* < 0.05 *vs* group B1.

T0, prior to anesthesia; T1, immediately after losing consciousness in response to induction of anesthesia; T2, the colonoscope reached the ileocecal; T3, consciousness regained. MAP: Mean arterial pressure; HR: Heart rate; bpm: Beats per minute.

**Table 4 Comparison of frequency of adverse events in perianesthesia among the different groups**

Groups	<i>n</i>	Hypoxemia	Sinus bradycardia	Hypotension	Nausea, vomiting	Vertigo
Group C	38	5 (13.2%)	1 (2.6%)	1 (2.6%)	2 (5.3%)	4 (10.5%)
Group B1	36	2 (5.6%)	0 (0%)	0 (0%)	1 (2.8%)	3 (8.3%)
Group B2	32	3 (9.4%)	2 (6.3%)	0 (0%)	2 (6.3%)	3 (9.4%)

**Figure 3** The mean arterial pressure and heart rate at different time points during the procedures in each group are shown. A: The mean arterial pressure at different time points during the procedures in each group; B: The heart rate at different time points during the procedures in each group. The mean arterial pressure (MAP) and heart rate (HR) were examined at the following four time points: prior to anesthesia (T0), immediately after consciousness disappeared in response to induction of anesthesia (T1), when the colonoscope reached the ileocecal region (T2), and when consciousness was regained (T3). The MAP represents the average arterial pressure throughout one cardiac cycle, with a normal range of 70–110 mmHg. The MAP values at time points T1 and T2 were significantly lower in group C, when compared to groups B1 and B2 (*P* < 0.05). The HR value at time point of T1 was significantly lower in group C, when compared to groups B1 and B2 (*P* < 0.05).

## DISCUSSION

The efficacy and safety of propofol TCI co-administrated with different doses of butorphanol have not yet been evaluated for sedated colonoscopy in the Chinese population. To the best of our knowledge, the present study is the first controlled clinical trial that investigated the effects of different doses of butorphanol on the efficacy and safety of propofol TCI for sedated colonoscopy in Chinese patients. The main novel findings are summarized, as follows. Butorphanol co-administrated with propofol for TCI can significantly improve the efficacy of propofol TCI, as supported by the following evidence: (1) Patients with anesthesia induced by propofol TCI plus high-dose butorphanol had a significantly lower EC50 of propofol for TCI *vs* patients induced by propofol TCI plus low-dose butorphanol and controls (all, *P* < 0.05); and (2) The amount of propofol needed for anesthesia was significantly lower in group B2 *vs* group B1. In addition, the rates for anesthesia-related AEs, including hypoxemia, sinus bradycardia, hypotension, nausea and vomiting, and vertigo, were similar in group C, group B1 and group B2. It is noteworthy that patients in group C had a higher incidence of hypoxemia and hypotension, when

compared to the other two groups. Furthermore, there is a possibility that the lower incidence of anesthesia AEs (hypoxemia and hypotension) is associated with the reduced amount of propofol due to the co-administration of butorphanol with propofol.

The primary aim of the present clinical trial was to determine the effects of the co-administration of butorphanol on the required dose of TCI propofol to achieve sedation during colonoscopic procedures. The TCI system can be programmed using either of the two main pharmacokinetic models: The Marsh model and Schnider model[13,14]. The Marsh model has weight as a model parameter, while the Schnider model has multiple parameters (*e.g.*, age, weight, height, and lean body mass). Chen *et al*[27] examined the performance of the Marsh model and Schnider model for TCI propofol, and suggested that the Marsh model was overall superior to the Schnider model, and more suitable for TCI propofol [27]. Therefore, in the present study, the Marsh model was selected as the pharmacokinetic model to program the TCI system for propofol. It was found that the duration of action and recovery time of propofol were significantly shorter for the TCI of propofol, when compared to the conventional infusion of propofol[11,14,17,18,28]. In addition, the co-administration of propofol with other anesthetics has been shown to reduce the required dose of propofol for targeted anesthesia, and improve patient satisfaction during diagnostic and therapeutic endoscopy[11,19-24,29]. Considering the various advantages of butorphanol, which are mainly associated with less anesthesia-related AEs (*e.g.*, respiratory depression, smooth muscle spasm, skin itches, urinary retention, physical and physiological dependence, nausea and vomiting)[25,26], the co-administration of butorphanol with propofol was examined in the present study. The up-and-down sequential method was used to determine the EC<sub>50</sub>, which is a commonly used measurement to evaluate the potency of a drug. The results revealed a significant reduction in the required propofol dose, when used in combination with both low-dose (5 µg/kg) and high-dose (10 µg/kg) butorphanol. Given that different anesthetics have various interactions, further studies are needed to determine the optimal combination of different anesthetics, such as propofol and butorphanol, and ensure the effectiveness and safety.

Despite these promising findings, the present study has several limitations. First, the baseline psychological state was not evaluated in the enrolled patients. Considering that preoperative anxiety has been shown to affect the dose of propofol required to achieve anesthesia induction, patients presenting with anxiety may need a higher dose of propofol. Second, the depth of sedation during the colonoscopic procedure was not monitored. Third, although the present study revealed that the butorphanol co-administration with propofol for TCI improved the efficacy without increasing the incidence of anesthesia-related complications, the level of patient satisfaction was not examined. Although propofol and butorphanol exhibited "synergic effects", the interaction between these two anesthetics should be further assessed, in order to ensure the potency and safety of this anesthesia for patients. Future studies with a larger sample size are presently being performed in our center to gain more insight into the combination of propofol TCI and butorphanol for sedation during colonoscopy.

## CONCLUSION

Overall, the present clinical study revealed that butorphanol co-administrated with propofol TCI can reduce the EC<sub>50</sub> of propofol for anesthesia without causing additional anesthesia-related complications in patients undergoing sedated colonoscopy. These findings may assist clinicians in performing anesthesia induction for colonoscopy, eventually helping to improve the care for patients who must receive colonoscopic procedures for colorectal diseases.

## ARTICLE HIGHLIGHTS

### Research background

Propofol, known as an effective anesthetic with rapid onset and short recovery, has been used in sedated colonoscopy. However, when used alone, high-dose propofol is usually needed for anesthesia, and this may cause anesthesia-related adverse events (AEs).

### Research motivation

This clinical study was intended to reduce the required dose of propofol by co-administration with butorphanol in patients receiving colonoscopy under sedation.

### Research objectives

The objective of this clinical trial was to assess the efficacy and safety of propofol target-controlled infusion (TCI) in combination with butorphanol for sedation during colonoscopy.

### Research methods

One hundred six patients were assigned into three groups to receive different doses of butorphanol before propofol TCI: Low-dose butorphanol group (B1), high-dose butorphanol group (B2), and control group (C). The primary outcome included the median effective concentration (EC50) of propofol TCI, and the secondary outcomes were AEs in perianesthesia and recovery characteristics.

### Research results

The EC50 of propofol for TCI was 3.03 µg/mL in group B2, 3.41 µg/ in group B1, and 4.05 µg/mL in group C. The amount of propofol necessary for anesthesia was 132 mg in group B2, lower than 142 mg in group B1. Notably, the propofol TCI plus butorphanol groups (groups B1 and B2) had a lower incidence of anesthesia AEs, when compared to group C. Moreover, there were no significant differences among the three groups in the rates of AEs in perianesthesia, including hypoxemia, sinus bradycardia, hypotension, nausea and vomiting, and vertigo.

### Research conclusions

This study has shown that propofol in combination with butorphanol reduces the EC50 of propofol TCI for anesthesia in patients undergoing sedated colonoscopy, and in turn may decrease anesthesia-related AEs in patients undergoing sedated colonoscopy.

### Research perspectives

Propofol in combination with butorphanol may improve care for patients undergoing colonoscopic procedures for colorectal diseases.

## Abstract

### BACKGROUND

Rehabilitation nursing is considered an indispensable part of the cerebral infarction treatment system. The hospital–community–family trinity rehabilitation nursing model can provide continuous nursing services across hospitals, communities, and families for patients.

### AIM

To explore the application of a hospital–community–family rehabilitation nursing model combined with motor imagery therapy in patients with cerebral infarction.

### METHODS

From January 2021 to December 2021, 88 patients with cerebral infarction were divided into a study ( $n = 44$ ) and a control ( $n = 44$ ) group using a simple random number table. The control group received routine nursing and motor imagery therapy. The study group was given hospital–community–family trinity rehabilitation nursing based on the control group. Motor function (FMA), balance ability (BBS), activities of daily living (BI), quality of life (SS-QOL), activation status of the contralateral primary sensorimotor cortical area to the affected side, and nursing satisfaction were evaluated before and after intervention in both groups.

### RESULTS

Before intervention, FMA and BBS were similar ( $P > 0.05$ ). After 6 months' intervention, FMA and BBS were significantly higher in the study than in the control group (both  $P < 0.05$ ). Before intervention, BI and SS-QOL scores were not different between the study and control group ( $P > 0.05$ ). However, after 6 months' intervention, BI and SS-QOL were higher in the study than in the control group ( $P < 0.05$ ). Before intervention, activation frequency and volume were similar between the study and the control group ( $P > 0.05$ ). After 6 months'

intervention, the activation frequency and volume were higher in the study than in the control group ( $P < 0.05$ ). The reliability, empathy, reactivity, assurance, and tangibles scores for quality of nursing service were higher in the study than in the control group ( $P < 0.05$ ).

## CONCLUSION

Combining a hospital–community–family trinity rehabilitation nursing model and motor imagery therapy enhances the motor function and balance ability of patients with cerebral infarction, improving their quality of life.

**Key Words:** Activities of daily living; Cerebral infarction; Hospital–community–family trinity rehabilitation nursing model; Motor skills; Motor imagery therapy; Postural balance

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core Tip:** Various clinical treatments are used for cerebral infarction patients, including motor imagery therapy and rehabilitation nursing. We evaluated a combination of the hospital–community–family trinity rehabilitation nursing model and motor imagery therapy in terms of balance ability, motor ability, and quality of life of cerebral infarction patients. Combined treatment enhanced patients' motor function and balance ability, with concomitant changes in the relevant sensorimotor cortical area brain area. This improved their abilities to conduct activities of daily life as well as in their quality of life, and also resulted in a higher degree of nursing satisfaction.

## INTRODUCTION

Cerebral infarction is a common clinical cerebrovascular disease, accounting for approximately 70% of stroke cases. Cerebral infarction can lead to pyramidal tract damage, causing central paralysis and sensorimotor dysfunction in the human body, which is manifested as decreased muscle strength and motor limitations in a particular limb[1-3].

At present, various clinical treatment methods are used to treat patients with cerebral infarction, including conventional drug therapy, acupuncture, rehabilitation therapy, and motor imagery therapy, and each has therapeutic effects with particular advantages[4-6]. Motor imagery therapy is an intervention administered under the guidance of professionals, in which the patient's own imagination is combined with tactile, auditory, visual, and other associative stimuli to promote motor function improvement in patients with cerebral infarction[7].

In recent years, rehabilitation treatment of patients with cerebral infarction has gradually attracted widespread clinical attention. The importance of rehabilitation nursing has also been reflected. Rehabilitation nursing is considered an indispensable part of cerebral infarction treatment. It is particularly important to select a scientific and reasonable rehabilitation nursing model[8,9]. The hospital–community–family trinity rehabilitation nursing model provides continuous nursing services across hospitals, communities, and families for patients by the cooperation of hospitals and community medical staff, which helps improve the quality of care and promote the rehabilitation of patients[10].

In this study, we explored the application value of a combination of the hospital–community–family trinity rehabilitation nursing model and motor imagery therapy in patients with cerebral infarction, in terms of its effects on balance ability, motor ability, and quality of life of these patients.

## MATERIALS AND METHODS

### General data

Eighty-eight patients with cerebral infarction who attended our hospital from January 2021 to December 2021 were selected and allocated to a study group and a control group, according to a simple random number table, with 44 cases in each group.

The control group consisted of 21 men and 23 women, aged 39–71 years, with an average age of  $55.82 \pm 6.15$  years. Their body weight ranged from 48 to 79 kg, with an average of  $63.79 \pm 7.02$  kg. In terms of paralysis, 20 cases were affected on the left side and 24 cases on the right side. Ten cases had an education of college degree or above, 23 cases had been educated to junior high school, and 11 cases had an education level of elementary school or below.

The study group consisted of 19 men and 25 women, aged 38–73 years, with an average age of  $56.37 \pm 5.84$  years. Their body weight ranged from 47 to 80 kg, with an average of  $64.12 \pm 6.80$  kg. Twenty-two cases were paralyzed on the left side and 22 cases on the right side. Nine cases had an education of college degree or above, 25 cases had an education up to junior high school, and 10 cases had an education of elementary school or below. Thus, sex, age, site of paralysis, and education level were balanced and comparable between the two groups ( $P > 0.05$ ).

### Selection criteria

Patients were included if cerebral infarction was diagnosed by clinical symptoms, brain computed tomography, magnetic resonance imaging, or other imaging examinations; if they had clear consciousness; if they provided informed consent for participation in this study and signed the consent form; and if they had hemiplegic dysfunction. The exclusion criteria were the presence of mental disorders; abnormal coagulation mechanisms; malignant hypertension; malignant tumors; respiratory failure; cognitive dysfunction; severe infection; and limb dysfunction before the occurrence of cerebral infarction.

### Treatments

Both groups continued their interventions for 6 mo.

**Control group intervention:** The control group was given routine nursing and motor imagery therapy. During the treatment, these patients were assisted to perform turning back and patting. They were given cerebral infarction health education, oral care, dietary intervention, daily exercise, and other routine nursing. Combined with the daily exercise content, the patients were verbally guided to imagine a gait using a fixed step, independent step, and lateral step. Dance videos could be played for square dance enthusiasts to guide them in imagining the dance movements and postural changes and feel the comfort of free exercise. Patients were guided to use their imagination through watching videos of walking on the beach, imagining themselves on the beach by touching and listening, walking on the beach, and feeling the comfort of free walking.

**Study group intervention:** The study group was given hospital–community–family trinity rehabilitation nursing based on the control group. The trinity rehabilitation nursing model included rehabilitation physicians, specialist nurses, community nurses, head nurses, and others. Unified trinity rehabilitation nursing theory training included education on the purpose, significance, and steps of its implementation. We developed a cerebral infarction health education manual, which was composed of the basic knowledge on cerebral infarction, preventive measures, rehabilitation training, home care, basic information on hospital–community–family-related responsible persons (telephone, WeChat), and other contents.

During hospitalization, a self-made cerebral infarction health education manual was distributed to explain the relevant information on cerebral infarction in plain language, emphasize the importance of rehabilitation training, and enhance patients' attention. We conducted one-on-one rehabilitation training, ensuring that rehabilitation training movements were standard and specific. We also played the rehabilitation training-related videos recorded by team members after completion of their training, conducted consolidation exercises, introduced the rehabilitation training effect, and enhance the confidence of patients' rehabilitation exercises. Before discharge, specialist nurses and rehabilitation physicians developed a continuous rehabilitation plan for patients, effectively communicated with the community nurses at discharge, and elaborated the rehabilitation status of patients during hospitalization and the rehabilitation plan after discharge. Community nurses could modify the rehabilitation training plan in real time according to individual circumstances during the rehabilitation training of patients.

Community outpatient sites were constructed. Community nurses were responsible for providing rehabilitation training guidance to patients and, at the same time, visit the patients once a week for follow-up. The follow-up time was controlled at approximately 30 min each time. The psychological status and rehabilitation status of patients were evaluated, and those with negative emotions were guided. Those with non-standard rehabilitation training movements were also corrected, and patients' families were urged to complete the rehabilitation training plan on time. Patients' families were invited to participate in the rehabilitation nursing process. If the implementation of patients' daily rehabilitation exercise plan was recorded, patients were urged to perform rehabilitation exercises actively every day. Rehabilitation exercise videos were distributed. Patients and their families were encouraged to watch these videos repeatedly. Those with non-standard rehabilitation exercise movements were helped to improve performance of their exercises under the guidance of family members and community nurses. Community activities such as patient exchange meetings and expert lectures on cerebral infarction

rehabilitation exercises were conducted once a month, and patients and their families were invited to participate.

### **Outcome measures**

Motor function was evaluated using the Fugl-Meyer Assessment (FMA), while balance ability was assessed using the Berg Balance Scale (BBS). The FMA scale includes 33 upper limb movements and 17 Lower limb movements, with a total score of 0–100 points. Lower scores indicated more severe dyskinesia. The BBS includes 14 items, with a score of 0–4 points for each item and a total score of 0–56 points, where higher scores indicate a stronger balance ability. These scores were compared between the two groups before and after 6 mo of intervention.

Additionally, we compared the activities of daily living using the Barthel Index (BI) as well as the quality of life using the Stroke-Specific Quality of Life scale (SS-QOL) before and after 6 mo of intervention between the two groups. The BI includes 10 items, including dressing, walking on a flat surface, toileting, bathing, and eating. Each item had a score range of 0–10 points and a total score of 0–100 points, with higher scores indicating better ability to conduct activities of daily living. The SS-QOL had a score range of 0–100 points, with higher scores indicating better quality of life.

We compared the activation status of the primary sensorimotor cortical area (SMC) contralateral to the affected side before and after 6 mo of intervention between the two groups. This included assessment of activation frequency and activation volume, in which the activation volume unit is k.

We also compared the satisfaction with nursing between the two groups. The Quality of Service (SERVQUAL) scale was used to assess patients' satisfaction with nursing, including five items: reliability, empathy, responsiveness, assurance, and tangibles. Each item was scored in a range of 1–5 points, with lower scores indicating worse satisfaction with nursing.

### **Statistical analysis**

SPSS v22.0 software (IBM Corp., Armonk, NY, USA) was used to analyze the data. Measurement data were expressed as mean  $\pm$  SD, *t* test and enumeration data as *n* (%). Data were compared using the  $\chi^2$  test. *P* < 0.05 indicated statistically significant differences.

## **RESULTS**

### **Changes in motor function and balance ability**

Before intervention, the FMA and BBS scores in the study group were not significantly different from those in the control group (both *P* > 0.05, Table 1). After 6 mo of intervention, the FMA and BBS scores in the study group were higher than those in the control group (both *P* < 0.05), as shown in Table 1.

### **Changes in activities of daily life and quality of life**

The BI and SS-QOL were not significantly different between the study and control groups before intervention (both *P* > 0.05, Table 2). After 6 mo of intervention, the BI and SS-QOL in the study group were higher than those in the control group (both *P* < 0.05, Table 2).

### **SMC activation state**

Prior to the intervention, no significant difference was observed in activation frequency or activation volume between the study and control groups (*P* > 0.05, Table 3). After 6 mo of intervention, the activation frequency and activation volume in the study group were higher than those in the control group (*P* < 0.05, Table 3).

### **Nursing satisfaction**

In the study group, the SERVQUAL scores for the reliability of nursing, empathy, reactivity, assurance, and tangibles were significantly higher than those of the control group (all *P* < 0.05), as shown in Table 4.

## **DISCUSSION**

In this study, we showed that combining a hospital–community–family trinity rehabilitation nursing model and motor imagery therapy enhanced the motor function and balance ability of patients with cerebral infarction, with concomitant changes in the relevant SMC area. This led to improvement in their abilities to conduct activities of daily life as well as in their quality of life and resulted in a higher degree of nursing satisfaction.

Cerebral infarction has a high mortality and disability rate. It can cause neurological deficits after onset, which result in motor, language, and other dysfunctions, to different degrees, which markedly impacts the daily activities and quality of life of patients[11,12]. Promoting the rehabilitation of patients

with cerebral infarction has become a crucial topic among clinicians and researchers worldwide. Patients and their families anticipate a scientific and practical rehabilitation nursing model that can reduce the disability rate of stroke and improve the self-care ability of these patients[13–15].

Previous studies have shown that motor imagery therapy can enhance compensatory function at the site of brain injury, activate the central nervous system in specific regions, increase blood flow in functional areas of the brain, promote neurotransmitter release, and reduce limb motor dysfunction[16, 17]. With the development of rehabilitation medicine, rehabilitation nursing has emerged as a discipline

that combines modern rehabilitation concepts with early nursing to promote the maximum functional recovery of patients[18]. The hospital–community–family trinity rehabilitation nursing model provides continuous and comprehensive nursing services for patients, which can significantly eliminate adverse factors of rehabilitation and improve the quality of nursing care[19,20]. In this study, we endeavored to apply the hospital–community–family trinity rehabilitation nursing model in combination with motor imagery therapy in patients with cerebral infarction. After 6 mo of intervention, the FMA and BBS scores in the study group were significantly higher than those in the control group ( $P < 0.05$ ), indicating that the above nursing model could improve the motor function and balance ability of patients with cerebral infarction. This may be because the hospital–community–family trinity rehabilitation nursing model not only imparts cerebral infarction knowledge and functional exercise training to patients during hospitalization but also handles patients *via* community nurses after their discharge from the hospital. Patients' families are invited to participate in the rehabilitation nursing process. Patients receive continuous rehabilitation nursing guidance and supervision, which can improve their motor function and balance ability and promote their rehabilitation.

Moreover, after 6 mo of intervention, the activation frequency and activation volume in the study group were higher than those in the control group ( $P < 0.05$ ), suggesting that the use of a combination of the hospital–community–family trinity rehabilitation nursing model and motor imagery therapy in patients with cerebral infarction enhances the patients' rehabilitation. In this study, repeated drills of motor scenarios in the brain by means of motor imagery therapy could induce the brain to control the trunk muscle groups on the affected side, activate dormant synapses, and enhance compensation for the brain injury site.

Consequently, combined application of hospital–community–family trinity rehabilitation nursing model and motor imagery therapy helped patients obtain continuous and complete professional guidance and care after discharge, correct inaccurate rehabilitation exercise behavior, improve the effect of rehabilitation exercise, and promote the rehabilitation of patients.

After 6 mo of intervention, the BI and SS-QOL scores in the study group were higher than those in the control group ( $P < 0.05$ ), which showed that the application of this combined rehabilitation and therapy in patients with cerebral infarction could significantly improve the ability to conduct activities of daily as well as the quality of life of patients. In addition, we compared the nursing satisfaction of the two groups and found that the reliability, empathy, reactivity, assurance, and tangible scores of the study group were higher than those of the control group ( $P < 0.05$ ). This suggests that the hospital–community–family trinity rehabilitation nursing model combined with motor imagery therapy is suitable for clinical application in patients with cerebral infarction.

The study was limited by the short observation time. Thus, the effect of the above intervention program on the long-term prognosis of patients with cerebral infarction needs to be explored further and confirmed by prolonging the follow-up time.

## CONCLUSION

In summary, the application of a combination of the hospital–community–family trinity rehabilitation nursing model with motor imagery therapy in patients with cerebral infarction can improve the motor function and balance ability of patients, cause corresponding changes in the SMC area on the affected side, improving their abilities to conduct the activities of daily life and quality of life of patients, and resulting in a high degree of patient satisfaction with nursing care. In addition, based on the hospital–community–family trinity rehabilitation nursing model, nursing staff are required to ensure close linkage between hospitals, communities, and patients' families and provide continuous and complete professional care to patients.

## ARTICLE HIGHLIGHTS

### Research background

Cerebral infarction is a common clinical cerebrovascular disease.

### Research motivation

Rehabilitation treatment of patients with cerebral infarction has gradually attracted widespread clinical attention.

### Research objectives

This study aimed to explore the application value of a combination of the hospital–community–family trinity rehabilitation nursing model and motor imagery therapy in patients with cerebral infarction.

**Research methods**

Eighty-eight patients with cerebral infarction who attended our hospital.

**Research results**

After 6 mo' intervention, the activation frequency and volume were higher in the study than in the control group.

**Research conclusions**

Combining a hospital–community–family trinity rehabilitation nursing model and motor imagery therapy enhances the motor function and balance ability of patients with cerebral infarction, improving their quality of life.

**Research perspectives**

The effect of the above intervention program on the long-term prognosis of patients with cerebral infarction needs to be explored further and confirmed by prolonging the follow-up time.

### Abstract

#### BACKGROUND

Congenital biliary atresia (CBA) is a serious hepatobiliary disease in children with unknown etiology. Its outcome is often liver transplantation or death. Clarifying the etiology of CBA is of great significance for prognosis, treatment, and genetic counseling.

#### CASE SUMMARY

A male Chinese infant at an age of 6 mo and 24 d was hospitalized because of "yellow skin for more than 6 mo". Soon after birth, the patient developed jaundice, which then progressively intensified. A "laparoscopic exploration" indicated "biliary atresia". After coming to our hospital, genetic testing suggested a *GPC1* mutation [loss 1 (exons 6-7)]. The patient recovered and was discharged after living donor liver transplantation. After discharge, the patient was followed up. The condition was controlled by oral drugs, and the patient's condition was stable.

#### CONCLUSION

CBA is a complex disease with a complex etiology. Clarifying the etiology is of great clinical importance for treatment and prognosis. This case reports CBA caused by a *GPC1* mutation, which enriches the genetic etiology of biliary atresia. However, its specific mechanism needs to be confirmed by further research.

**Key Words:** Congenital biliary atresia; Jaundice; Etiology; *GPC1*; Liver transplantation; Case report

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Congenital biliary atresia (CBA) often results in a poor prognosis. Most patients need liver transplantation as the final treatment. If the opportunity for liver transplantation is missed, death often occurs. However, the etiology of CBA is still unclear. Clarifying the etiology is of great significance for prognosis, treatment, and genetic counseling. Through the report of a patient with a *GPC1* mutation, this paper enriches the genetic etiology of CBA and provides a new basis for clinical and scientific research.

## INTRODUCTION

Congenital biliary atresia (CBA) is a congenital disease that occurs in infants and young children. Due to the atresia of intrahepatic and extrahepatic bile ducts, the discharge of conjugated bilirubin into the intestine is blocked. This causes inflammation of intrahepatic and extrahepatic bile ducts, resulting in cholestatic cirrhosis. This condition is usually called CBA. The incidence rate of this disease is different in different countries and regions. The incidence rate in Europe is 1/15000-1/19000, and the incidence rate in Japan is 1/9000-1/10000[1]. However, the cause of CBA is not clear. At present, there are many hypotheses, including viral infection (cytomegalovirus, reovirus, rotavirus, human papillomavirus, retrovirus, etc.), immune and/or autoimmune injury[2,3], gene-related factors (inversion and *MDR3*[2], *EFEMP1*[4]), abnormal bile duct development, microchimerism, cytokines, miRNA gene expression abnormalities, and biliary malformation[5,6]. In addition, its incidence rate also differs by race, geography, season, and other factors[7]. The main clinical manifestations include the following: (1) Jaundice, which is usually gradually exposed 2-3 wk after birth; and (2) the color of stool becomes lighter, and white pottery-like stool and, is very common in the clinical findings (also it can be just: acholia). The surgical management is the actual approach and it is a by hilar jejunal Roux-Y anastomosis (Kasai operation) within 3 mo after birth. However, the 5-year survival rate of this treatment is low, at approximately 30%-50%[8,9]. Liver transplantation is proposed when the Kasai operation fails to retain the hope of continued survival (as a suggestion you can give the survival rate with transplantation. Clarifying the etiology of CBA have great significance for its treatment and prognosis.

## CASE PRESENTATION

### Chief complaints

The patient came to our outpatient clinic because of "yellow skin and sclera staining for more than 6 mo".

### History of present illness

Soon after birth, there was no obvious incentive for the child to have yellow skin and sclera staining, which gradually intensified. This yellowing was accompanied by a white stool color, but no other discomfort was reported. After many phototherapies at the local hospital, the conditions did not improve, and the yellow skin and sclera staining showed progressive aggravation. Then, the patient went to the local hospital and underwent "laparoscopic exploration suggestive of biliary atresia" (family members complained privately, and no report was found). Later, the family members did not allow further diagnoses and treatments. After discharge, oral symptomatic Chinese patent medicine was administered, but the above symptoms were not relieved. The patient was then admitted to the hospital with "bile duct atresia" for living donor liver transplantation.

### History of past illness

Previous "history of laparoscopic surgery".

### History of family past illness

The patient's father and mother were in good health. The patient had a sister who had a history of "biliary atresia" and underwent "liver transplantation" at an age of more than 6 mo. This sister died at an age of more than 2 years.

**Physical examination**

Physical examination results were as follows: T 37°C, P 134 bpm, BP 95/52 mmHg, a clear mind, fair spirit, soft neck, yellow skin and sclera, thick respiratory sounds of both lungs, no dry and wet rales, uniform heart rhythm, no obvious pathological murmur in heart sound, abdominal distention, abdominal circumference of 44 cm, no exposure of abdominal wall vein, touch approximately 7 cm under liver rib, hard texture, blunt edge, 6 cm under spleen rib, negative neurological examination, and limb temperature.

**Laboratory examinations**

The blood examination on December 18, 2019 results were as follows: Leukocyte count  $20.0 \times 10^9/L$ , neutrophils (%) 41.1%, lymphocytes (%) 49.6%, red blood cell  $3.08 \times 10^{12}/L$ , hemoglobin 99 g/L, and platelet count  $234 \times 10^9/L$ . On December 18, 2019, the plasma D-dimer determination was 4597  $\mu g/L$  FEU. Examination of coagulation function on December 18, 2019 was as follows: International standardized ratio 2.36, fibrinogen 0.50 g/L, activated partial thromboplastin time 90.5 seconds, thrombin time 26.6 s, and prothrombin time 27.4 s. On December 18, 2019, the liver examination and kidney lipid glucose electrolyte determination were as follows: total protein 78.4 g/L, albumin 59.3 g/L, globulin 19.1 g/L, white globulin ratio 3.1, alanine aminotransferase 16U/L, aspartate aminotransferase 53U/L, total bile acid 522.7  $\mu mol/L$ , total bilirubin 347.6  $\mu mol/L$ , direct bilirubin 222.5  $\mu mol/L$ , indirect bilirubin 125.1  $\mu mol/L$ , glomerular filtration rate (EPI-cr) 285.95 ml/min, creatinine 14  $\mu mol/L$ , uric acid 88  $\mu mol/L$ , total cholesterol 0.93 mmol/L, high-density lipoprotein-c 0.25 mmol/L, low-density lipoprotein-c 0.09 mmol/L, fasting blood glucose 3.54 mmol/L, and potassium 4.86 mmol/L.

**Imaging examinations**

Full abdominal computed tomography showed that the intrahepatic bile duct and common bile duct were dilated. It also showed signs of exudation around the portal vein and an unclear display of the gallbladder. Thus, effusion of gallbladder fossa and peritoneal effusion were considered. Imaging also showed a patch shadow of the left lower lobe, bilateral pleural effusion, and bilateral hip soft tissue swelling. The biopsy results showed biliary stasis and hepatic cirrhosis (Figure 1).

**FINAL DIAGNOSIS**

The diagnosis was CBA and cholestatic hepatitis.

**TREATMENT**

On January 7, 2020, "reduced volume liver transplantation" was performed under general anesthesia. After the operation, meropenem was administered to fight infection, ganciclovir was administered for virus infection prevention, liver protection, and phlegm removal, tacrolimus was administered to fight rejection, and albumin and human immunoglobulin were supplemented. The patient's condition improved. On January 31, 2020, the color Doppler ultrasound of the portal vein system of the transplanted liver (color Doppler ultrasound) revealed that the blood circulation of the transplanted liver was satisfactory, and there was a small amount of effusion near the cutting edge of the liver. On January 31, 2020, the serum drug concentration of FK506 was 8.1 ng/mL. Blood coagulation function was checked, and the international standardized ratio was 2.24. On January 21, 2020, the blood biochemical test results were as follows: Alanine aminotransferase 17 U/L, aspartate aminotransferase 19 U/L, total bilirubin 8.0  $\mu mol/L$ , and glutamyl transphthalase 77 U/L. The patient recovered, the liver function was stable, and the antirejection drugs and coagulation function reached the standards. On January 10, 2020, whole liver + cholecystectomy specimens were submitted for examination. The liver surface was fine granular, the section was gray-red and gray-yellow, and diffuse fine granular. Microscopically, the structure of normal liver lobules was damaged, hepatocytes and small bile ducts were silted, small bile ducts in the portal area were proliferated, inflammatory cells were infiltrated, pseudolobules of liver tissue were formed, and cholestatic cirrhosis was changed. The first hilar lymph node was reactive hyperplasia. The bile duct indicated chronic cholecystitis. In conclusion, the findings in the total liver and cholecystectomy specimens are consistent with a diagnosis of cholestatic cirrhosis with CBA and chronic cholecystitis.

**OUTCOME AND FOLLOW-UP**

The patient was discharged after being in a stable condition. Follow-ups occurred regularly in the outpatient department of the liver transplantation department, and the patient took long-term oral

DOI: 10.12998/wjcc.v11.i3.629 Copyright ©The Author(s) 2023.

**Figure 1** The biopsy results showed biliary stasis and hepatic cirrhosis. A: Hematoxylin staining of hepatic tissue; B: Eosin staining of hepatic tissue. Hematoxylin and eosin staining showed biliary stasis and hepatic cirrhosis.

drugs to control the condition after transplantation. At present, there is no obvious yellowing of the skin, the color of stool is normal, the abdominal circumference is significantly reduced, and the functional evaluation of the transplanted liver is basically within the normal range.

## DISCUSSION

At present, there is no clear understanding of the etiology of CBA. Clinical scholars have put forward many independent and interrelated hypotheses that mainly focus on the following aspects.

The first aspect is congenital dysplasia. The developmental abnormality hypothesis is mainly aimed at CBA with other organ malformations. It is generally believed that biliary tract lesions begin at 5-6 wk of pregnancy, rather than during the development of the intrahepatic bile duct (7-10 wk of pregnancy). The differentiation and morphogenesis of embryonic cells are key factors of organ development[10]. The most important factor is gene mutations. For example, the inversion mutations in *MDR3*[2], *EFEMP1*[4], and *GPC1* reported in this paper may lead to the production of CBA through corresponding signaling pathways. In addition, in animal experiments of miRNAs, zebrafish lacking miR-30a have abnormal bile duct development. This indicates that genetic factors contribute to the etiology of CBA.

The second aspect is the study of autoimmune-related microchimeras. Kasai hilar jejunostomy after birth in children with CBA can effectively alleviate the development of this disease. However, even if the bile drainage is unobstructed, the process of liver fibrosis does not stop, and histologically, the CBA intrahepatic bile duct is very similar to sclerosing cholangitis, graft-versus-host disease, and other immune diseases. Therefore, some scholars regard CBA as an autoimmune disease. There is also some theoretical and research support for the influence of maternal microchimeras and the second strike theory. In addition, studies have confirmed that there is a large amount of C4d deposition in portal vein blood endothelium[11], indicating that liver fibrosis and portal hypertension in the later stage of CBA are autoimmune reactions that participate in cellular and humoral immunity. Third, the immune imbalance caused by infection may also be an important cause of CBA. Since Benjamin first attributed CBA to viral infection in the liver and biliary system, the mechanism of viral infection immune imbalance has gradually become a hot spot in the etiology of CBA. From the initial discovery of a large amount of monocyte infiltration in the vascular and bile duct endothelium of the hilar region to the establishment of animal models and immune response research, an increasing number of results support this view. The most studied factor is virus infection. At present, research on external infection sources mainly focuses on respiratory enterovirus, cytomegalovirus, and rotavirus[12]. In addition, increasing attention has been given to specific immunity and natural immunity[13]. The presence of bile duct-specific autoantibodies was found in a mouse model infected with rotavirus[14], which also provides a new idea for the exploration of the etiology of CBA.

According to the current paper data, CBA is a serious disease with multiple etiologies and phenotypes, and the etiologies of different types are different. Multiple hypotheses are independent and interdependent and need to be carefully identified in further clinical practice.

## CONCLUSION

CBA is a serious childhood disease with a difficult etiology and poor prognosis. *GPC1* mutations are one of the important causes of CBA. Clarifying the etiology of CBA is of great importance for its early

diagnosis and prognosis. It is also of great importance to popularize prenatal gene diagnoses in high-risk groups.

## ACKNOWLEDGEMENTS

The authors would like to thank the patient's family for agreeing to participate in this research.

### Abstract

#### BACKGROUND

Tooth avulsion is one of the most severe types of dental trauma. Most avulsed teeth undergo long-term ankylosis and replacement resorption after delayed reimplantation and exhibit a poor prognosis. The aim of this work was to improve the success rate of avulsed teeth after delayed reimplantation using autologous platelet-rich fibrin (PRF).

#### CASE SUMMARY

Case 1 was a 14-year-old boy who fell and knocked out his left upper central incisor 18 h prior to his arrival at the department. The diagnoses were avulsion of tooth 21, lateral luxation of tooth 11 and alveolar fracture of teeth 11 and 21. In case 2, a 17-year-old boy fell 2 h prior to his presentation to the hospital, and his left upper lateral incisor was completely knocked out of the alveolar socket. The diagnoses included avulsion of tooth 22, complicated crown fracture of tooth 11 and complicated crown-root fracture of tooth 21. The avulsed teeth were reimplanted along with autologous PRF granules and splinted using a semiflexible titanium preshaped labial arch. The root canals of the avulsed teeth were filled with calcium hydroxide paste, and root canal filling was performed 4 wk after reimplantation. The reimplanted teeth showed no symptoms of inflammatory root resorption or ankylosis at the 3-, 6-, and 12-mo follow-up examinations after reimplantation with autologous PRF. In addition to the avulsed teeth, the other injured teeth were treated using corresponding conventional treatment methods.

#### CONCLUSION

These cases provide examples of the successful use of PRF to reduce pathological

root resorption of the avulsed teeth, and the application of PRF may provide new healing opportunities for traditionally “hopeless” avulsed teeth.

**Core Tip:** Tooth avulsion is one of the most severe types of dental trauma. Most avulsed teeth will undergo ankylosis and replacement resorption after delayed reimplantation and generally experience a poor prognosis. We previously demonstrated that autologous platelet-rich fibrin (PRF) could effectively help to control the occurrence and development of initial root resorption. In this report, we presented two clinical cases of avulsed teeth with delayed reimplantation that were treated with autologous PRF. Ideal periodontal healing over 12 mo of follow-up suggested that PRF, as an adjuvant therapy, may provide new insights and perspectives on the management of traditionally hopeless avulsed teeth.

## INTRODUCTION

Tooth avulsion is defined as a complete displacement of the tooth from its original alveolar socket and is one of the most severe types of dental trauma. Permanent tooth avulsion accounts for 0.5%-3.0% of dental trauma, whereas some studies report an incidence as high as 16.0% [1,2]. A recent study from China showed that 8.0% of all dental injuries were tooth avulsion; these injuries are more likely to occur in individuals 7-20-years-old and generally occur more often in males than females [3]. The prognosis depends on the measures taken at the site of the accident, such as immediate replantation of avulsed teeth, the use of an effective preservation medium for the avulsed tooth, and timely and professional dental treatment performed after avulsion [4]. It was noted that a delay of more than 5 min could be defined as delayed replantation, affecting tooth survival [5]. Unfortunately, in most cases, an avulsed tooth is kept out of the alveolar socket for a significantly long time or is stored under improper conditions, which eventually contribute to periodontal ligament cell necrosis and result in ankylosis and replacement resorption of the tooth root after reimplantation [6]. The commercial enamel matrix protein Emdogain has been used clinically. However, its effectiveness in preventing root resorption has not been demonstrated [7].

Platelet-rich fibrin (PRF) is a second-generation platelet concentrate that is prepared from the patient's own blood without the use of an anticoagulant through a single-step centrifugation process [8,9]. This concentrate is classified as L-PRF or PRF based on its leukocyte content as well as standard PRF or advanced PRF depending on the centrifugation process. In addition, PRF is available in a membrane or injectable form depending on the centrifugation process and consistency of the final product [10]. The main scaffold component of PRF is fibrin, which develops a three-dimensional mesh crossover structure that is visible under a scanning electron microscope with a large interfiber space that contains numerous red blood cells, white blood cells and clusters of platelets [11,12]. The fibrin network of PRF protects platelets from immediate activation but progressively activates them during the process of fibrin degradation, slowly releasing growth factors, eventually prolonging the duration of growth factors in PRF and promoting wound healing effects [13,14]. Thus, PRF has the potential to enhance tissue regeneration, accelerate wound healing and induce stem cell differentiation through the consistent release of multiple growth factors [15,16]. Our previous study demonstrated that autologous PRF could effectively promote the periodontal healing of avulsed teeth after delayed replantation in dogs and thus control the occurrence and development of initial root resorption [15].

In this report, we presented two clinical cases of delayed reimplantation of avulsed teeth using autologous PRF granules with a 12-mo follow-up. In both cases, the avulsed teeth were separated from the alveolar socket for far longer than the optimal reimplantation time of 5 min, and the residual periodontal ligament tissue on the root surface was either damaged or seriously polluted, which would traditionally deem them as “hopeless” teeth. Upon simultaneous reimplantation of avulsed teeth with autologous PRF, the injured teeth showed no symptoms of inflammatory root resorption or ankylosis in both cases, suggesting that the application of PRF may offer new therapeutic opportunities for traditionally “hopeless” avulsed teeth.

## CASE PRESENTATION

### Chief complaints

**Case 1:** A 14-year-old boy was referred to the Department of General Dentistry and Emergency of the Fourth Military Medical University with complaints of pain and that his left upper central incisor fell out 18 h prior.

**Case 2:** A 17-year-old boy visited the Department of General Dentistry and Emergency of the Fourth Military Medical University with complaints that his left upper lateral incisor had completely fallen out 2 h prior.

### History of present illness

**Case 1:** The patient accidentally fell 18 h prior to presentation, and his left upper central incisor was knocked out. The patient was conscious with stable vital signs.

**Case 2:** The patient suffered avulsion of the left upper lateral incisor from an accidental fall and came to the hospital 2 h later. The patient was conscious with stable vital signs.

### History of past illness

The patients did not have a relevant medical history. They did not report any history of drug allergies or systemic diseases and exhibited no apparent dental treatment contraindications.

### Personal and family history

There were no specific family health histories.

### Physical examination

**Case 1:** After excluding damage to other important organs, an oral examination was performed. His general medical history did not obviously contribute to the injury, and an examination revealed no evidence of nerve injury. We performed clinical examinations, and the extraoral findings did not reveal serious wounds. Intraoral examination found that tooth 21 was missing, and the alveolar nest was empty. Blood clots had formed in the alveolar socket, and there was no obvious lacerated wound in the gums. The crown of tooth 11 was shifted to the palatal side and exhibited occlusal interference. Tooth H was retained on the lingual side of tooth 13 and was loose (Figure 1A and B). The avulsed tooth was wrapped in dirty dry paper towels (Figure 1C).

**Case 2:** Intraoral examination found that tooth 22 was missing, and the corresponding alveolar socket was empty with blood clots filling it. The patient had a complicated crown fracture of tooth 11 and a complicated crown-root fracture of tooth 21 with the fracture surfaces being approximately 4 mm below the enamel-dentinal junction (Figure 2A and B). The avulsed tooth was wrapped in dry paper towels, and numerous pollutants were present on the periodontal ligament tissues of the root surface (Figure 2C).

### Laboratory examinations

These cases did not undergo any laboratory examinations.

### Imaging examinations

**Case 1:** Digital-X radiograph (FOCUS, Instrumentarium Dental, Finland) revealed that the alveolar socket of tooth 21 was empty, and no high-density foreign body images were noted. The periodontal membrane space was widened in tooth 11 without significant root fracture (Figure 3A). Cone-beam computed tomography (Hires3D, Beijing, China) revealed that the lip side of the alveolar bone wall of tooth 21 was fractured (Figure 3B).

**Case 2:** Periapical radiography revealed that the alveolar socket of tooth 22 was empty, and no high-density foreign body images were observed (Figure 4A). Cone-beam computed tomography revealed no alveolar fracture around the empty tooth socket (Figure 4B), and the fracture position of tooth 21 was approximately 3 mm above the top of the alveolar crest (Figure 4C).

## FINAL DIAGNOSIS

**Case 1:** Based on the patient's medical history and findings of the imaging examinations, the diagnoses for this patient included lateral luxation of tooth 11, avulsion of tooth 21 and alveolar fracture of teeth 11 and 21.

**Case 2:** The diagnoses of this patient included avulsion of tooth 22, complicated crown fracture of tooth

**Figure 3 Periapical radiograph and cone beam computed tomography images of Case 1 at the first visit.** A: The periodontal membrane space was widened in tooth 11, the alveolar socket of tooth 21 was empty, and no high-density foreign bodies were observed; B: Cone-beam computed tomography images showed that tooth 21 had been completely replanted, and the lip side of the alveolar bone wall of teeth 11 and 21 was fractured.

11, and complicated crown-root fracture of tooth 21.

## TREATMENT

**Case 1:** We obtained a 10-mL blood sample from the median cubital vein and transferred the blood into a 10-mL glass tube without anticoagulation as soon as possible. The tube was immediately centrifuged at  $400 \times g$  for 10 min (TD3, CENCE, China) (Figure 5A). The fibrin clot that contains PRF formed in the middle of the tube; thus, the clot was easily separated from the red corpuscles at the bottom (Figure 5B and C). The clot was compressed with sterile dry gauze to remove the fluids trapped in the fibrin matrix. The PRF formed a very resistant autologous fibrin membrane, which was subsequently cut into

**Figure 5** Preparation process of the platelet-rich fibrin. A: The tube was immediately centrifuged at  $400 \times g$  for 10 min; B: The fibrin clot contained platelet-rich fibrin and was located in the middle of the tube; C: The clot was easily separated from the red corpuscles at the bottom; D: The platelet-rich fibrin membrane was cut into approximately  $1 \text{ mm}^3$  granules, and the red and white ends were mixed evenly.

approximately  $1 \text{ mm}^3$  granules (Figure 5D). Tooth 21 was reimplanted along with the PRF granules, and tooth 11 received manipulative reduction. Then, the teeth were splinted using a preshaped semiflexible titanium labial arch (Titanium Trauma Splint, Zhongbang Titanium Biological Materials Co., Ltd., Xi'an, China) for 4 wk (Figure 6A). The digital X-ray radiograph obtained immediately after the surgery showed complete reduction of teeth 21 and 11 (Figure 7A). According to the International Association of Dental Traumatology guidelines[17], root canal therapy of avulsed teeth 21 should be started within 7–14 d. For tooth 11, negative dental pulp activity was found. In addition, the tooth was sensitive to percussion, and a small transmission shadow was observed in the apical region at the return visit after 2 wk. Root canal therapy of the laterally dislocated tooth 11 and avulsed tooth 21 was performed 2 wk after the first visit. Calcium hydroxide paste was used as an intracanal medication sealant for 4 wk. Then, a biotype root canal filling sealer and hot-melt gutta-percha (SuperEndo B&L, Korea) were adopted for root canal filling. After root canal treatment, teeth 11 and 21 were restored with nanoment resin (3M Dental Products, MN, United States). The fixtures were removed 4 wk after the first treatment (Figures 6B and 7B).

**Case 2:** After obtaining informed consent, blood was collected from the patient, and PRF was prepared. Then, tooth 22 was reimplanted with PRF and splinted for 2 wk using a preshaped semiflexible titanium labial arch (Figure 6C). The digital X-ray radiograph obtained immediately after surgery showed complete reduction of tooth 22 (Figure 7C). After pulp vitality assessment, the dental pulp of teeth 11, 21 and 22 was removed after 2 wk, and calcium hydroxide paste was used as an intracanal medication sealant for 4 wk. Then, a biotype root canal filling sealer and hot-melt gutta-percha (SuperEndo B&L, Korea) were adopted for root canal filling. The fixtures were removed after 2 wk, and the root canal was completed after 6 wk (Figure 7D). After root canal treatment, teeth 11 and 21 were filled with fiber piles

**Figure 7 Periapical radiograph.** A and C: In Case 1 and 2, the teeth were splinted using a pre-shaped semiflexible titanium labial arch at the first visit; B and D: 6 wk after the initial visit of Case 1 and 2, the fixtures were removed, and the root canal treatment for the injured teeth was accomplished.

(3M Deutschland GmbH, Germany) and resin (3M Dental Products, MN, United States) and finally repaired with full crown restoration. Tooth 22 was restored with nanomert resin (3M Dental Products, MN, United States) (Figure 6D).

## OUTCOME AND FOLLOW-UP

**Case 1:** A follow-up examination was performed 3 mo, 6 mo and 12 mo after the treatment. Clinical examination found no obvious periodontal pockets, tooth discoloration or swelling of the gums around tooth 21 (Figure 8A and B). The radiographic images obtained during the follow-up examination showed that the periodontal membrane space was continuous, and no sign of pathological root absorption was observed (Figure 9A-D).

**Case 2:** A follow-up examination was performed 3 mo, 6 mo and 12 mo after the treatment. Clinical examination revealed no obvious periodontal pockets, tooth discoloration or swelling of the gums around tooth 22 (Figure 8C and D). Radiographic images obtained during the follow-up examination showed that the periodontal membrane space was continuous, and no sign of pathological absorption was observed (Figure 9E-H).

## DISCUSSION

Tooth reimplantation is the most important and fundamental treatment for tooth avulsion. The time interval between avulsion and reimplantation is the most important factor for successful reimplantation and is directly related to the number of live periodontal ligament cells on the root surface of the avulsed teeth[11]. If the tooth is not reimplanted as soon as possible, the residual periodontal ligament tissues on the root surface could be damaged or even exhibit necrosis. These conditions can lead to serious pathologic resorption and loss of the reimplanted tooth. Inflammation and replacement root resorption are the most common causes of reimplantation failure. The development of the lesion greatly depends on pulp vitality. When the root canal becomes infected, microbial toxins can move to the root surface

**Figure 9** Periapical radiograph and cone beam computed tomography images of two cases during follow-up observation. The periodontal membrane space was continuous, and no sign of pathological root absorption was observed in the avulsed teeth. A and E: 3-mo follow-up radiograph images of Cases 1 and 2; B and F: 6-mo follow-up radiograph images of Cases 1 and 2; C and G: 12-mo follow-up radiograph of Cases 1 and 2; D and H: 12-mo follow-up cone-beam computed tomography images of Cases 1 and 2.

through dentinal tubules, leading to the occurrence of root resorption[6,18]. Inflammatory root absorption on the outer surface can be prevented or controlled by the timely removal of the etiological origin, *i.e.* root canal intervention. The most effective method to prevent the replacement absorption of roots is to immediately replant or place the tooth in an appropriate storage medium[19,20].

It has been reported in the literature that ideal periodontal healing can be achieved when the avulsed tooth is reimplanted within 5 min. If reimplantation is delayed for more than 1 h after avulsion, complete necrosis of the injured periodontal ligament tissue is expected[17,21]. The storage of the avulsed tooth is also crucial to the periodontal healing process by affecting the viability of the periodontal ligament cells[22]. Unfortunately, due to the lack of common knowledge of early treatment and preservation of the avulsed teeth, few patients save the avulsed teeth in an ideal media in a timely manner. Studies have shown that 28.6% of patients place dislocated teeth in dry tissues for preservation, and only 11% of dislocated teeth were held in the mouth or placed in milk during transport to the clinic [23]. In the present cases, the patients washed the avulsed tooth with running water, which removed the periodontal tissues from the root surface. The teeth were then wrapped in paper towels, and the patients visited the doctor more than 1 h later (even up to 18 h later). Therefore, periodontal cells, which are essential for periodontal membrane healing, were almost completely destroyed.

In our previous study, we demonstrated that autologous PRF effectively promotes the periodontal healing of avulsed teeth during delayed tooth reimplantation[15]. Similarly, Hiremath *et al*[24] demonstrated that PRF increased the cellular activity of periodontal ligament cells *in vitro*[24,25]. A previous study reported that when a PRF membrane was used to wrap the root surface and condense into the canal, it promoted pulp vitality and periodontal healing of the avulsed teeth, whereas a thick radiolucent area surrounding the root was always obvious even after 24 mo of follow-up[26]. Here, PRF granules instead of PRF membranes were adopted; thus, the problem that the PRF graft might prevent the root from fitting into the alveolar bone was avoided. In case 1, the avulsed tooth was reimplanted after 18 h when its periodontal membrane was necrotic, and the probability of root absorption was greatly increased. Therefore, we used PRF together with tooth replantation to reduce the probability of root resorption. These results were also consistent with our expectations, and no signs of root resorption were noted during the 3-mo, 6-mo and 12-mo postoperative follow-up. To our knowledge, this is the longest successful delayed replantation of an avulsed tooth reported in the literature to date. These results suggest that PRF may provide a new treatment opportunity for traditionally hopeless avulsed teeth.

We assume that PRF promotes the healing of avulsed teeth *via* two mechanisms based on our previous *in vitro* and *in vivo* studies. First, the periodontal ligament tissues remaining within the original alveolar socket contain periodontal ligament cells and stem cells. During the tissue repair process, multiple growth factors are released by PRF. Additionally, cell homing will occur, and host stem cells from the circulation will be recruited to the injury region by factors released by the PRF to promote their proliferation and induce their differentiation toward the periodontal membrane, facilitating the formation of periodontal membrane-like structures[15,27]. Second, we demonstrated that PRF consists of concentrated blood platelets, and the  $\alpha$ -granules are activated and degranulated. Thus, many growth factors, such as platelet-derived growth factor, transforming growth factor- $\beta$ , insulin-like growth factor, epidermal growth factor and vascular endothelial growth factor, can be released for at least a week and up to 4 wk. Thus, PRF supports the regenerative and remodeling environment for a certain period of time[28-31]. These growth factors increase the mitotic activity of periodontal fibroblasts by 20%-37% [19], thereby improving the proliferation and periodontal differentiation of target cells and further promoting periodontal healing of avulsed teeth[15]. We also note that when a variety of growth factors act together, synergistic or even antagonistic effects among them cannot be ruled out. Therefore, the natural proportion of various growth factors is particularly important. This is just one of the important reasons why we chose PRF, which contains numerous active growth factors. The growth factors in PRF are not only rich in content and variety but also maintain natural proportions under normal physiological conditions. Only by their synergistic effects can they jointly maintain the balance of the tissue environment and play an important role in regulating wound healing and tissue regeneration.

Although we did not observe obvious ankylosis in these cases, it is a common finding in patients with avulsed teeth[6,15,32,33]. Previous studies have shown that PRF can inhibit the osteogenic differentiation of periodontal ligament stem cells *in vitro*, which might reduce the possibility of ankylosis based on three reasons. First, PRF promotes cell proliferation to promote the generation of fibroblasts and repair tissue with more seed cells instead of mobilizing bone stromal cells and bone-derived cells. Second, the main component of PRF is collagen fiber, which can act as a physical barrier when placed in the periodontal space. PRF prevents direct contact between the tooth root and the inner wall of the alveolar socket, thus reducing the bone repair between them[15]. Third, PRF inhibits the generation of osteoclasts by promoting osteoprotection secretion. By inhibiting osteoclast activity, the opportunity for external resorption can be suppressed to some extent[26]. Of course, the present study also has some limitations, such as a short follow-up time and a small sample size. Thus, the long-term effect of PRF in promoting the periodontal healing of avulsed teeth is unclear. Future evaluations including long-term follow-up with a large sample size are planned.

## CONCLUSION

Enriched with growth factors and leukocytes, PRF potentially reduces pathological resorption and promotes periodontal wound healing and periodontal ligament regeneration following delayed reimplantation of avulsed teeth. Although the viability of PRF must be demonstrated in more cases, the application of PRF may offer new therapeutic opportunities for traditionally hopeless avulsed teeth.

## Abstract

### BACKGROUND

Seminal vesicle abscess (SVA) is the manifestation of a relatively rare urinary system infection. In response to urinary system inflammation, an abscess forms in special locations. However, acute diffuse peritonitis (ADP) induced by SVA is unusual.

### CASE SUMMARY

We report a case of a left SVA in a male patient complicated with pelvic abscess, ADP, multiple organ dysfunction syndrome, infectious shock, bacteremia, and acute appendiceal extraperitoneal suppurative inflammation as a result of a long-term indwelling urinary catheter. The patient received a course of morinidazole + cefminol antibiotics but showed no obvious relief, so the perineal SVA underwent puncture drainage and abdominal abscess drainage + appendectomy was performed. The operations were successful. After the operation, anti-infection, anti-shock, and nutritional support treatments were continued and various laboratory indicators were regularly reviewed. The patient was discharged from the hospital after recovery. This disease is a challenge for the clinician because of the unusual spreading path of the abscess. Moreover, appropriate intervention and adequate drainage of abdominal and pelvic lesions are necessary, especially when the primary focus cannot be determined.

### CONCLUSION

The etiology of ADP varies, but acute peritonitis secondary to SVA is very rare. In this patient, the left SVA not only affected the adjacent prostate and bladder but also spread retrogradely through the vas deferens, forming a pelvic abscess in the loose tissues of the extraperitoneal fascia layer. Inflammation involving the peritoneal layer led to ascites and pus accumulation in the abdominal cavity, and

appendix involvement led to extraperitoneal suppurative inflammation. In clinical practice, surgeons need to consider the results of various laboratory tests and imaging examinations to make comprehensive judgments involving the diagnosis and treatment plan.

## INTRODUCTION

Acute diffuse peritonitis (ADP) is a common acute abdominal complication of general surgery. It has a high risk of mortality due to its rapid onset, rapid progression, and poor prognosis. The causes of ADP vary, but most cases are due to secondary infections. However, emergency surgery is needed regardless of the cause[1]. The main function of the seminal vesicles is to secrete nutrients and dilute the fluid in which the sperm resides. An infection of the seminal vesicle most commonly causes inflammation. Seminal vesicle abscess (SVA) is relatively rare, and diseases that develop from the “SVA–pelvic abscess–ADP” pathogenesis circuit, where the associated bacteria originate from the seminal vesicles and SVA, are even rarer. In 1978, Rajfer *et al*[2] reported the first case of SVA. According to Rajfer *et al* [2], less than 100 cases of SVA have been reported worldwide. Here, we report a male patient who developed a SVA due to a long-term indwelling catheter, analyze the basic condition and outcome, and provide the clinical diagnosis and treatment ideas.

## CASE PRESENTATION

### Chief complaints

An 86-year-old man was admitted to our hospital for lower abdominal distension and pain that lasted for 5 d. The patient had a sudden high fever of 39 °C.

### History of present illness

Five days prior to hospital admission, the patient suffered from intermittent abdominal distension and pain. He did not visit his doctor, the symptoms of lower abdominal pain gradually worsened the night prior, and the symptoms were accompanied by frequent nausea, vomiting, and loose watery stools. After symptomatic treatment in a local hospital, there was no obvious remission, so he came to our hospital for emergency treatment. He had no jaundice or anorexia symptoms.

### History of past illness

The patient underwent surgical treatment for benign prostatic hyperplasia 2 years prior and took finasteride + tamsulosin hydrochloride intermittently after the operation. Last year, he had difficulty urinating. Ultrasound examination showed that there was an increase in the residual urine volume and urinary retention. He had an indwelling catheter. The catheter was regularly removed and replaced in

the outpatient clinic, which led to dysuria recurrence. The patient also experienced hypertension for many years, which was partly controlled with medications.

### Personal and family history

No relevant family history, travel history, or animal contact was reported.

### Physical examination

The patient's initial vital signs at admission were as follows: Blood pressure 146/79 mmHg, pulse 62 bpm, respiratory rate 18 breaths/min, and body temperature 39 °C. He had an altered mental state, slight abdominal distension, slightly weak bowel sounds (3/min), obvious tenderness and rebound pain in the lower abdomen, slightly tense abdominal muscles, and percussive tympany abdominal sounds. He had an indwelling urinary catheter, drainage was unobstructed, urine was dark yellow, and flocculent was visible. Scrotal symmetry, bilateral testis, and epididymis tenderness were observed.

### Laboratory examinations

The in-hospital laboratory examination showed the following: White blood cell (WBC) count:  $12.61 \times 10^9$  /L (79.1% neutrophils and 11.7% lymphocytes); C-reactive protein: 82.6 mg/L. The routine urine examination showed red blood cells 85/UL and WBCs 291/UL, indicating hematuria and pyuria. However, the patient's liver and kidney function, electrolytes, myocardial enzymes, and coagulation at the first day of admission were normal.

### Imaging examinations

Pelvic magnetic resonance imaging (MRI) was performed 2 d after admission, which showed a lumpy and patchy left lower abdomen, with a high possibility of inflammation, a thickened sigmoid wall, blurred fatty space surrounding the pelvic cavity, and a possible left SVA (Figure 1). Combined pelvic and abdominal computed tomography (CT) showed encapsulated effusion and gas accumulation in the left lower abdomen with peripheral exudative changes, suggesting the possibility of an abscess. The left seminal vesicle was unclear with corresponding cystic foci, suggesting the possibility of an abscess (Figure 2A and B). Chest CT revealed scattered chronic inflammation in both lungs.

## FINAL DIAGNOSIS

The discharge diagnoses were: (1) Septic shock; (2) ADP and acute extraserosal suppurative appendicitis; (3) Left SVA; (4) Pelvic abscess; and (5) Hypertension grade 3 (high risk).

## TREATMENT

After admission, the patient's condition gradually worsened. Morlinidazole + cefminol was administered as anti-infection agents, and fluid resuscitation, abrosia, nutritional support, and other treatments were administered. Four days after admission, puncture drainage of the perineal SVA was performed, and a small amount of purulent fluid (bacterial culture: *Klebsiella pneumoniae*) was drained. Infection with Gram-positive cocci and *Candida parapsilosis* was detected in urine smears. However, multiple cultures were negative, so the possibility of sample contamination was considered. Abdominal pain was not obviously relieved postoperatively, and on the 5<sup>th</sup> day, blood pressure decreased and septic shock symptoms, such as weak consciousness, liver and kidney insufficiency, and abnormal coagulation function, were observed (Table 1). His vital signs at that time were as follows: Blood pressure 76/40 mmHg, pulse 118 bpm, respiratory rate 22 breaths/min, and body temperature 39 °C. The Acute Physiology and Chronic Health Evaluation II score was 15, and the Sequential Organ Failure Assessment score was 7. Considering that the patient's vital signs were not stable and after communicating with his family, it was decided to perform emergency exploratory laparotomy for active fluid replacement, volume expansion, and vital sign monitoring to identify the focus of infection and to fully drain the abscess.

After preoperative preparation and general anesthesia, the patient underwent surgery in the supine position, and the surgery was performed by the attending physician, who had approximately 25 years of specialized training. During the operation, the intraperitoneal suppurative fluid volume was approximately 100 mL and was mainly found in the intestines and around the appendix. The head and body of the appendix were suppured, and a large amount of pus was around the surface of the surrounding intestinal canal and sigmoid colon, without obvious intestinal perforation or tumor formation. Thus, abdominal abscess drainage + appendectomy was performed (Figure 3A-C).

After the operation, the patient was transferred to the intensive care unit due to his critical condition. He fasted and underwent electrocardiogram monitoring and continued anti-infection, anti-shock, and nutritional support treatments. The internal environment and water electrolyte balance was maintained.

**Figure 1** Magnetic resonance imaging results of the patient after admission. A and B: Pelvic magnetic resonance imaging (MRI) showed a rounded abnormal signal shadow in the left seminal vesicle, with low signal on T1-weighted imaging (T1WI) and high signal on T2-weighted imaging (T2WI) + lipid inhibition, and a size of approximately 2.3 cm  $\times$  1.6 cm; C and D: Pelvic MRI showed a nodular mass in the left inguinal region, with low signal on T1WI and high signal on T2WI + lipid inhibition, and a size of approximately 5.0 cm  $\times$  4.0 cm. The white arrowheads show the left seminal vesicle. The white arrows show the pelvic abscess (secondary focus).

The function of various organs was monitored. Plasma was infused to achieve coagulation, and wound dressings were changed regularly. Various laboratory indicators were routinely checked. On the 1<sup>st</sup> day after the operation, the patient had dyspnea and atrial fibrillation with a fast ventricular rate after taking off the line. He received high flow oxygen inhalation and his heart rate was regulated with amiodarone. Treatment to resolve abdominal distension and promote gastrointestinal motility was performed. The pus culture showed *Klebsiella pneumoniae* infection. A combination of meropenem and linezolid was administered, and the patient's symptoms and signs were gradually resolved. On the 3<sup>rd</sup> day after the operation, the patient's heart rate returned to normal, oxygen saturation was maintained with low-flow oxygen inhalation, the infection was eradicated, and abdominal distension was relieved. Later, the patient returned to general surgery ward for further treatment. On the 4<sup>th</sup> day after the operation, a liquid diet was initiated. The amount of intravenous fluid replacement was reduced and he was encouraged to get out of bed to prevent embolization. On the 7<sup>th</sup> day after the operation, abdominal distension recurred. He continued to fast, and the wound suture was removed. On the 10<sup>th</sup> day after the operation, the patient complained of hunger but abdominal distension was relieved. Abdominal CT showed less abdominal inflammation than before (Figure 2C and D). Three days later, the patient's diet was changed to a semiliquid diet. Two days later, the patient did not complain of any special discomfort, his body temperature returned to normal, and he was allowed to resume a normal diet. The other catheter was replaced, and the patient was discharged.

**Figure 2** Computed tomography results of the patient throughout the diagnosis and treatment processes. A-D: The results of pelvic computed tomography examinations on the 2<sup>nd</sup> day after admission, on the 10<sup>th</sup> day after surgery, at 1 mo after discharge, and at 3 mo after discharge; E-H: The primary focus of the left seminal vesicle abscess and the secondary focus of the extraperitoneal fascial abscess were gradually controlled and narrowed after treatment and outpatient and emergency follow-up. The white arrowheads show the left seminal vesicle. The white arrows show the pelvic abscess (secondary focus).

DOI: 10.12998/wjcc.v11.i3.645 Copyright ©The Author(s) 2023.

**Figure 3** The appendix. A and B: During the operation, the appendix was congested and edematous, with accumulation of the surrounding suppurative fluid, and the sigmoid colon was coated with a large amount of pus; C: A section of the appendix with a length of 3.5 cm and a diameter of 0.8-1.2 cm was cut; D: The suppurative inflammation of the appendix was confined outside the serosa (microscopy, × 100).

## OUTCOME AND FOLLOW-UP

Postoperative pathology of the appendix showed extraserous suppurative inflammation, AB (+), and PAS (+) (Figure 3D). After discharge, the patient underwent a 1-year follow-up. The two inflammatory foci were managed and their size was gradually reduced after treatment and follow-up (Figure 2E-H).

## DISCUSSION

The seminal vesicles are located at the bottom of the bladder and the outer side of the ampulla of the ureter. Together with the ampulla of the vas deferens and the ejaculatory duct, they form the distal structure of the seminal tract[3]. Seminal vesicle secretions account for approximately 60% of the total semen volume and include high concentrations of fructose, prostaglandin, and other substances[4]. SVA is very rare. In 2004, Sağlam *et al*[5] pointed out that a total of 26 related cases were reported in the literature. By searching PubMed, ScienceDirect, and other literature databases, as of August 2022, a total of 51 cases of SVA were identified worldwide. Table 2 shows the SVA cases reported since 2004. SVA can occur in all age groups and is more common unilaterally, and *Escherichia coli* is the main pathogenic bacteria. The etiology of SVA is unknown, but long-term indwelling catheters, diabetes, prostate puncture biopsy, and endoscopic operation are factors contributing to the susceptibility to this disease [6,7]. SVAs are mostly secondary to urinary tract infections such as prostatitis. Infections causing a SVA can also involve the blood, lymph, and other pathways[8]. In our case, the patient underwent surgical treatment of benign prostatic hyperplasia. He suffered difficulty urinating and had a long-term indwelling urinary catheter. We speculate that his previous medical history is an important risk factor for SVA.

SVA lacks specific clinical symptoms. Because the vesicles are anatomically adjacent to the bladder and other tissues, dysuria, testicular and groin pain, tenesmus, *etc.* are common clinical manifestations. Pandey *et al*[9] reviewed reports on these clinical manifestations; 74% of patients had fever, 58% had dysuria, and 32% had mild prostatitis[9]. Swollen glands can be found on digital anal examination.

US: Ultrasound; CT: Computed tomography; MRI: Magnetic resonance imaging; IVP: Intravenous pyelography; CUS: Cystourethroscopy; N/A: Not applicable.

Ultrasound, CT, and other imaging examinations are the methods used for diagnosing SVA[6]. The typical CT manifestations include unilateral or bilateral seminal vesicle dilation, central irregular low-density areas, and thickening of adjacent organs[5]. On MRI, the abscesses are usually round, with low T1-weighted imaging and high T2-weighted imaging signals[10].

**Figure 4** Three-dimensional computed tomography reconstruction showing the primary and secondary abscesses. A: Transverse view; B: Sagittal view; C: Coronal view. The primary focus is located at the baseline center, the white arrows indicate the vas deferens, and the arrowheads show the secondary focus.

Infectious diseases can occur in the seminal vesicles, for which antibiotic anti-infective treatment is the first choice. However, once an abscess is formed, conservative treatment is often ineffective[5]. Because of the trauma and long recovery time of open surgery, abscess puncture and drainage is currently the first choice for treatment. The common puncture methods include transurethral/transvesical drainage under cystoscopy and ultrasound-guided transrectal drainage[11,12]. Regarding the diagnosis and treatment of this case, the patient was admitted to the hospital and due to the ineffectiveness of conservative treatment, the left SVA of the perineum was punctured and drained under local anesthesia, and a small amount of purulent fluid was aspirated out. However, the symptoms were not significantly relieved after puncture, and the infection was exacerbated. In addition, abdominal CT showed the possibility of an abdominal abscess, so an exploratory laparotomy was performed.

Abdominal cavity infection is a common and frequently occurring disease in general surgery and is caused by bacteria, chemical stimulation, and other factors. Intraperitoneal organ rupture, perforation, trauma, and other diseases are common causes of peritonitis. The common pathogenic bacteria of peritonitis include hemolytic *Streptococcus*, *Pneumococcus*, and *Escherichia coli*[13,14]. Direct diffusion is one of the main routes by which bacteria enter the abdominal cavity. In this case, neither preoperative imaging examination nor intraoperative exploration revealed perforation or rupture of any abdominal organs that may have led to secondary peritonitis. Culture of the pus showed *Klebsiella pneumoniae*, which is not surprising, considering that this species originates from the urinary system. By repeating the preoperative abdominal imaging examination, we found that the primary foci of the SVA spread through the ejaculatory duct-vas deferens and accumulated in the loose connective tissue of the extraperitoneal fascia to form secondary foci. The transverse abdominis muscle was anterior to the secondary abscess, and the peritoneal reflex was superior, where purulent material contacted the peritoneum, resulting in acute peritonitis and intra-abdominal inflammation (Figures 4 and 5).

## CONCLUSION

By reviewing the diagnosis and treatment of this case, we summarize our experience and conclusions as follows: (1) An indwelling urinary catheter increases the risk of urinary tract infection, and the catheter indwelling time should be shortened as much as possible. For patients who must have a long-term indwelling catheter, the catheter should be replaced regularly, and high-quality nursing care should be actively performed. Elderly and frail patients with urinary tract infection should be treated in a timely

**Figure 5** Sagittal computed tomography image showing the relationship between the secondary focus and the pelvis and abdominal cavity. The white arrows indicate the peritoneum, and the arrowhead shows the secondary focus.

manner to prevent the occurrence of complications; (2) For bacterial resistance, multiple infections, and other problems, broad-spectrum antibiotics are used for anaerobic bacteria and Gram-negative bacteria; and (3) Early primary disease and complications should be considered at the same time, including the full drainage of SVA in the early stage, as well as active surgical intervention for abdominal infection. Clinicians can use various imaging examinations to fully understand the occurrence, development, and prognosis of the disease. In this case, the general condition of the patient before surgery was poor, and the patient's condition was complicated with sepsis. Early exploratory laparotomy, removal of the abscess, and adequate drainage were the best options.

## ACKNOWLEDGEMENTS

We sincerely thank Sheng-Song Huang and Wei Le for their help in the treatment and differential diagnosis of this patient.

### Abstract

#### BACKGROUND

Diffuse idiopathic skeletal hyperostosis (DISH) is a disorder characterised by the calcification and ossification of ligaments and entheses. It is a frequent occurrence in elderly males, but rarely encountered in younger individuals.

#### CASE SUMMARY

A 24-year-old male was admitted to the hospital due to low back pain accompanied with numbness in both lower limbs for 10 d. Upon clinical examination and imaging tests, the patient was diagnosed with DISH with Scheuermann disease and thoracic spinal stenosis. Before the operation and medical treatment, the patient had hypoesthesia of the skin below the xiphoid process. Afterward, a standard laminectomy was conducted using ultrasonic bone curette and internal fixation was applied. Subsequently, the patient was given corticosteroids, neurotrophic drugs, hyperbaric oxygen and electric stimulation. As a result of the treatment, the patient's sensory level decreased to the navel level and there was no major change in the muscle strength of the lower limbs. During follow-up, the patient's skin sensation has returned to normal.

#### CONCLUSION

This case is a rare instance of DISH co-existing with Scheuermann's disease in a young adult. This provides a valuable reference point for spine surgeons, as DISH is more commonly observed in middle-aged and elder adults.

**Key Words:** Diffuse idiopathic skeletal hyperostosis; Scheuermann disease; Thoracic spinal stenosis; Case report

**Core Tip:** This case report presents a rare instance of diffuse idiopathic skeletal hyperostosis in a 24-year-old male patient, which is a condition that is usually seen in elderly males. The patient was also diagnosed with Scheuermann disease. By providing clinical data and treatment experience of this patient, it is hoped that it will help to improve the understanding of related diseases, and reduce the chances of misdiagnosis.

## INTRODUCTION

Diffuse idiopathic skeletal hyperostosis (DISH) is an ailment caused by the calcification and ossification of the entheses that primarily affects the spine and other peripheral areas[1]. Primarily, DISH affects the thoracic spine of the axial skeleton; however, other spinal regions are often affected too. Studies demonstrate that DISH is more predominant among middle-aged and elderly individuals and the rate of occurrence increases with age. Moreover, there is a higher rate of male patients than female patients [2]. Scheuermann's disease was initially described by Scheuermann[3], a Danish physician, in 1921. The main symptom of this condition is the formation of three adjacent vertebrae that are angled by at least 5 degrees, resulting in the spine's kyphoscoliosis. Radiographic features of Scheuermann's disease include wedged vertebrae, irregular vertebral endplates, and Schmorl's nodes[4]. In this paper, we present a case of a young patient who was eventually diagnosed with DISH in combination with Scheuermann disease and thoracic spinal stenosis (TSS) in our hospital. While DISH is usually observed in middle-aged and elderly individuals, there is a lack of reports on young DISH patients. Moreover, it is even rarer for young DISH to be associated with Scheuermann disease, thus making this case worth reporting. We have reviewed the characteristics of the case, as well as the diagnosis and treatment process, in order to expand the current knowledge on the diagnosis and treatment of related diseases.

## CASE PRESENTATION

### Chief complaints

The 24-year-old male patient was hospitalized for 10 d due to lower back pain and numbness in both lower limbs.

### History of present illness

The 24-year-old male patient was hospitalized for 10 d due to lower back pain and numbness in both lower limbs. On physical examination, thoracodorsal kyphosis was observed and the skin below xiphoid had hypoesthesia. Furthermore, the muscle strength of the right iliopsoas, quadriceps femoris and biceps femoris was graded as III, while the right tibialis anterior and extensor dorsi were graded as IV. At admission, the patient experienced radiating pain in his waist, which had a VAS score of 8.

### History of past illness

The patient reported no other medical history such as hypertension and diabetes.

### Personal and family history

The patient denied any personal and family history of illness.

### Physical examination

On physical examination, thoracodorsal kyphosis was observed and the skin below xiphoid had hypoesthesia. Furthermore, the muscle strength of the right iliopsoas, quadriceps femoris and biceps femoris was graded as III, while the right tibialis anterior and extensor dorsi were graded as IV. At admission, the patient experienced radiating pain in his waist, which had a VAS score of 8.

### Laboratory examinations

To differentiate DISH from ankylosing spondylitis, it is necessary to test for human leukocyte antigen-B27 (HLA-B27). The patient's HLA-B27 index is within the normal range. Additionally, the patient's erythrocyte sedimentation rate, blood routine test and other biochemical indicators are all within the normal range.

### Imaging examinations

Anterior-lateral X-ray: Kyphosis of the thoracic spine is present, with calcification of the anterior longitudinal ligament and lamellar ossification/floating bone bridge on the medial-inferior and medial-superior sides of the anterior and lateral edges of vertebral plates. Additionally, there is a local wedge-shaped deformation of the lower thoracic vertebra (Figure 1).

Thoracic computed tomography (CT) scan revealed a kyphosis in the thoracic spine and calcification of the anterior longitudinal ligament of multiple vertebral bodies. The T8-12 vertebral body was wedge-shaped with a narrow front and wide back. The T5/6, T7/8, and T8/9 intervertebral discs were observed to protrude backward, resulting in compression of the corresponding horizontal segment dural sac. Furthermore, the adequate space of the spinal canal was constricted, and the spinal cord was compressed due to hyperplasia and sclerosis of the bilateral facet joints of the T7-9 vertebral body (Figure 2).

Results of a three-dimensional reconstruction revealed calcification of the anterior longitudinal ligament of numerous vertebral bodies, which has formed a bony bridge. The T8-12 vertebral body was found to be wedge-shaped, with a narrow front and wide back, as well as hyperplasia and sclerosis of both facet joints of the T7-9 vertebral body (Figure 3).

Thoracic magnetic resonance imaging showed kyphosis in the local thoracic spine. The T8-12 vertebrae have a wedge-like shape, with a thin anterior side and a wide posterior side. The intervertebral discs between T5/6, T7/8, and T8/9 protrude posteriorly and the adjacent dural sac is compressed. Additionally, no alterations in the spinal cord signal intensity were observed (Figure 4).

### FINAL DIAGNOSIS

The patient was diagnosed with DISH with Scheuermann disease and TSS.

### TREATMENT

The patient's TSS symptoms were serious, resulting in paraplegia of the lower limbs. To address this, we opted for a laminectomy with an ultrasonic bone curette and internal fixation. After the procedure, we administered corticosteroids, neurotrophic medications, hyperbaric oxygen, and electrical stimulation to the patient for further treatment.

### OUTCOME AND FOLLOW-UP

After the surgery and medication, the patient's sensory level decreased to the navel level with no noteworthy alteration in the muscle strength of the lower limbs. The VAS score was also decreased to 2 points. During the follow-up, the lumbar pain was completely gone and the patient's skin sensation was back to normal. The patient was also capable of walking 1.5 kilometers. The postoperative reexamination revealed that the internal fixation position was successful (Figure 5).

### DISCUSSION

The diagnosis of DISH is based on radiographic criteria proposed by Resnick and Niwayama[5] in 1976, which include the presence of flowing calcification and ossification along the anterolateral aspects of at least four contiguous vertebral bodies, relative preservation of disc height in the problematic areas, and absence of apophyseal joint bony ankylosis and sacroiliac joint erosion, sclerosis or bony fusion. This patient fulfilled these criteria and was thus diagnosed with DISH. DISH is most commonly found in the thoracic spine, where it presents as wavy ossification in front of the thoracic centrum, forming bone bridges across the intervertebral spaces, and is most commonly located on the right side[6]. It may also occur in the lower cervical spine and the upper lumbar segments[7]. It is important to differentiate DISH from ankylosing spondylitis, which can be done by examining the patient's joint space, inflammatory manifestations of the articular surface, morning stiffness, and limited joint mobility, as well as HLA-B27 values. In this case, the patient did not present with any of these features and had normal HLA-B27 values, thus excluding the possibility of ankylosing spondylitis.

Patients with DISH usually do not present with any noticeable symptoms and rarely require treatment. However, when DISH is accompanied by ossification of the ligamentum flavum and posterior longitudinal ligament, which compresses the spinal cord or nerve, surgery is necessary[8]. This condition is usually discovered incidentally during imaging tests, and the prevalence rate increases with age[6]. Studies have found that the incidence of DISH in males over 50 is more than 25% [2], and is

associated with age, obesity, and diabetes[9]. In contrast, the incidence of DISH in individuals under 40 is extremely low, with only a few cases reported in the literature[10]. A Japanese study of 345 patients with spinal column diseases revealed that the youngest patient with DISH was 37 years old[11]. Additionally, a study of 1479 patients undergoing chest CT scans showed that the average age of DISH was 54.7 years old, with only one patient under the age of 40[6]. A cross-sectional study of 2000 subjects in China found that the mean age of DISH was 58.7 years old, and there were no cases of DISH in

subjects under 40[10].

In 1964, Sorensen first proposed X-ray imaging diagnostic criteria for Scheuermann's disease[12], which includes at least three adjacent vertebrae with a minimum of 5° wedging. Subsequent research has expanded the understanding of the condition and refined the diagnostic criteria, which include vertebral body wedging, vertebral endplate irregularity, Schmorl's nodes, and narrowing of intervertebral disk spaces. Common symptoms in the early stages of the disease include chest and back pain. Our patient was a young individual with no prior history of spinal deformity, and they presented with the aforementioned symptoms. Scheuermann's disease is a relatively common condition in adolescents, with an estimated prevalence of 1%-8%[13]. It usually presents as mild kyphosis and does not usually cause functional impairment. However, if the kyphosis worsens and is accompanied by disc herniation or spinal stenosis, prompt surgical intervention may be necessary[12]. Furthermore, a recent study reported a prevalence of syringomyelia of 5.8% in patients with Scheuermann's disease[14], therefore,

**Figure 5 X-ray after treatment.** A and B: Anterior X-ray of thoracic vertebra before operation. They showed that the internal fixation position was suitable.

any changes in spinal cord signals should be taken seriously and prompt surgical intervention should be considered.

TSS is associated with secondary pathological factors such as ossification of ligamentum flavum and ossification of posterior longitudinal ligament secondary to ankylosing spondylitis and DISH. It is reported that the highest incidence of TSS is seen in individuals aged 50-60 years old[15]. When TSS has resulted in obvious spinal cord compression and deformation (grade IV) and the patient has developed neurologic deficits, decompression surgery should be considered[16]. Depending on the location of the lesion, TSS surgery mainly includes dorsal spinal canal decompression and ventral or annular spinal canal decompression[17]. In the present case, spinal canal decompression and pedicle screw fixation were performed taking into account the patient's medical history and rate of disease progression. Post-operatively, the patient's sensory level decreased without any worsening such as spinal cord ischemia-reperfusion injury. Additionally, the physiological curvature and stability of the spine were restored.

## CONCLUSION

The rarity of DISH with Scheuermann disease and TSS in a 24-year-old patient poses a challenge in terms of early detection and diagnosis. Thus, medical practitioners should strive to broaden their knowledge and differential diagnosis skills regarding related diseases in order to improve the accuracy of diagnosis. By studying the clinical data and treatment experience of similar patients, doctors can gain a better understanding of DISH in young patients and reduce the chances of misdiagnosis or delayed diagnosis.

## FOOTNOTES

**Author contributions:** Liu WZ and Chang ZQ conceived the research, performed clinical examinations, and wrote and revised the manuscript; Bao ZM and Chang ZQ evaluated the imaging of the patient; and all authors contributed to the article and approved the final version. Liu WZ and Bao ZM are co-first authors of the article.

### Abstract

#### BACKGROUND

Extraskeletal osteosarcoma (ESOS) is a highly malignant osteosarcoma that occurs in extraskeletal tissues. It often affects the soft tissues of the limbs. ESOS is classified as primary or secondary. Here, we report a case of primary hepatic osteosarcoma in a 76-year-old male patient, which is very rare.

#### CASE SUMMARY

Here, we report a case of primary hepatic osteosarcoma in a 76-year-old male patient. The patient had a giant cystic-solid mass in the right hepatic lobe that was evident on ultrasound and computed tomography. Postoperative pathology and immunohistochemistry of the mass, which was surgically removed, suggested fibroblastic osteosarcoma. Hepatic osteosarcoma reoccurred 48 d after surgery, resulting in significant compression and narrowing of the hepatic segment of the inferior vena cava. Consequently, the patient underwent stent implantation in the inferior vena cava and transcatheter arterial chemoembolization. Unfortunately, the patient died of multiple organ failure postoperatively.

#### CONCLUSION

ESOS is a rare mesenchymal tumor with a short course and a high likelihood of metastasis and recurrence. The combination of surgical resection and chemotherapy may be the best treatment.

**Key Words:** Extraskeletal osteosarcoma; Hepatic; Primary; Relapsed; Case report

**Core Tip:** Hepatic osteosarcoma is a rare mesenchymal tumor with a short duration and a high likelihood of metastasis and recurrence. Although the imaging examination can help detect lesions, it is difficult to distinguish from other lesions with multiple osteosarcoma-like lesions and make accurate preoperative diagnosis. If hepatic osteosarcoma is suspected, a biopsy and surgery should be performed as soon as possible.

## INTRODUCTION

Extraskelletal osteosarcoma (ESOS) is a highly malignant osteosarcoma that occurs in extraosseous tissues. It is characterized by a low incidence, invasive growth, a high likelihood of metastasis and recurrence, and a poor prognosis[1]. ESOS often involves the soft tissues of the limbs. Few reports of ESOS occurring in organs are available, and relevant publications are mostly case reports[2,3]. The pathogenesis of ESOS is still unclear. The imaging manifestations of hepatic osteosarcoma are not specific, and its diagnosis depends on pathology and immunochemistry. The treatment of ESOS mainly relies on the combination of surgery, radiotherapy, and chemotherapy.

## CASE PRESENTATION

### Chief complaints

A 76-year-old male was readmitted to the hospital on September 14, 2020, due to abdominal distension and pain.

### History of present illness

The patient had a history of resection of malignancy and had undergone surgery for right hemihepatectomy more than a month prior; however, the patient's symptoms improved until significant abdominal distension developed a week ago.

### History of past illness

On July 20, 2020, the patient was admitted to the hospital due to aggravation of existing abdominal pain and discomfort. Abdominal color Doppler ultrasound suggested a giant mixed echogenic mass in the right hepatic lobe, and color Doppler flow imaging revealed a small number of blood flow signals in and around the mixed echogenic mass (Figure 1A). Computed tomography (CT) indicated liver enlargement and a giant cystic-solid mass in the right hepatic lobe, and an enhanced scan showed mild to moderate enhancement of the solid component of the mass (Figure 1B). On July 21, 2020, a hospital-wide general consultation was held. After analyzing the patient's imaging data, laboratory findings, and physical signs, doctors concluded that the large intrahepatic mass was malignant and that a mesenchymal origin was probable; furthermore, the patient was in a hypercoagulable state, and blood clots may occur during or after surgery. Ultimately, doctors who participated in the consultation believed that surgical resection and chemotherapy constituted the best treatment for this patient, as did the patient and his family. On July 28, 2020, the patient underwent right hemihepatectomy. During the operation, a cystic-solid mass was observed in the section of the liver next to the liver capsule. The cystic fluid was already lost, and the grayish-red and grayish-yellow solid areas of the tumor were soft with a cut-fish-like surface (Figure 2A). A rapid intraoperative pathology examination suggested mesenchymal sarcoma. Immunohistochemistry yielded the following results: CK (pan) (-), EMA (-), CD34 (-), S-100 (-), SMA (scattered -), STAT6 (-), Ki67 (+, 30%), SATB2 (partially weak +), p16 (-), CD163 (scattered +), CD68 (scattered +), CD56 (-), desmin (-), and H-Cald (-). Postoperative pathology and immunohistochemistry suggested fibroblastic osteosarcoma (Figures 2B and 2C). The patient received capecitabine monotherapy and was discharged on August 30, 2020.

### Personal and family history

The patient denied any family history of malignant tumors.

**Figure 1 Imaging examination.** A: Liver ultrasound: A giant mixed echogenic mass (as indicated by the red arrow, approximately 18 cm × 11 cm × 12 cm) was observed in the right lobe of the liver with poorly defined boundary, irregular morphology, and uneven internal echoes. The mass was mainly cystic, with multiple solid parts inside. CDFI: A small number of blood flow signals were visible in and around the mixed echogenic mass, and the intrahepatic and right hepatic veins were compressed and offset; B: Enhanced computed tomography (CT) scans: The liver was enlarged and there was a large cystic-solid mass (as indicated by the red arrow, approximately 17 cm × 13 cm × 12 cm) in the right hepatic lobe with irregular morphology, unclear boundary, uneven attenuation, and CT values ranging from 11 to 62 HU. The solid component of the mass was mildly to moderately enhanced. The arterial branches were observed in the mass. The intrahepatic and right hepatic veins and the right anterior branch of the portal vein were occluded.

DOI: 10.12998/wjcc.v11.i3.662 Copyright ©The Author(s) 2023.

**Figure 2 Pathology of hepatic osteosarcoma.** A: Macroscopic view: A cystic-solid mass was observed in the section of the liver next to the liver capsule. The cystic fluid was already lost, and the grayish-red and grayish-yellow solid area of the tumor was soft with a cut-fish-like surface; B: Pathological microscopy: The short spindle-shaped tumor cells had medium density, an increased nucleus-to-plasma ratio, atypical nuclei, and pathological mitosis. Some tumor cells were converted to osteoblasts. There was osteoid matrix between tumor cells and osteoclast-like giant cells; C: Immunohistochemistry: SATB2 was partially weakly positive.

### Physical examination

The abdominal muscles of the upper abdomen were slightly tense, tenderness was noted in the right upper quadrant, and percussion pain was evident in the liver area; the abdominal mass was not touched, and an old scar measuring approximately 14 cm long was visible in the right upper quadrant.

### Laboratory examinations

Laboratory tests indicated that inflammatory indicators were elevated, and cancer antigen 125 was slightly increased, suggesting poor liver and coagulation functions. In addition, alpha-fetoprotein was 7.86 ng/mL, a hepatitis B virus (HBV) surface antigen test and hepatitis C antibodies were negative, and HBV-DNA was < 1.00E + 02 IU/mL.

### Imaging examinations

Whole-abdomen nonenhanced and contrast-enhanced CT examinations indicated that the residual liver parenchyma had a patchy lesion with mixed attenuation and apparently uneven enhancement near the inferior vena cava and that the hepatic segment of the inferior vena cava was significantly compressed and narrowed (Figure 3), suggesting tumor recurrence.

## FINAL DIAGNOSIS

Given the patient's medical history, the final diagnosis was ESOS recurrence.

## TREATMENT

Considering that the patient had inferior vena cava compression, stenosis, and a large amount of ascites,

**Figure 3 Abdominal contrast-enhanced computed tomography.** The residual liver parenchyma showed a patchy lesion (as indicated by the red arrow, approximately 11 cm × 8 cm × 10 cm) with mixed attenuation and clear boundary near the inferior vena cava. The lesion grew out of the liver contour and had multiply small, patchy hypoattenuating areas. The lesion showed obviously uneven enhancement, while the hypoattenuating areas of the lesion had no obvious enhancement. The hepatic segment of the inferior vena cava was significantly compressed and narrowed.

inferior vena cava stent implantation and transcatheter arterial chemoembolization were carried out on September 22, 2020.

## OUTCOME AND FOLLOW-UP

The patient died on September 29, 2020, due to multiorgan failure after surgery.

## DISCUSSION

ESOS is a highly malignant osteosarcoma that occurs in extraosseous tissues. This tumor was first reported in 1941 by Wilson[4]. Its incidence is low, and it occurs primarily in elderly adults. The average age of patients with ESOS is 47.5 to 61 years. ESOS accounts for 1% of all soft tissue sarcomas and 4% of osteogenic osteosarcomas[5]. ESOS is characterized by invasive growth, a high likelihood of metastasis and recurrence, and a poor prognosis[1]. The initial clinical symptom is usually a painless mass[6]. ESOS often involves the soft tissues of the limbs. Few reports of ESOS occurring in organs are available, and most publications are case reports[2,3]. This study reports a primary osteosarcoma occurring on the liver, which is very rare, and only 13 articles were found in the literature search[2,7-18]. Of these patients, ten cases occurred in men, and three occurred in women. Five of the patients had underlying liver cirrhosis. Sumiyoshi and Niho[8] proposed possible tumorigenesis in mesenchymal tissue that proliferates in cirrhosis. However, in our case, the patient had no history of liver cirrhosis or chronic HBV and hepatitis C infection.

The pathogenesis of ESOS is still unclear. Two theories on the pathogenesis of ESOS have been proposed[19]: (1) The tissue residual theory: Residual mesenchymal components from the embryonic development stage form bone and osteosarcomas; and (2) The metaplasia theory: Interstitial fibroblasts in muscle tissues are converted into osteoblasts and chondroblasts in response to internal or external stimuli and then evolve into osteosarcoma. Currently, most scholars support the metaplasia theory. According to their origin, ESOS are classified as primary or secondary ESOS[20]. Primary ESOS occurs in extraskeletal organs and soft tissues and does not attach to the bone or periosteum. No primary ESOS is of bone origin. In contrast, secondary ESOS is mostly metastases from an osteosarcoma of bone origin to the extraskeletal organs and soft tissues or is secondary to certain primary diseases, such as myositis ossificans. In this report, except for the cystic-solid mass in the liver, no evidence of primary tumors or primary bone lesions was found. Therefore, osteosarcomatous foci in other parts of the body were excluded.

Although imaging examinations can help identify lesions, the imaging findings of hepatic osteosarcoma are nonspecific and not different from those of a variety of tumor-like lesions; consequently, hepatic osteosarcoma is difficult to accurately diagnose preoperatively. In this study, the hepatic osteosarcoma manifested as a cystic-solid mass. The histology of hepatic osteosarcoma is similar to that of skeletal osteosarcoma. Although the direct production of osteoid components by osteosarcoma cells has significant diagnostic value, it has no specificity[21]. Pathologists diagnose ESOS based on the appearance of osteoid matrix and osteoblastic-like tumor cells, the differentiation of tumors without fat cells, myogenic or neurogenic properties, and the absence of dedifferentiated or highly differentiated

liposarcoma components at specimen crossover and microscopy[22,23]. In this study, immunohistochemistry suggested SATB2 (partially weak+). Special AT-rich sequence-binding (SATB2) is a nuclear matrix-associated protein. SATB2 expression has tissue and stage specificity, and SATB2 is specifically expressed in glandular cells of the lower digestive tract and osteoblasts of bone tumors, which can be used as a marker for differential diagnosis[18]. This case is morphologically consistent with mesenchymal-derived sarcoma, with tumor cells producing a bone-like stroma, combined with positive immunohistochemical SATB2, which is consistent with the diagnosis of osteosarcoma. Therefore, the diagnosis of hepatic osteosarcoma still relies on pathology and immunochemistry.

At present, the treatment of ESOS mainly relies on the combination of surgery, radiotherapy, and chemotherapy. Radical surgery is considered to reduce local recurrence of ESOS but has no obvious inhibitory effect on the distant metastasis of tumors[24]. As adjuvant therapies for ESOS, radiotherapy and chemotherapy are helpful for improving the tumor resection rate and reducing local recurrence and distant metastasis. Since osteosarcoma is a malignant tumor, ESOS has a short course, rapid progression, a high local recurrence rate, and a high risk of distant metastasis[2]. Lee *et al*[19] reported that the 5-year survival rate of a group of patients diagnosed with ESOS was only 37% and that most of them died within 2 to 3 years after the initial diagnosis. Studies have demonstrated that distant metastasis, large tumors ( $\geq 10$  cm), tumors of the axial skeleton, and advanced age are poor prognostic factors for ESOS, while radiotherapy and chemotherapy have no significant correlation with mortality [25-28]. The patient described in this study was 76 years old. He had a large intrahepatic tumor measuring 17-18 cm. After surgical resection, he underwent chemotherapy. However, local recurrence occurred within a short time after surgery, and the disease progressed rapidly. The patient died within 3 mo after symptom onset. Among the 13 primary hepatic osteosarcoma cases in the literature, most patients died within 2 to 4 mo after initial diagnosis[2,7-15,17,18], but one article reported no tumors within 3 years of surgical resection and adjuvant chemotherapy[16]. At present, the treatment methods for hepatic osteosarcoma are similar to those used for other soft tissue sarcomas. Because this disease is rare, no evidence-based treatment plan has been established to date. Surgical resection combined with adjuvant chemoradiotherapy seems to be the best treatment option[24,25,28-30].

## CONCLUSION

Hepatic osteosarcoma is a rare mesenchymal tumor with a short course and a high likelihood of metastasis and recurrence and is difficult to distinguish from other tumors by imaging. Its diagnosis still relies on pathological and immunochemical examinations. Compared with simple surgery or chemotherapy, the combination of surgical resection and chemotherapy may be the best treatment for the disease, which can slow disease progression, reduce the recurrence frequency, and prolong patient survival.

### Abstract

#### BACKGROUND

Heterotopic pregnancy (HP) is a rare condition in which both ectopic and intrauterine pregnancies occur. HP is uncommon after natural conception but has recently received more attention due to the widespread use of assisted reproductive techniques (ART) such as ovulation promotion therapy.

#### CASE SUMMARY

Here, we describe a case of HP that occurred after ART with concurrent tubal and intrauterine singleton pregnancies. This was treated successfully with surgery to preserve the intrauterine pregnancy, resulting in the birth of a low-weight premature infant. This case report aims to increase awareness of the possibility of HP during routine first-trimester ultrasound examinations, especially in pregnancies resulting from ART and even if multiple intrauterine pregnancies are present.

#### CONCLUSION

This case alerts us to the importance of comprehensive data collection during regular consultations. It is important for us to remind ourselves of the possibility of HP in all patients presenting after ART, especially in women with an established and stable intrauterine pregnancy that complain of constant abdominal discomfort and also in women with an unusually raised human chorionic gonadotropin level compared with simplex intrauterine pregnancy. This will allow symptomatic and timely treatment of patients with better results.

**Key Words:** Heterotopic pregnancy; Assisted reproductive techniques; Preterm labor; Premature rupture of membranes; Case report

**Core Tip:** Extrauterine pregnancies are collectively known as ectopic pregnancies. Heterotopic pregnancy (HP) is a rare type of ectopic pregnancy where both ectopic and intrauterine pregnancies occur. The more frequent use of assisted reproductive technologies (ART) leads to a rise in ectopic pregnancy, consequently leading to an increase in the incidence of HP. We report a case of HP that occurred after ART. Combined with the analysis of the cases indexed in PubMed, we concluded several possible factors related to the correlation. Symptomatic and timeous treatment of patients could lead to improved outcomes.

## INTRODUCTION

Ectopic pregnancies occur in 1%–2% of all pregnancies. Heterotopic pregnancy (HP) is a rare type of ectopic pregnancy that involves the coexistence of both intrauterine and ectopic pregnancies. A recently estimated incidence of HP is about 1/30000 [1] in spontaneous pregnancies, increasing to 1/360 to 1/100 [2] in pregnancies resulting from assisted reproductive techniques (ART). ART can result in pelvic inflammatory disease which also contributes to HP. Here, we describe a case of HP after ART in a 26-year-old woman, and through a literature review of previous cases, we summarize the possible causes and related mechanisms accounting for the higher rate of HP after ART.

## CASE PRESENTATION

### Chief complaints

A 26-year-old Chinese woman presented to the gynecology clinic with a complaint that led to the suspicion of HP.

### History of present illness

Suspicion of heterotopic pregnancy after *in vitro* fertilization and embryo transfer cycles (IVF-ET).

### History of past illness

Three months before, the patient presented to our reproductive department with a complaint of infertility. After a detailed examination, she was diagnosed with primary infertility, polycystic ovary syndrome, and compound chronic inflammation of the left fallopian tube. Her husband's semen analysis revealed mild asthenospermia. After obtaining their consent, ART was performed.

The patient was pretreated with oral medroxyprogesterone pills (2 mg per pill) given at a dose of 20 mg per day for seven days until the following menses. Controlled ovarian hyperstimulation (COH) was performed on the third day of the period with the use of clomiphene citrate pills (100 mg qd) for five days. After completion of this oral management, the COH was continued with urofollitropin for injection (uFSH) (75 units qd) for four days, with the addition of the same dose of menotrophin for the following four days. Follicle maturation was monitored by ultrasonography. After three days, instead of repeated COH by injection, the patient received further treatment with chorionic gonadotrophin given at a dose of 10000 units and it was suggested that she had sex on that day with the expectation of natural conception.

Two days later, ovulation of the right ovary was detected on the ultrasound scan, and we suggested that the patient take vitamin complex tablets from then onward as well as dydrogesterone starting two days hence to form a habitable place for a fetus and create a suitable internal environment to nurture a growing child.

The urinary pregnancy test was positive 15 days after ovulation and the serum human chorionic gonadotropin (hCG) level was 520 mIU/mL. A transvaginal ultrasound examination showed an intrauterine pregnancy with a 10-mm-thick endometrium at the C stage, with six follicles in the right ovary, four echoless regions in the left ovary, and mild pelvic effusion. Early intrauterine pregnancy with additional ectopic pregnancy in the right tube was strongly suspected due to the enhanced clinical clues. As the patient was strongly in favor of continuing the pregnancy, they decided to anticipate spontaneous abortion of the ectopic pregnancy and treated the intrauterine pregnancy as before.

Six days later, the follow-up serum hCG level was 3754.54 mIU/mL and transvaginal sonography reexamination showed an intrauterine singleton without a clearly visible yolk sac and multiple echoless areas in the bilateral adnexa. Finally, after another six days had passed, the detection of an intrauterine gestational sac (GS) of 14 mm × 6.0 mm, an embryonic bud of 3 mm, an embryonic heartbeat, and a GS of 9 mm × 7 mm with a yolk sac beside the right ovary confirmed the presence of HP. These findings combined with the clinical factors provided the main indications for surgery. (Figure 1) Having taken our advice, the patient (1 gravida, 0 para) presented to the gynecology clinic.

### **Personal and family history**

The patient denied any family history of malignant tumors.

### **Physical examination**

On physical examination, the vital signs were as follows: Body temperature, 36.5°C; blood pressure, 115/85 mmHg; heart rate, 97 beats per min; respiratory rate, 19 breaths per min.

### **Laboratory examinations**

The human chorionic gonadotropin level was 20295.14 mIU/mL.

### **Imaging examinations**

An intrauterine gestational sac appropriate for seven weeks of pregnancy was seen on transvaginal sonography (Figure 2A). Both ovaries were larger than normal, with dimensions of 11 cm × 5 cm for the right and 8 cm × 4 cm for the left. A mass in the right ovary suggested the presence of an ectopic pregnancy (Figure 2B).

---

## **FINAL DIAGNOSIS**

Combined with the patient's medical history and intraoperative findings, the final diagnosis was HP.

---

## **TREATMENT**

Laparoscopic surgery was performed. On removal of the blood in the peritoneal cavity (approximately 300 mL), the bilateral ovaries were immediately visible, clearly larger than normal as had been seen on the transvaginal sonography. The right fallopian tube was thickened with a bluish-purple lump of approximately 5.0 cm × 3.0 cm. The left fallopian tube was normal. The uterus was regular in shape and normal in size. After sufficient and short intraoperative communication with her medical authorizer, the surgeon excised the swollen right fallopian tube. During the operation, the estimated blood extravasation was approximately 50 mL. After the operation, the patient was given Ceftriaxone Sodium injection (0.2 g bid) to prevent inflammation which was discontinued after normal WBC counts were obtained on routine blood test reexamination. The patient recovered well during the remaining hospitalization and her reexamination by transvaginal sonography was satisfactory (Figure 3). She was discharged six days after surgery and was monitored for the duration of her pregnancy.

---

## **OUTCOME AND FOLLOW-UP**

The patient's obstetric follow-ups and fetal assessments were normal showing good fetal growth of her intrauterine singleton. The course of pregnancy was unremarkable until the patient experienced contractions at 30+5 wk of gestation. She was admitted to the hospital and, after confirming premature rupture of membranes, cervical effacement, and complete cervical dilatation, we continued with the delivery process, resulting in a baby boy with a birth weight of 1430 g. He was admitted to the neonatal unit. The postpartum course was uneventful for both the mother and baby.

---

## **DISCUSSION**

Many recent articles on ART have paid particular attention to the link between ART and an increased incidence of HP, with some reports indicating HP rates as high as 8.6% after ART[3].

HP is diagnosed when ultrasound findings demonstrate an intrauterine pregnancy and a concurrent ectopic pregnancy[4]. As discussed in the Introduction, there is inescapable evidence that the incidence of HP is higher in pregnancies resulting from ART than in spontaneous pregnancies. However, many cases are still clinically misdiagnosed during first-trimester examinations due to poor awareness of this

**Figure 1 The complete process of diagnosis and treatment of the patient.** ART: Assisted reproductive techniques; hCG: Human chorionic gonadotropin; HP: Heterotopic pregnancy; PCOS: Polycystic ovary syndrome; TVS: Transvaginal scanning; uFSH: Urofollitropin for injection.

**Figure 2 Transvaginal sonography.** A: The intrauterine gestational sac was about 7 wk of pregnancy; B: The bilateral ovaries were larger than normal. The left ovary measured 8 cm × 4 cm, while the right ovarian mass measured about 11 cm × 5 cm, suggestive of an ectopic pregnancy.

fact[5]. The differences in HP incidence between natural HP and HP after IVF-ET are apparent and present an additional problem, namely, how to explain this phenomenon and how to prevent it.

To answer this question, we first need to understand the ART procedure itself, which includes all clinical fertility treatments. In this respect, after analysis of earlier studies, we focus on the IVF-ET, typically performed by culturing embryos for a few days before transferring them through the cervix to the uterus. IVF-ET consists of four successive steps, commonly stated as stimulation of the growth of multiple ovarian follicles, egg retrieval from the woman's ovaries, fertilization in vitro, and, finally, the transfer of viable embryos into the uterine cavity (Figure 4). However, in many cases, these four steps are not fully performed due to reasons such as allowing the possibility of natural conception, as in the present case[6]. Furthermore, during the steps described above, there are several factors that predispose to higher rates of HP in pregnant women after ART[7].

Firstly, as in the case of the present patient, ovarian induction is widely used for the retrieval of multiple follicles, indicating the presence of often more than one follicle in the body ready to be fertilized after the intervention. Therefore, in the period following attempts at either natural or *in vitro* fertilization, multiple zygotes are often present, implying the availability of more than one embryo ready for implantation, which could occur spontaneously in different places. An experimental study has

Figure 4 Commonly used fertility treatments.

demonstrated that the adhesion of mouse embryos to the human endometrium reduces gradually with increasing concentrations of estradiol (E2)[8]. It has been shown that very high levels of serum E2 influence implantation[9,10]. Recent studies have also shown that normal gene expression in endometrial tissue is disturbed during IVF-ET cycles as a result of high levels of serum E2 or increases in follicular progesterone[11,12].

Secondly, the majority of patients undergoing IVF-ET suffer from one or more types of reproductive dysfunction, with tubal dysfunction accounting for approximately 95% of these[13,14]. Various processes, including ovum and sperm transport, fertilization, and early stages of embryogenesis, occur in the fallopian tubes[15]. Gametes and fertilized embryos are propelled along the tubes by the action of smooth muscles and ciliary beating[5,15], and dysfunction of these systems may affect the correct homing of the oocyte and embryo. A perusal of the recent literature supports the hypothesis that tubal implantation is a result of tubal malfunction, specifically caused by alterations both in tubal transport mechanisms and expression of factors normally responsible for preventing implantation within the fallopian tube[16-19]. Such malfunctions can result from disease, such as chronic salpingitis or the effects of surgery, as well as endocrine disruptions during ovulation induced by hyperstimulation by exogenous gonadotropins or the chronic administration of low-dose progestogen[15]. It is presumed that the amount of administered estrogen is sufficient to prevent increases in progesterone or its tubal effects, delaying the passage of the ovum through the ampulla-isthmus junction for sufficient time to allow hatching of the blastocyst in the ampulla. These mechanisms appear to be associated with an increased risk of HP[14,15].

However, some scientists hold a different perspective, namely, that the increased incidence of embryonic implantation outside the uterus is determined by the embryo itself rather than by tubal factors. E-cadherin is known to be responsible for the anchorage of placental villi and its expression is reduced when differentiation occurs outside of the villi. Previous studies on E-cadherin-knockout mice have shown that the protein is required for normal implantation, as knockout embryos did not form functional trophoblast and died during implantation[20]. In normal embryos, insulin-like growth

factor 1 receptor (IGF-1R) is present throughout the membrane but on activation, is found exclusively at cell contact sites, colocalizing with E-cadherin. It has been found that abrogation of IGF-1R signaling with specific inhibitors blocks trophoctoderm formation and compromises embryo survival during murine blastocyst formation and that E-cadherin is required to maintain the proper activation of IGF-1R. Perturbation of E-cadherin extracellular integrity, independent of its cell-adhesion function, was shown to block IGF-1R signaling, inducing cell death in the trophoctoderm, and thus indicating a crucial and non-substitutable role of E-cadherin for these processes[21]. Strong E-cadherin expression is only seen at tubal implantation sites in patients after IVF-ET[13]. E-cadherin staining in the fallopian tubes of IVF-ET patients has been found to be restricted to the trophoblast, supporting the hypothesis of the dominant influence of the embryo in ectopic pregnancy after IVF-ET treatment[13]. Thus, it is possible that ectopic pregnancies in IVF-ET patients with normal fallopian tubes may be associated with reduced abilities of the embryos for implantation.

Furthermore, ARTs, such as ovarian induction and oocyte retrieval, are known to enhance uterine contraction, which could also impede embryonic implantation[22].

The recognized risks of ectopic pregnancy have led clinicians to turn their attention to ways in which these risks can be reduced in clinical practice.

Firstly, to reduce the risk of multiple births, milder and more physiological approaches to ovarian stimulation during IVF-ET are being considered; these have been shown to have several advantages despite the likelihood of producing fewer embryos. The term mild-stimulation IVF (MS-IVF) is defined as the administration of follicle-stimulating hormone or human menopausal gonadotropin at lower doses or shorter durations during a cycle with co-treatment of gonadotropin-releasing hormone antagonists or the administration of oral anti-estrogens or aromatase inhibitors either individually or combined with gonadotropins to collect fewer oocytes[23]. The advantages of MS-IVF, namely, improved safety, tolerance, and affordability, in IVF-ET cycles have been demonstrated, and many studies have shown an association between this gentle stimulation and improved perinatal outcomes [24].

Secondly, to reduce the effects of reproductive disorders such as tubal dysfunction that hinder oocyte and zygote transport within the fallopian tube, it is advisable to instigate treatment to restore the system to its normal state as far as possible before ART[25]. In addition, considering prognosis and perinatal outcomes, salpingectomy is considered a better treatment for women diagnosed with ectopic pregnancy compared with conservative treatment due to the reduced likelihood of future ectopic pregnancies after treatment[26].

Furthermore, it is suggested that the optimum time for embryo transfer is five to six days after oocyte retrieval when the embryo is exactly in the blastocyst stage. This is supported not only by basic experimental studies but also by the consistent results of clinical trials[25-27].

In addition, options for embryo transfer are not only limited to the cleavage or blastocyst phases but also include techniques such as fresh or frozen embryo transfer. It has been found that the transfer of fresh blastocysts does not affect perinatal outcomes in singleton live births compared with the transfer after the cleavage stage[28]. No significant differences were observed in the incidence of ectopic pregnancy between fresh and frozen/thawed cycles in a large patient sample[22]. The risk of recurrent ectopic pregnancy was found to be lower with fresh embryo transfer[26]. However, no definite conclusions on the effects of fresh or frozen embryos on the risk of ectopic pregnancy can be made at this time, and further robust evidence is required.

## CONCLUSION

The increased incidence of HP is considered a clinical disadvantage of ART and also alerts us to the importance of collecting comprehensive data during regular consultations. It is important for us to remind ourselves of the possibility of HP in all patients presenting after ART, especially in women with an established and stable intrauterine pregnancy that complain of constant abdominal discomfort and also in women with unusually raised hCG levels compared with simplex intrauterine pregnancy. This will allow symptomatic and timely treatment of patients leading to improved outcomes.

## Abstract

### BACKGROUND

Brucellosis is the most common zoonosis worldwide and is endemic in the Middle East, Africa, Asia, and Latin America. However, it is uncommon in Central Europe, and periprosthetic infections caused by *Brucella* are therefore rare. Due to the low prevalence and nonspecific clinical presentation of the disease, accurate diagnosis can be challenging; no gold standard currently exists for treating brucellosis.

### CASE SUMMARY

Here, we present a 68-year-old Afghan woman living in Austria with a periprosthetic knee infection caused by *Brucella melitensis*. The interval from total knee arthroplasty to septic loosening was five years. A profound medical history and examinations suggested that the patient had been suffering from unrecognized chronic osteoarticular brucellosis prior to total knee arthroplasty. She was successfully treated by two-stage revision surgery and combined antibiotic therapy over three months.

### CONCLUSION

Clinicians should consider brucellosis as a possible cause of chronic arthralgia and periprosthetic infection in patients originating from countries with a high brucellosis burden.

**Key Words:** Brucellosis; Arthroplasty; Infection; Osteoarticular; Knee; Case report

## INTRODUCTION

Brucellosis is a zoonotic bacterial infection caused by different species of gram-negative coccobacilli *Brucellae*[1]. While it is the most common zoonosis worldwide and endemic in large parts of the Middle East, Mediterranean, Central Asia, Africa, and Latin America, it is rare in Central Europe and Northern America[2].

Transmission usually occurs through the consumption of unpasteurized milk, and less commonly through direct contact with animals or the inhalation of infected particles[3]. Diagnosis is made by serological tests for antibodies against *Brucella* and culture of blood, joint aspirates, or other tissue samples. Cultivation of germs may be hampered by the slow-growing nature of *Brucella* species and therefore culture can require prolonged incubation. Highly sensitive molecular methods (nucleic acid amplification tests) can enable a quick diagnosis; however, they are still under development and no sufficiently validated commercial tests are currently available[4].

The disease itself usually presents with nonspecific symptoms such as fever, fatigue, loss of appetite, and weight loss[3]. Hematogenous spread may affect any organ; however, osteoarticular involvement (arthritis, osteomyelitis) is the most common complication[3,5,6]. Periprosthetic infections due to *Brucella* are extremely rare, and only 30 cases have been reported in the literature to date[6,7].

## CASE PRESENTATION

### Chief complaints

In December 2020, a 68-year-old female presented with pain, redness, and swelling in her left knee.

### History of present illness

At the time of presentation, the complaints had been present for three months, and antibiotic therapy (oral amoxicillin 1 g twice daily) had already been started by her general practitioner.

### History of past illness

Total knee arthroplasty (TKA) in the affected joint had been performed five years prior due to osteoarthritis (Figure 1). The initial postoperative course was uneventful. In the following years however the patient repeatedly presented to our outpatient clinic with pain in the operated knee and lumbar spine. Complaints always improved with physiotherapy, oral pain medication, and local cryotherapy to the knee.

### Personal and family history

Neither the patient nor her family members had previous episodes of similar symptoms.

### Physical examination

There was marked effusion, warming, and swelling in the left knee. The range of motion was quite limited due to pain. The patient was afebrile without any feeling of illness.

### Laboratory examinations

The C-reactive protein (CRP) level was 2 mg/dL (norm < 1 mg/dL), and the leukocyte count was within the normal range. No aspirate could be withdrawn by intraarticular puncture.

**Figure 1** Radiograph showing total knee arthroplasty five days after surgery. A: Anterior-posterior view; B: Lateral view.

### Imaging examinations

X-ray imaging showed a tilt of the tibial plateau and radiolucent lines around the femoral component (Figure 2).

## INITIAL DIAGNOSIS AND TREATMENT

Despite suspicion of septic loosening, an outpatient procedure was initially agreed upon because the patient refused surgical intervention. Therefore, she was fitted with a rigid knee brace and antibiotic therapy with amoxicillin was continued. We scheduled her for a check-up in our orthopedic outpatient clinic.

One week later, the pain and redness were reduced and the CRP level and leukocyte count remained unchanged. However, considerable effusion remained. Ten milliliters of intraarticular serohemorrhagic fluid were aspirated, and qualitative determination of alpha-defensin (Synovasure®, Zimmer Biomet) was positive. The cell count in the aspirate was 9800: 76% of these cells were granulocytes, thus confirming a periprosthetic joint infection. Revision surgery was agreed upon with the patient.

After removal of the prosthesis, a mobile vancomycin- and gentamicin-loaded spacer (VancoGenx™ SPACE Knee, Medix Medical) was implanted (Figure 3). Seven tissue samples were taken intraoperatively for culture and histopathology, and the prosthesis was sent for sonication. The antibiotic regimen was changed to intravenous (*i.v.*) cefuroxime.

Eight days after surgery *Brucella melitensis* was successfully cultivated in synovial fluid. Serological tests were positive for antibodies against *Brucella melitensis* and *Brucella abortus*.

## FINAL DIAGNOSIS

The final diagnosis was a periprosthetic knee joint infection caused by *Brucella melitensis*.

## TREATMENT

Antibiotic therapy was adapted to oral doxycycline 200 mg daily plus oral rifampicin 450 mg twice daily for 12 wk, and *i.v.* gentamicin was administered for two weeks under the close monitoring of serum levels due to severe renal insufficiency. Six weeks after implant removal a revision TKA was performed. To protect the new prosthesis from superinfection with rifampicin-resistant *staphylococci*, our patient received a single 1.5 g shot of *i.v.* cefuroxime preoperatively and *i.v.* daptomycin 500 mg for 14 d after reimplantation. After a total of 12 wk targeted antibiotic therapy was terminated (Figure 4).

**Figure 4** Postoperative antibiotic regimen after implant removal.

## OUTCOME AND FOLLOW-UP

Nineteen months after reimplantation, the patient was free of pain and walked without crutches. The affected joint showed no swelling, and the active range of motion was 115 degrees without a fixed flexion deformity or extensor lag. Inflammatory markers were within the normal range, and the levels of anti-*Brucella* antibodies had decreased. X-ray imaging showed no signs of loosening (Figure 5).

## DISCUSSION

Periprosthetic infections with *Brucella* species are rare; therefore, diagnosis can be a challenge especially in nonendemic countries such as Austria. Our patient is originally from Afghanistan and had been living in Austria since 2013. The pain in her left knee started years before she emigrated to Austria, but no cause could be found in Afghanistan. TKA was performed in our department in 2015 after several attempts of conservative treatment for osteoarthritis.

When asked about the possible transmission of *Brucella* species, the patient denied consumption of unpasteurized milk or raw meat, but she reported that she had kept livestock in Afghanistan. The fact that the periprosthetic infection occurred five years after implantation but seven years after the last contact with livestock suggests that the patient had a latent infection with *Brucella melitensis* prior to TKA. Brucellosis has a tendency towards chronicity similar to tuberculosis. By evading the host immune defense, it can persist for long periods in practically any organ system, thus causing chronic granulomatous infections[5,8]. It is debatable whether the real cause of knee pain eventually leading to TKA in 2015 was chronic osteoarticular brucellosis rather than osteoarthritis. In fact, our patient complained of recurrent load-dependent knee pain after her initial surgery. Minimal effusion was observed in various visits to our department. There was no warming or redness, and the pain always improved with cryotherapy and oral analgesics. Minor radiolucent lines at the anterior and posterior flanges of the femoral component were already evident one year postoperatively (Figure 6). However, such radiological changes are common, and the incidence is reported to be up to 20% for the type of prosthesis used here[9,10]. Therefore, infection was suspected in December 2020 only because the patient had severe pain, and the X-ray showed definite signs of loosening.

After the diagnosis of brucellosis was confirmed we performed magnetic resonance imaging (MRI) of the spine due to the patient's history of chronic lower back pain. The MRI showed depleted intervertebral space in L4/L5 and post-inflammatory alterations indicating a residual state after spondylodiscitis. In conclusion, the history and clinical findings retrospectively and strongly suggest that the patient had suffered from chronic brucellosis with involvement of the knee and lumbar spine for years.

Our case also demonstrates the difficulty in detecting brucellosis especially because the patient was already receiving broad-spectrum penicillin when the diagnostic testing began. Culture was positive in one out of two synovial fluid samples and only one in seven intraoperative tissue samples. It took two weeks of culture until bacterial growth was noted. Sonication was negative. Antibody detection was performed after receiving the microbiological findings and was positive for *Brucella melitensis* and *Brucella abortus*; the latter, however, was considered a serological cross-reaction. Our diagnostic

DOI: 10.12998/wjcc.v11.i3.677 Copyright ©The Author(s) 2023.

**Figure 6** Radiograph one year after the initial surgery showing radiolucent lines around the femoral component. A: Anterior-posterior view; B: Lateral view.

experience is consistent with reports in the literature stating that the detection of brucellosis can be challenging and complicated by the long cultivation required due to slow bacterial growth[4,6,7]. We therefore concur with recommendations suggesting screening for anti-*Brucella* antibodies early in patients from endemic countries or in close contact with livestock[6,7]. When serology is positive, invasive procedures such as joint aspiration or surgery should be performed using special protection including an apron, eye protection, and filtering face piece-3 mask to prevent transmission *via* aerosols. Laboratory staff must be informed about special hazards when handling samples[6,7,11].

Treatment of systemic brucellosis requires antibiotic combination therapy for at least six weeks. Monotherapy or a shorter duration of therapy carries a high risk of treatment failure and relapse[3,7,8]. The most common antibiotic combinations are doxycycline plus rifampicin or doxycycline plus streptomycin. Fluoroquinolones, trimethoprim/sulfamethoxazole, or gentamicin are also used. To date, no gold standard in antibiotic combination and duration of therapy has been established[3,7].

Antibiotic therapy for at least 12 wk is recommended in osteoarticular brucellosis[7,12]. Antimicrobial therapy without surgical intervention may be feasible in cases of periprosthetic infection and the absence of radiological loosening[6,13,14]. Thus, successful outcomes have been reported in eight out of nine joints with periprosthetic infections due to *Brucella* and with well-fixed implants when treated solely with antibiotics over six to 52 wk[6]. However, the sample number of patients described is too small to derive firm recommendations. Revision surgery is mandatory in cases of loose implants. Good results have been described for both one-stage and two-stage revision surgery with short or long intervals[6,7]. The prognosis of brucellosis, whether local or systemic, is generally good: Mortality is low but with high morbidity due to the multilocal and often protracted course of disease[3].

We opted for a two-stage revision with a six-week interval given the long history of pain over three months and the profound radiological changes in our case. The antibiotic regimen consisted of doxycycline and rifampicin for 12 wk, gentamicin for two weeks after implant removal, and daptomycin for two weeks after reimplantation. No side effects (changes in blood count or transaminases) were encountered. The treatment of our patient with multiple comorbidities was an interdisciplinary challenge involving orthopedics, internal medicine, and microbiology, and we would like to thank all the disciplines for their contribution to the good outcome.

## CONCLUSION

Brucellosis can be easily missed given the low prevalence in nonendemic countries. We recommend that clinicians consider brucellosis as a possible cause for chronic arthralgia, backache, and periprosthetic infection in patients from countries with a high brucellosis burden. If brucellosis is considered, then serological tests should be performed prior to joint aspiration or surgery because those procedures pose a risk of transmission *via* aerosols and therefore require special safety precautions. There is currently no uniform treatment concept in surgical intervention or choice and duration of antibiotic therapy for periprosthetic joint infections caused by *Brucella*; however, our antibiotic regimen was successful and can be used to guide future cases.

### Abstract

#### BACKGROUND

This report describes and discusses recurrent intramuscular lipoma (IML) of the extensor pollicis brevis (EPB). An IML usually occurs in a large muscle of the limb or torso. Recurrence of IML is rare. Recurrent IMLs, especially those with unclear boundaries, necessitate complete excision. Several cases of IML in the hand have been reported. However, recurrent IML appearing along the muscle and tendon of EPB on wrist and forearm has not been reported yet.

#### CASE SUMMARY

In this report, the authors describe clinical and histopathological features of recurrent IML at EPB. A 42-year-old Asian woman presented with a slow-growing lump in her right forearm and wrist area six months ago. The patient had a history of surgery for a lipoma of the right forearm one year ago with a scar of 6 cm on the right forearm. magnetic resonance imaging confirmed that the lipomatous mass, which had attenuation similar to subcutaneous fat, had invaded the muscle layer of EPB. Excision and biopsy were performed under general anesthesia. On histological examination, it was identified as an IML showing mature adipocytes and skeletal muscle fibers. Therefore, surgery was terminated without further resection. No recurrence occurred during a follow-up of five years after surgery.

#### CONCLUSION

Recurrent IML in the wrist must be examined to differentiate it from sarcoma. Damage to surrounding tissues should be minimized during excision.

**Key Words:** Intramuscular; Lipoma; Recurrence; Wrist; Case report

**Core Tip:** Lipoma is one of the most common benign tumors. Intramuscular lipoma (IML) is a lipoma that has invaded the muscular layer, sometimes with unclear boundaries. It may recur if complete resection is not performed. IMLs that recur with unclear boundaries might need to be differentiated from soft tissue sarcoma. Therefore, imaging tests such as computed tomography or magnetic resonance imaging should be performed before surgery and a thorough preoperative plan should be established to reduce recurrence and preserve hand function.

## INTRODUCTION

A lipoma is a common benign mesenchymal tumor that can occur anywhere in our body. It is one of the most common soft tissue tumors[1]. Lipomas are usually capsulized and well distinguished from surrounding subcutaneous adipose tissues. However, when they infiltrate structures such as muscles, nerves, or synovium, they are less circumscribed and not well-distinguished from surrounding tissues than usual lipoma. Among them, cases of invasion of the muscle layer are called intramuscular lipoma (IML) or infiltrating lipoma[2]. As reported in several cases, IML usually occurs in a large muscle of the limb or torso[3-8]. To treat an IML, complete removal including capsules is performed, similar to conventional lipoma treatment methods. However, of all IMLs, 83% are infiltrative and 17% are well-defined. In case of infiltrative IML, it is difficult to distinguish from surrounding tissues[4]. There are also important structures around the periphery of the IML that can make it difficult to achieve complete excision. There is a possibility of recurrence if there is no complete excision[5,8]. Additionally, it might be difficult to differentiate a recurrent IML from well-differentiated liposarcoma, because an IML is clinically or histologically indistinguishable from a well-differentiated liposarcoma[4,9]. Therefore, it is important to perform a preoperative radiology examination. Magnetic resonance imaging (MRI) is a device that can effectively diagnose lipoma. It can also help diagnose IML[10]. In this report, the authors report a recurrent IML in the extensor pollicis brevis (EPB) muscle treated surgically without showing any signs of recurrence after five years of follow-up.

## CASE PRESENTATION

### Chief complaints

A 42-year-old Asian woman presented with a slow-growing lump in her right forearm and wrist area six months ago.

### History of present illness

Symptoms started six months ago with a recurrent lump on the previous operative wounds of wrist and forearm.

### History of past illness

The patient had a history of surgery with a lipoma of the right forearm one year ago and had a scar of 6 cm on the right forearm. There was no other medical history or surgical history.

### Personal and family history

The patient denied any family history of tumors.

### Physical examination

Soft, painless lumps along the EPB of the right thumb were found on physical examination. One had a size of 1 cm × 2 cm in the medial area of the right wrist. One had a size of 2 cm × 5 cm on the medial side of the forearm. Her sensation of fingers and wrists, range of motion, and motor power were all normal (Figure 1).

DOI: 10.12998/wjcc.v11.i3.684 Copyright ©The Author(s) 2023.

**Figure 1 Preoperative photographs.** A: One 2 cm × 5 cm in size in the medial part of the forearm; B and C: A soft, painless lump was palpated along the extensor pollicis brevis of the right thumb, one 1 cm × 2 cm in size on the medial side of the right wrist. The black dotted line signifies the border of the lump to the touch. The patient's sensation, range of motion of fingers and wrists, and motor power were normal. The previously operated scar is identified about 6 cm on the radial side of the right forearm.

### Laboratory examinations

There were no specific findings in laboratory examinations.

### Imaging examinations

MRIs showed lumps in muscles and ligaments of EPB that appeared to be due to fat attenuation. Invaded muscles and ligaments showed unclear boundaries (Figure 2).

---

## FINAL DIAGNOSIS

Biopsy results also confirmed the IML of EPB (Figure 3).

---

## TREATMENT

General anesthesia was performed with inhalation anesthesia using sevoflurane after induction using intravenous propofol. After drawing a longitudinal 12 cm incision along the path of the EPB and previous scars, incision was performed with No 15-scalpel blade. Intact presence of the superficial radial nerve and artery running next to the EPB was confirmed. After meticulous dissection of adjacent normal tissues (including muscles, ligaments, nerves, blood vessels, *etc.*), the IML was exposed using sharp mosquito. A lipomatous mass with a lobulated aspect measuring 12 cm × 4 cm × 5 cm was invading muscles and ligaments (Figures 4 and 5). Blunt Metzenbaum scissor and electrocautery were then used to remove the mass. 200cc HemoVAC was inserted after normal saline irrigation. The superficial fascia and subcutaneous layer were sutured layer by layer with 4-0 Maxon and the skin was sutured with 5-0 Nylon.

---

## OUTCOME AND FOLLOW-UP

Immediately after the surgery, her sensory function was intact and circulation was well maintained (Figure 6). Her extension power was slightly weakened by partial excision of the EPB. However, her extension function was preserved. After 5 years of follow-up, there were no recurrences, side effects, or functional limitations.

**Figure 2** Preoperative magnetic resonance imaging showing lipomatous masses with fat-like attenuation in extensor pollicis brevis muscles and ligaments. A: In the coronal view, lipomatous mass infiltrated in the muscle was identified. Boundaries with surrounding muscles and ligaments were unclear; B: In the axial view, lipomatous mass of similar attenuate to fat was identified. An orange arrow indicates a lipomatous mass that infiltrates muscle and ligaments.

DOI: 10.12998/wjcc.v11.i3.684 Copyright ©The Author(s) 2023.

**Figure 3** Histological findings. A: Microscopic findings of intramuscular lipomas showing mature adipocytes and skeletal muscle fibers (pink color) ( $\times 10.25$  magnification, hematoxylin and eosin staining); B: Skeletal muscle fibers (pink color) are observed between mature adipocytes ( $\times 100$  magnification, hematoxylin and eosin staining). Yellow arrows indicate muscle components in fat. Blue arrows indicate muscle belly of extensor pollicis brevis.

## DISCUSSION

An IML can be distinguished from a conventional lipoma by its rarity and its clinical and pathological characteristics[2]. Histologically, IML can be divided into an infiltrative type, a well-circumscribed type, and a mixed type. Among them, the infiltrative type of IML has distinctive features[11-13]. Clinically, IMLs are characterized by a slow-growing mass that is asymptomatic or accompanied by local edema. Pain is a rare symptom that appears at the end of the course of the disease. It can occur when a deep, huge lipoma causes nerve compression with a mass effect or compresses surrounding soft tissues[12]. In some cases, it has been reported that IML itself is associated with functional limitation of muscles[13, 14]. Paresthesia and nerve distribution caused by nerve impingement are also among symptoms that might appear[15,16]. Trauma, chronic irritation, obesity, developmental disorders, endocrine, dysmetabolic factors, and genetic factors have been suggested to play roles in the pathogenesis of IML [17-19].

Papakostas *et al*[6] have reported cases of IML of the thenar. Lui[7] have reported cases of IML occurring in the abductor digiti minimi. Kim *et al*[1] have presented a lipoma occurring in the flexor tenosynovium. Kostas-Agnantis *et al*[20] have reported a lipoma case in the palmaris longus tendon. Lee *et al*[15] have reported cases of IML occurring in thenar and hypothenar area. However, cases of recurrent IML involving both extensor muscle and tendinous portion at the wrist and forearm level have not been reported yet.

Murphey *et al*[10] have stated that there is no possibility of malignant transformation of lipomas. It was often claimed that the reports were probably sampling errors or misdiagnoses.

Currently, the recurrence rate of IML is believed to be very low[21]. The patient in this case had previously undergone a surgery. However, it was not completely removed during the previous operation, which might have led to the recurrent. Therefore, attention should be paid to complete

DOI: 10.12998/wjcc.v11.i3.684 Copyright ©The Author(s) 2023.

**Figure 4 Intraoperative photographs.** A: The previous surgical scar was used, and an incision was applied along the run of the extensor pollicis brevis (EPB) to expose the lipomatous mass. A radial artery marked with yellow vessel loop and lipoma in the EPB tendon sheath marked with blue vessel loop were identified; B: Lipoma infiltrating into the muscle portion of EPB was removed while preserving the superficial radial nerve marked with yellow and red arrows.

DOI: 10.12998/wjcc.v11.i3.684 Copyright ©The Author(s) 2023.

**Figure 5 Photograph of the specimen.** A lipomatous mass of 12 cm × 4 cm × 5 cm was excised. It infiltrated the extensor pollicis brevis (EPB) muscle and tendon sheath. Most of the mass burden was located in the muscle portion of the EPB, presenting as yellow tissue with lobulated aspect and muscular fibers throughout.

excision to reduce the possibility of recurrence and to exclude the possibility of malignancy. By minimizing trauma and meticulous dissection during the surgical procedure, both nerves and blood vessels were preserved with only the area with lipoma invasion removed. The patient has been observed for five years without showing any signs of recurrence.

Computed tomography scan and MRI are both useful for detecting IML and evaluating its invasion in surrounding tissues[10,22]. On computed tomography (CT) scan, IML in the muscle shows a hypodense mass, similar to dense subcutaneous fat[23]. Its morphology can vary widely, ranging from ovoid to fusiform. Its margin might be well-circumscribed or infiltrative[24]. In MRI, IML appears to show a high signal in both T1 and T2, similar to fatty tissue with low signal similar to normal fat in fat-suppressed sequences[10]. MRI can identify IML more specifically than CT. However, results seen on the image might not be exactly the same as actual histological examination results[10].

Histopathologic exam is one of the essential tests for diagnosis. In most cases, there is a uniform appearance of mature uni-vacuolated adipocytes with uniform size and shape. In rare cases, IML can

DOI: 10.12998/wjcc.v11.i3.684 Copyright ©The Author(s) 2023.

**Figure 6 Postoperative photographs.** A and B: Primary closure was performed after removal of the intramuscular lipoma and 200cc Hemovac was inserted. There was no contour deformity on postoperative physical examination. Sensory function was intact, and circulation was well maintained; C: However, some extensor pollicis brevis motor weakness occurred. Nevertheless, no deformation of the thumb was seen in the neutral state. Other ranges of motion remained intact.

invade muscles, fascia, and tendon[11]. Histological and cytological analyses of IML are extremely important for differentiating it from well-differentiated liposarcoma. Well-differentiated liposarcomas differ from normal IMLs in the presence of atypical cells, vacuolated lipoblasts admixed with fibroblasts-like spindle cells, and several other features[25].

## CONCLUSION

In conclusion, considering that IML can occur and recur in hand muscles as observed in this case, careful physical examination and imaging examination should be performed before surgery to diagnose it and completely remove it to reduce the recurrence rate. Additionally, since hands have many important structures, careful attention should be paid to effectively removing the IMLs while preserving surrounding nerves, blood vessels, and ligaments.

## Abstract

### BACKGROUND

Hemangioblastoma typically occurs in the cerebellum, spinal cord, and central nervous system. However, in rare cases, it could occur in the retina or optic nerve. The prevalence of retinal hemangioblastoma is 1 in 73080, and it occurs either alone or as the manifestation of von Hippel Lindau (VHL) disease. Here, we reported a rare case with the imaging features of retinal hemangioblastoma without VHL syndrome, along with the relevant literature review.

### CASE SUMMARY

A 53-year-old man had progressive swelling, pain and blurred vision in the left eye without obvious inducement for 15 d. Ultrasonography revealed a possible optic nerve head melanoma. Computed tomography (CT) showed punctate calcification on the posterior wall of the left eye ring and small patchy soft tissue density in the posterior part of the eyeball. Magnetic resonance imaging showed slightly hyperintense signal on T1-weighted images and slightly hypointense-to-isointense signal on T2-weighted images at the medial and posterior edges of the left eyeball, a significant enhancement was observed in the contrast-enhanced scans. Positron emission tomography/CT fusion images showed that the glucose

metabolism of the lesion was normal. Pathology was consistent with hemangioblastoma.

## CONCLUSION

Early identification of retinal hemangioblastoma based on imaging features is of great value for its personalized treatment.

## INTRODUCTION

Retinal hemangioblastoma (RCH) is a rare benign tumor that was first reported by Von Hippel, a German ophthalmologist, in 1911. Since then, more than 900 families worldwide have been diagnosed with the disease[1]. RCH has also been shown to be the most common and earliest manifestation in 49%-85% of patients with von Hippel Lindau (VHL) disease, and only a very small number of cases are sporadic. Its diagnosis is mainly based on clinical suspicion and confirmation by molecular testing and imaging techniques[2-4]. Moreover, retinal hemangiomas can be usually observed directly and diagnosed by eye fundus examination, which may be the main reason why radiologists infrequently perform RCH diagnosis. We retrospectively analyzed the relevant literature and found that the imaging features of RCH are rarely reported[1-11]. Herein, we reported the computed tomography (CT), magnetic resonance (MR) imaging, and positron emission tomography (PET)/CT features of a sporadic RCH case.

## CASE PRESENTATION

### Chief complaints

On February 23, 2022, a 53-year-old male was admitted to our hospital because of 15 d history of progressive swelling, pain and blurred vision in the left eye, in the absence of obvious inducement.

### History of present illness

Fifteen days ago, the patient developed swelling, pain and blurred vision in the left eye, and was admitted to the 9<sup>th</sup> Hospital of Hangzhou. He was diagnosed with "neovascular glaucoma" and was given tobramycin dexamethasone eye drops and pranoprofen eye drops for anti-inflammatory therapy, timolol eye drops and brinzolamide eye drops for ocular hypotensive therapy. However, the disease symptoms did not improve, and he visited the First People's Hospital of Hangzhou on February 23, 2022, for further diagnosis and treatment.

### **History of past illness**

The patient had no past illness.

### **Personal and family history**

The patient had no special personal or family history of illness.

### **Physical examination**

Ophthalmological examination showed that visio oculus dexter was 0.8 and Visus Oculi Sinistri was sensitive to light (mainly contains distorted light that is located above and below the nose). Noncontact tonometer showed that R/L = 16.3/Tn + 3 mmHg. There was no hyperemia of right bulbar conjunctiva. The cornea was clear and the depth of anterior chamber was satisfactory. Pupils were round in shape and reactive to light while light was mixed in the lens of right eye, optic disc boundary was clear and flat, while omentum was located in the fundus, mixed congestion in the conjunctiva of left eye and corneal edema were also noted. There was mild swelling in one-third of the anterior chamber, pupil was round in shape and not reactive to light and it was not extending to posterior chamber of eye, while the other details were unclear.

### **Laboratory examinations**

Relevant antibody tests and other laboratory tests were further performed, and the results were all negative.

### **Imaging examinations**

Ophthalmic ultrasound showed a solid lesion in the left eye, indicating possible optic nerve head melanoma (Figure 1). CT showed patchy slightly hyperdense shadows anterior to the posterior wall of the left eyeball, suggesting a mass (Figure 2A and B). MR imaging showed left eyeball mass with slightly short T1, equal short T2 abnormal signals, about 8 mm × 5 mm in size, which were significantly enhanced after contrast enhancement (Figure 2C-H). PET/CT fusion images showed that the posterior left eyeball was locally thickened. The glucose metabolism of the lesion was normal (Figure 3). No significant abnormality was observed in the pancreas, spinal cord, cerebellum, adrenal gland, or kidney. The patient signed a written informed consent form before the examination. This retrospective study involving human participants was reviewed and approved by the Medical Ethics Committee of Hangzhou First People's Hospital, Zhejiang University School of Medicine (Approval No. 2022-007-01).

---

## **FINAL DIAGNOSIS**

Postoperative histopathological findings showed that the "left eyeball" lesion was consistent with hemangioblastoma, with a maximum tumor diameter of 0.4 cm and no involvement of the optic nerve resection margin. Immunohistochemical results showed D2-40 focal [+], inhibin focal [+], S-100 few [+], CD34 vessels [+], CD56 [-], NSE [-], CD68 [-], CD163 [-], GFAP [-], CD10 [-], MelanA [-], EMA [-], CK [-], SOX10 [-], and Ki-67 [+], 1%-2% (Figure 4).

---

## **TREATMENT**

After excluding surgical contraindications, the patient underwent "left eye enucleation" under general anesthesia on March 4, 2022, and received postoperative anti-inflammatory treatment with levofloxacin eye drops and tobramycin dexamethasone eye ointment (TobraDex ointment).

---

## **OUTCOME AND FOLLOW-UP**

Early identification of retinal hemangioblastoma based on imaging features is of great value for its personalized treatment.

---

## **DISCUSSION**

The retinal hemangioblastoma in the present case was a solid mass, and ultrasound showed an isoechoic mass. CT showed a mildly hyperdense patchy lesion surrounded by spotty calcifications. MR imaging showed a slightly hyperintense signal on T1-weighted images and slightly hypointense-to-isointense signal on T2-weighted images, and the lesions were significantly enhanced after Gadolinium-

DOI: 10.12998/wjcc.v11.i3.692 Copyright ©The Author(s) 2023.

**Figure 1** Ultrasound images of left retinal hemangioblastoma. A: Ultrasound showed an irregular isoechoic mass of about 6.3 mm × 7.4 mm in front of the left optic nerve head; B: Color doppler flow imaging showed abundant blood flow signals in the lesion.

DOI: 10.12998/wjcc.v11.i3.692 Copyright ©The Author(s) 2023.

**Figure 2** Computed tomography and magnetic resonance imaging of left retinal hemangioblastoma. A: Computed tomography (CT) transverse soft tissue window of orbit showed punctate calcification on the posterior wall of the left eye ring and small patchy soft tissue density in the posterior part of the eyeball. The lesion measured about 5 mm × 8 mm, with an ill-defined border; B: CT transverse bone window of orbital showed no obvious abnormal change of orbital bone; C: The lesion was hypointense on transaxial T2-weighted sequence; D and E: The lesion was slightly hyperintense on transaxial T1-weighted images (D) and transaxial T1-weighted + fat-suppression images (E); F-H: Left posterior para-bulbar lesions were significantly enhanced on gadolinium-enhanced T1-weighted + fat-suppression images [mainly included transverse (F), coronal (G), and sagittal sequences (H)] (White arrows represent lesion).

DTPA injection. PET/CT showed no abnormally increased metabolism of the lesion. These imaging features mainly depended on its histological structure. Retinal hemangioblastoma is mainly composed of vacuolar interstitial cells and abundant capillary networks. Interstitial cells are the main component of the tumor, which are rarely associated with necrotic or specific infectious components, while PET metabolism is characterized by minor metabolic changes due to the competition between tumor cells and macrophages[12,13]. Moreover, retinal hemangioblastomas show low levels of 18F-FDG dose that may be associated with over-expression of somatostatin receptors on the surface of tumor cells, and the PET/CT findings are consistent with Papadakis *et al*[9]. Furthermore, retinal hemangioblastoma is essentially a vascular lesion, and these tumors release various angiogenic factors, including vascular endothelial growth factor (VEGR), erythropoietin, and platelet-derived growth factor[14,15]. Vascular endothelial growth factor was significantly increased, which can induce massive capillary proliferation and increase vascular permeability, which leads to significant vascular-like enhancement of the lesion. In addition, hemangioblastoma has different imaging features based on different sites of occurrence. Solid tumors are also the main form of optic nerve hemangioblastoma, but most of the lesions are

DOI: 10.12998/wjcc.v11.i3.692 Copyright ©The Author(s) 2023.

**Figure 3** Transaxial computed tomography image, transaxial and coronal positron emission tomography metabolograms, color fusion map of positron emission tomography / computed tomography images at the orbital level. The transaxial computed tomography (CT) image at the orbital level showed a patchy slightly hyperdense lesion. The transaxial positron emission tomography (PET) metabologram, coronal PET metabologram and PET/CT color fusion map at the orbital level showed no metabolic changes, and its  $SUV_{max}$  was 50.9.

surrounded by edema[16]. Large cysts with small nodules are characteristic of cerebellar and spinal hemangioblastomas, and are mainly associated with intratumoral and peritumoral flow void effects [17]. According to the location and imaging characteristics of the lesion, hemangioblastomas also need to be differentiated from the following diseases. Choroidal melanoma: It is the most common ocular malignancy in adults, wherein CT shows a localized well-defined mass isodense to the extraocular muscles, generally without calcification. MR imaging shows hyperintense signal on T1-weighted images and hypointense signal on T2-weighted images, which is the characteristic feature, because the tumor contains paramagnetic melanin material. It also shows mild to moderate enhancement after contrast enhancement. PET metabolism indicated that glucose uptake was often increased in choroidal melanoma, and its  $SUV_{max}$  was  $> 10$ [18,19]. Therefore, it is not difficult to differentiate from this case of retinal hemangioblastoma. Choroidal hemangioma: CT shows local thickening of eyeball wall. It shows progressive significant enhancement after contrast enhancement. MR imaging shows higher signal than vitreous on T1-weighted images and lower than vitreous on T2-weighted images, but isointense signal compared with optic nerve and extraocular muscles on T2-weighted images, 90% of patients have concomitant mild retinal detachment. It shows progressive significant enhancement after contrast enhancement. PET metabolism suggests that choroidal hemangioma usually has no change in glucose uptake[20,21]. Therefore, enhanced dynamic delayed scanning is of great significance in the diagnosis and differentiation of choroidal hemangioma. Retinoblastoma: It occurs in children within 5 years of age and presents with localized thickening or heterogeneous mass shadows of the eye ring on CT, more than 90% of which are mixed with dot-like calcifications. Typical MR imaging features of retinoblastoma include a slightly higher signal on T1-weighted images and low signal on T2-weighted images, with contrast enhancement and diffusion restriction. PET metabolism mostly shows a slight increase in glucose uptake in retinoblastoma[22,23]. Thus, it is not difficult to differentiate from this case. Retinal HB is usually the initial manifestation of VHL. A comprehensive clinical examination of the patient and systematic genetic review of his family revealed that the patient had no other features of VHL syndrome or a family history of genetic diseases. Thus, it was a case of sporadic retinal hemangioblastoma, which may be due to the loss of a tumor suppressor gene similar to retinoblastoma rather than somatic mutations in the *VHL* tumor suppressor gene[24]. Although RHB is inherently benign and slow-growing, it can lead to retinal exudation, detachment, or macular edema resulting in severe visual loss. Advanced cases can present with extensive retinal scarring leading to blind eye pain. Therefore, early detection of retinal hemangioblastoma is important for ocular preservation and long-term visual acuity [25]. Minimally invasive laser photocoagulation is the best early treatment with less side effects, and

**Figure 4 Postoperative histopathological and immunohistological images of left retinal hemangioblastoma.** The left eyeball lesions were mainly composed of two components, capillaries and interstitial cells surrounded by vacuolated or eosinophilic cytoplasm, which showed epithelioid stromal cells and staghorn dilated thin-walled vessels in capillaries (hematoxylin-eosin staining, magnification  $\times 4$ ).

vitreoretinal surgery is the main treatment in the late stage[1].

## CONCLUSION

Retinal hemangioblastoma, as a rare disease type, with or without VHL syndrome, should be used as a routine differential diagnosis when a solid retinal mass is found on ultrasound, CT, or MR imaging in patients with no change in PET/CT metabolic characteristics.

### Abstract

#### BACKGROUND

Osteopetrosis is a rare genetic disorder characterized by increased bone density due to defective bone resorption of osteoclasts. Approximately, 80% of autosomal dominant osteopetrosis type II (ADO-II) patients were usually affected by heterozygous dominant mutations in the chloride voltage-gated channel 7 (*CLCN7*) gene and present early-onset osteoarthritis or recurrent fractures. In this study, we report a case of persistent joint pain without bone injury or underlying history.

#### CASE SUMMARY

We report a 53-year-old female with joint pain who was accidentally diagnosed with ADO-II. The clinical diagnosis was based on increased bone density and typical radiographic features. Two heterozygous mutations in the *CLCN7* and T-cell immune regulator 1 (*TCIRG1*) genes by whole exome sequencing were identified in the patient and her daughter. The missense mutation (c.857G>A) occurred in the *CLCN7* gene p. R286Q, which is highly conserved across species. The *TCIRG1* gene point mutation (c.714-20G>A) in intron 7 (near the splicing site of exon 7) had no effect on subsequent transcription.

#### CONCLUSION

This ADO-II case had a pathogenic *CLCN7* mutation and late onset without the usual clinical symptoms. For the diagnosis and assessment of the prognosis for

osteopetrosis, genetic analysis is advised.

**Core Tip:** Autosomal dominant osteopetrosis (ADO-II) is an autosomal dominant form of osteopetrosis. In ADO-II patients, the clinical spectrum ranges from nonsymptomatic to recurrent fractures, anemia, and a favorable prognosis. We reported a 53-year-old female patient with persistent joint pain, who was accidentally diagnosed with ADO-II at a later age. Her asymptomatic daughter was also diagnosed with ADO-II, as confirmed by whole exome sequencing.

## INTRODUCTION

Osteopetrosis, also known as "marble bone disease," is a rare genetic disease characterized by increased bone mass and density due to bone resorption failure[1]. Dr. Albers-Schonberg, a radiologist in Germany, described it for the first time in 1904[2]. It has a broad clinical spectrum, ranging from asymptomatic to life-threatening bone marrow failure and cranial nerve dysfunction. Based on clinical severity and inheritance patterns, osteopetrosis is classified into three types: a "malignant" autosomal recessive infantile form (ARO), a "benign" autosomal dominant form (ADO type II), and an intermediate recessive form[1,3,4]. To date, mutations in at least ten genes have been identified to cause failure of osteoclast differentiation or function in humans, including the T-cell immune regulator gene (*TCIRG1*), chloride voltage-gated channel 7 (*CLCN7*), tumor necrosis factor (TNF) superfamily member 11, TNF receptor superfamily member 11a, osteopetrosis-associated transmembrane protein, sorting nexin 10 (*SNX10*), pleckstrin homology and RUN domain containing M1, and NF-κB essential modulator genes[3, 5].

The most prominent characteristic of ADO-II is its dense yet fragile bones. We present a rare case of limb joint pain that was accidentally diagnosed as ADO-II based on clinical findings and genetic analysis.

## CASE PRESENTATION

### Chief complaints

A 53-year-old woman was admitted to the hospital with a complaint of limb joint pain for 11 mo.

### History of present illness

The patient presented with pain in her shoulder, elbow, wrist, and metacarpophalangeal joints with swelling, tenderness and numbness for 1 mo before pain began in her bilateral knee, ankle, toe and finger joints for approximately 10 mo.

### History of past illness

The patient had no history of fractures and bone injury.

### Personal and family history

Her parents were not consanguineous. Her father and mother died of bone cancer and esophageal cancer, respectively. She has a daughter, a brother and two sisters who are asymptomatic. The pedigree of her family is shown in [Figure 1](#).

### Physical examination

On admission, her blood pressure was 120/70 mmHg, pulse rate 98/min, and respiratory rate 20/min.

DOI: 10.12998/wjcc.v11.i3.700 Copyright ©The Author(s) 2023.

**Figure 1 Pedigree of a family with osteopetrosis.** Circles indicate females, and squares indicate males. The affected individuals are denoted by solid symbols. The arrow indicates the proband (II:4). Diagonal lines represent deceased subjects. The status of II:3 is unknown because this individual did not agree to participate in this study.

Her height and body weight were 155 cm and 63 kg, respectively. Physical examinations showed slight swelling of her wrists, hands, knees and ankles, accompanied by tenderness, limited retral swing of the upper limbs and slightly restricted movement of the lower limbs.

### Laboratory examinations

The patient had mild anemia; decreased levels of serum bone alkaline phosphatase (BALP), 25-dihydroxy vitamin D3, urinary calcium and phosphorus; and an elevated level of serum phosphorus. The levels of serum calcium, urinary fluoride, lactate dehydrogenase, creatine kinase, C-telopeptide of type I collagen, N-terminal mid-fragment of osteocalcin, and parathyroid hormone (PTH) were within the normal reference ranges. Her spectrum of antinuclear antibodies, anti-cyclic citrullinated peptide, anti-streptolysin O and rheumatoid factor were negative.

The biochemical measurements of her daughter, brother and sister were normal except that her daughter had mild anemia (partial data not shown). All laboratory findings are summarized in [Table 1](#).

### Imaging examinations

The bone mineral density (BMD) was measured by dual-energy X-ray absorptiometry (iDXA, GE Lunar, United States). The results showed that the hips and lumbar spines of the patient and her daughter significantly increased. The T scores of the patient were higher than those of Chinese female youth, and the Z scores of her daughter were also higher than those of the age-matched Chinese women ([Table 2](#)). The results of the BMD tests for her brother and sister revealed low bone mass (osteopenia) compared with the Chinese sex-matched adolescents (data not shown).

X-ray images of the limbs, including the wrist and ankle joints of the patient, showed increased bone density in the pelvis, femurs, humerus, knees and shoulder joints; mild degeneration in the hips, knees, ankles, shoulders, elbows and wrist joints; and slight soft tissue swelling around the wrist joints ([Figure 2A-C](#)). The chest computerized tomography (CT) scan of the patient showed that bone mineral density increased in the bilateral humeral head, sternum, scapula, ribs and multiple thoracic vertebrae ([Figure 2D](#)). Whole-body bone single-photon emission computed tomography of the patient revealed extremely high uptake in the long bone, ribs, and spine with no renal or bladder radioactivity visualization. The features from imaging showed a “bone super scan” ([Figure 2E](#)). The results of the ultrasound examination of the patient showed synovitis in both the first metatarsophalangeal joints and the wrist joint, tenosynovitis of the fourth compartment of the left wrist, and joint effusion on the right ankle (data not shown).

X-ray images of the limbs of the patient’s daughter showed that the density of the bone tip and flat bone increased, and the marrow cavity became narrow ([Figure 2F-H](#)). The CT scan of the lumbar spine of the patient’s daughter showed that bone mineral density increased at the upper and lower edges from the twelfth thoracic vertebra to the first sacral vertebra and slightly decreased in their center ([Figure 2I](#)).

### Pathological study

A bone biopsy of the patient on the right posterior iliac crest showed cortical bone sclerosis, some thickened bone trabeculae, and active proliferation of bone marrow hematopoietic cells ([Supplementary Figure 1](#)). Immunohistochemical staining of the bone marrow biopsy showed a few CD20 (+) or CD3 (+) lymphocytes and scattered CD138 (+), IGκ (+) or IGλ (+) plasma cells (data not shown).

### Genetic analysis

Whole exome sequencing (whole-exome library construction by xGen Exome Research Panel v2.0 (IDT, Iowa, United States), high-throughput sequencing by a DNBSEQ-T7 sequencer (MGI, Beijing, CHN), and not less than 99% of target sequence were sequenced) identified two heterozygous mutations,

**Table 1 Laboratory test results for the proband and her daughter**

	The proband	The proband's daughter	Reference
Sex	Female	Female	
RBC ( $10^{12}$ /L)	3.64	3.55	3.8-5.1
Hb (g/L)	99	105	115-150

RBC: Red blood cell count; PLT: Blood platelet count; ALT: Alanine transaminase; AST: Aspartate transaminase; ALP: Serum alkaline phosphatase; CK: Creatine kinase; LDH: Lactate dehydrogenase; eGFR: Estimated glomerular filtration rate; 25-OH-VD: 25-hydroxyvitamin D3; PTH: Parathyroid hormone; B-ALP: Bone alkaline phosphatase; CTX: C-terminal telopeptides of type I collagen; N-MID OC: Serum N-terminal mid-fragment of osteocalcin; IGF-1: Insulin-like growth factor-1; ACTH: Adrenocorticotrophic hormone; NA: Not available.

including c.857G>A (p. Arg286Gln, rs760956030) in exon 10 of the *CLCN7* gene (NCBI reference sequence: NM\_001287) and c.714-20G>A (-, rs200087340) in intron 7 of the *TCIRG1* gene (NCBI reference sequence: NM\_006019.4). Her daughter carried the same heterozygous mutation in the *CLCN7* and *TCIRG1* genes by genetic analysis (Figure 3).

#### **Prediction of functional effects of the *CLCN7* and *TCIRG1* gene mutations**

The R286 position was highly conserved among various species in the *CLCN7* gene (Supplementary Figure 2). Moreover, Polymorphism Phenotyping v2 (<http://genetics.bwh.harvard.edu/pph>) prediction results of p. R286Q in the *CLCN7* gene was probably damaging, with a score of 1.000 (Supplementary Figure 3), and Mutation Taster (<https://www.mutationtaster.org/>) predicted it to be a disease-causing variant. Mutation Taster predicted c.714-20 (IVS7) G>A in the *TCIRG1* gene as no change in potential splicing sites.

Table 2 Bone mineral density results for the proband and her daughter

	The BMD values of the proband (g/cm <sup>2</sup> )	T/Z score of the proband	The BMD values of the proband's daughter (g/cm <sup>2</sup> )	T/Z score of the proband's daughter
L1	2.013	8.2/8.8	1.777	5.2/5.4
L2	2.146	8.7/9.4	1.811	5.0/5.1
L3	2.256	9.2/9.9	1.785	4.5/4.7
L4	2.335	9.9/10.4	1.900	5.3/5.5
L1-L4	2.203	9.1/9.7	1.820	5.1/5.2
Femoral neck	1.838	7.6/8.2	1.391	2.5/2.9
Total hip	1.851	6.7/7.2	1.344	2.7/2.9

T scores were calculated by comparison with the age-specific bone mineral density reference value of Chinese adolescents; Z scores were calculated by comparison with age-matched and sex-matched Chinese adults. BMD: Bone mineral density.

**Figure 2** The imaging examination of the proband and the proband's daughter. A-C: X-ray image of the proband (II:4) demonstrated increased bone density in the right upper extremity (A), the left upper extremity (B) and the lower extremities (C); D: The chest X-ray of the proband (II:4) showed increased bone density of pelvic, with a "bone-within-bone" appearance in lateral of the spine, indicating classic vertebral endplate thickening (white arrow indicates the "sandwich vertebrae" sign); E: Whole-body bone technetium-99m single-photon emission computed tomography scan revealed extremely high bone uptake of long bone, ribs, and spine with absent renal radioactivity visualization (white arrows indicate "helmet" and "tie" sign); F and G: X-ray image of the proband's daughter (III:1) showed that the bone density of the bone tip, the humerus and the ribs and the medullary cavity became narrow in the right upper extremity (F) and the left upper extremity (G); H and I: X-ray image of the proband's daughter (III:1) in the lower extremities (H) and the lumbar vertebra (I) indicated classic vertebral endplate thickening (white arrow indicates the "sandwich vertebrae" sign).

FINAL DIAGNOSIS

Combined with the patient's medical history and radiological examination results, the final diagnosis was osteopetrosis. In light of genetic typing, the case belonged to ADO II.

DOI: 10.12998/wjcc.v11.i3.700 Copyright ©The Author(s) 2023.

**Figure 3** Genetic analysis identified mutations in chloride voltage-gated channel 7 and T-cell immune regulator 1 in the osteopetrosis family. A: The proband (II:4) and her daughter (III:1) carried T-cell immune regulator 1-c.714-20 (IVS7) G>A; B: The proband (II:4) and her daughter (III:1) carried *CLCN7*-c.857 (exon10) G>A/R286Q mutations. II:1 and II:2 did not carry any of the two mutations. *CLCN7*: Chloride voltage-gated channel 7; *TCIRG1*: T-cell immune regulator 1; WT: Wild type.

## TREATMENT

During hospitalization, celecoxib capsules, wet packing of Lihuedan (a traditional Chinese medicine recipe), ketoprofen gel, and flurbiprofen paste were all given. Her hemoglobin level increased from 99 g/L to 109 g/L with normal serum phosphorus after 16 days of treatment. Her regular activities were unaffected, and the discomfort and swelling in her joints subsided after she was discharged.

## OUTCOME AND FOLLOW-UP

After 2 years of follow-up, her joints were no longer painful, and no complications developed. However, her daughter experienced mild lumbar spine discomfort and received analgesic treatment.

## DISCUSSION

Osteopetrosis is a rare inherited metabolic bone disorder characterized by a generalized increase in bone density due to osteoclastic insufficiency, impaired bone absorption and poor bone remodeling[4]. Once osteoclasts have defective proton pumps, chloride channels, or carbonic anhydrase II proteins, the mineral matrix is unable to be resorbed effectively[6]. Published studies have shown that most defects in genes result in impaired acidification of bone[7].

With a prevalence of approximately 1:20,000 Live births, ADO is far more common and less severe than ARO[8,9]. The clinical phenotype of osteopetrosis is highly variable, making diagnosis difficult for clinicians. Patients with osteopetrosis may present with no symptoms, fractures following minor trauma, osteomyelitis, early arthritis, anemia, hearing and vision problems due to cranial nerve compression, or all of the above[4]. Some differential diagnoses should be ruled out, such as congenital diseases (*e.g.*, hypoparathyroidism, pseudohypoparathyroidism), chemical poisoning (*e.g.*, with fluoride, lead, or beryllium), and malignancies (leukemias and myeloproliferative diseases). This patient had normal urinary fluoride and PTH serum levels without arthritis, and she was eventually diagnosed with ADO-II. Her daughter was asymptomatic, and ADO-II was confirmed by increased BMD, radiological examination, and the p. R286Q mutation. Their anemia was mild due to relatively sufficient marrow cavity retention for normal hematopoiesis[10]. It is worth noting that, in contrast to ARO, this patient had a mildly decreased BALP concentration. The majority of ADO-II patients have an imbalance in osteoblast serum markers, with low BALP and high osteocalcin levels[11]. As a result, bone

biomarkers may be useful in disease classification.

Increased BMD and radiographic findings are most commonly used to diagnose osteopetrosis. The classic radiographic features of osteopetrosis are the bare minimum for diagnosis[7]. Radiographic features of osteopetrosis include diffuse bone sclerosis with "bone-within-bone" in the pelvis, long bones, phalanges, and vertebrae. A bone marrow biopsy may be required to confirm the diagnosis and differentiate between osteoclast-poor and osteoclast-rich subtypes of osteopetrosis. Bone marrow biopsy can also distinguish hematological disorders such as myelofibrosis, sickle cell disease, leukemia, and osteoblastic bony metastases. It is, however, more invasive to the patient and carries some risks. Whole exome sequencing, on the other hand, is becoming less expensive and faster to obtain a diagnosis and is not invasive. Therefore, therapeutic approaches must be tailored to each patient.

Approximately 80% of ADO-II patients are affected by heterozygous dominant negative mutations of the *CLCN7* gene, while 17% of ARO patients have recessive mutations in the *CLCN7* gene[5,12]. *CLCN7* encodes the chloride channel involved in osteoclast HCl secretion, which is critical in osteoclast dissolution of bone mineral and organic bone matrix[13,14]. A single nucleotide change (c.857G>A, p. R286Q) in exon 10 of *CLCN7* results in a protein with the amino acid glutamine instead of arginine. This variant appears to be located at one of the "hot spots" as the most common *CLCN7* mutations causing ADO and three known disease-related *CLCN7* mutations at the R286 position (p. R286P, p. R286W and p. R286Q) have previously been reported among Caucasians and Asians[15-17]. The mutations (p. R286Q) in the *CLCN7* gene are located in the intramembrane  $\alpha$ -helices, creating a positive electrical potential to prevent the fast flux of chloride at the binding site[18]. Approximately 80% of *CLCN7*-dependent ADO-II patients discovered the disease after fractures, implying that osteoblast malfunction likely results in low-quality bone tissue[5,11]. However, no fractures have occurred in this patient thus far. As a result, even if the mutations are identical, the clinical phenotypes may differ.

Osteopetrosis may also be caused by an intronic nucleotide change in the *TCIRG1* gene[19]. *TCIRG1* encodes the  $\alpha 3$  subunit of H<sup>+</sup> ATPase, and V-ATPase with  $\alpha 2/\alpha 3$  is a major proton pump of osteoclasts [20]. Mutations in *TCIRG1* account for approximately 50% of ARO cases[5]. The *TCIRG1* variant (c.714-20 G>A) is a point mutation, but there is insufficient evidence to conclude that it is pathogenic. Furthermore, published reports of digenic inheritance suggested that *TCIRG1* and *CLCN7* interact in the two mutations[15,21].

The majority of benign ADO treatments are symptomatic and supportive. Good nutrition is critical for patients with osteopetrosis, especially for those who have hypocalcemia and require calcium and vitamin D supplements[7]. Hematopoietic stem cell transplantation is reserved for osteopetrosis that is malignant[4]. The majority of ADO patients have a better prognosis. Nonetheless, for mild osteopetrosis, it is critical to monitor the disease status and progression by the affected organs.

## CONCLUSION

A case of rare ADO-II was accidentally diagnosed in a late-onset patient and her daughter based on increased BMD, classic radiographic features, and a *CLCN7* gene mutation. It was suggested that genetic testing be used to identify precision classifications of osteopetrosis and to provide useful information for therapeutic decisions and prognosis.

## ACKNOWLEDGEMENTS

We thank the patient and her relatives for kindly contributing to this study.

### Abstract

#### BACKGROUND

Soft tissue tuberculosis is rare and insidious, with most patients presenting with a localized enlarged mass or swelling, which may be factors associated with delayed diagnosis and treatment. In recent years, next-generation sequencing has rapidly evolved and has been successfully applied to numerous areas of basic and clinical research. A literature search revealed that the use of next-generation sequencing in the diagnosis of soft tissue tuberculosis has been rarely reported.

#### CASE SUMMARY

A 44-year-old man presented with recurrent swelling and ulcers on the left thigh. Magnetic resonance imaging suggested a soft tissue abscess. The lesion was surgically removed and tissue biopsy and culture were performed; however, no organism growth was detected. Finally, Mycobacterium tuberculosis was confirmed as the pathogen responsible for infection through next-generation sequencing analysis of the surgical specimen. The patient received a standardized anti-tuberculosis treatment and showed clinical improvement. We also performed a literature review on soft tissue tuberculosis using studies published in the past 10 years.

#### CONCLUSION

This case highlights the importance of next-generation sequencing for the early diagnosis of soft tissue tuberculosis, which can provide guidance for clinical treatment and improve prognosis.

**Key Words:** Mycobacterium tuberculosis; Soft tissue infection; Next-generation sequencing; Extrapulmonary tuberculosis; Diagnosis; Case report

**Core Tip:** The diagnosis of extrapulmonary tuberculosis can be challenging, especially for tuberculosis in rare sites such as soft tissues. Soft tissue tuberculosis is rare and easily misdiagnosed. A delay in soft tissue tuberculosis diagnosis may worsen the disease, increase tuberculosis transmission, and accelerate the evolution of drug resistance. This case report emphasizes the importance of next-generation sequencing for early diagnosis of soft tissue tuberculosis, which can provide guidance for clinical treatment and improve prognosis.

## INTRODUCTION

Tuberculosis (TB) is a chronic infectious disease caused by mycobacterium TB (MTB). Extrapulmonary TB (EPTB) in China constitutes 15%-20% of all TB cases, it can involve any organ, with the most usual sites of infection being the pleura (49.8%), bronchi (14.8%), lymph nodes (8.56%), meninges (7.6%), thoracic vertebra (2.55%), and skeletal joints (0.56%)[1,2]. Isolated soft tissue TB is rare and accounts for only 1-2% of all pulmonary TB (PTB) and EPTB cases. Current knowledge of soft tissue TB is largely based on the analysis of a single patient and case series[3,4]. Therefore, the low incidence and lack of typical symptoms of soft tissue TB may lead to difficulties and delays in diagnosis.

The traditional gold standard for TB diagnosis is the MTB culture assay, which has a lower positivity rate of 23.03%. In EPTB, the positivity rate is approximately 18.45%[5]. The MTB culture assay demands laboratory biosafety requirements, and rapid diagnosis is challenging. Molecular biology techniques, such as real-time fluorescent polymerase chain reaction (PCR) and cross-primer amplification, have facilitated the rapid diagnosis. However, the diagnostic sensitivity of these methods for EPTB is limited and varies among specimen types[6]. For example, the sensitivity of Xpert MTB/ rifampin (RIF) assay for PTB and EPTB was found to be 95.5% and 76.5%, respectively[7].

Next-generation sequencing (NGS) is an emerging and promising technology that is used for disease diagnosis, drug resistance determination, and epidemiological investigations. It has the potential to significantly reduce response time for the identification of pathogens, such as bacteria, viruses, tuberculosis, fungi, and parasites[8-12]. For TB, next-generation sequencing can be used for early diagnosis, identification of drug resistance gene mutations associated with conventional anti-TB drugs, and detection of mixed infections[13]. However, there are only a few reports on the rapid diagnosis of MTB infection in soft tissue using NGS. In this report, we present a case of soft tissue TB in an immunocompetent patient with no history of TB. We used NGS technology to detect the surgically resected lesion tissue, and the patient was finally diagnosed with soft tissue TB. In addition, we reviewed the main features of soft tissue TB cases reported in the past decade.

## CASE PRESENTATION

### Chief complaints

A 44-year-old man admitted to Department of Orthopaedics of the First Affiliated Hospital of Nanjing Medical University presented with a history of left thigh ulceration and swelling for 10 d.

### History of present illness

The patient showed similar symptoms in 2018, some tests including bacterial and tuberculosis culture, acid-fast staining, and tuberculosis infection T-lymphocyte spot test (T-SPOT). TB tests, were negative at that time. And the patient recovered gradually after debridement. Through careful history investigation, we found that the patient had an open wound on the left thigh caused by trauma 18 years ago, which improved after debridement and suturing.

### History of past illness

There is no relevant history of past illness.

**Personal and family history**

The patient's personal and family histories were unremarkable.

**Physical examination**

Two old scars were observed on the patient's left thigh, and there was a red and swollen ruptured wound above them. The skin temperature of the limb was normal, and no movement limitation was observed. A physical examination revealed no other positive signs. Breath sounds of both lungs were clear, no obvious dry or wet rales were heard, and there was no pleural friction rub.

**Laboratory examinations**

On day 2 after admission, laboratory tests, such as routine blood examination, coagulation function tests, erythrocyte sedimentation rate, and serum biochemical indicators, did not show any significant abnormalities.

**Imaging examinations**

A radiograph of the left femur indicated no bone erosion (Figure 1A). Bone single-photon emission computed tomography did not reveal any abnormalities in bone metabolism (Figure 1B). On day five after admission, magnetic resonance imaging (MRI) of the left hip was performed, which revealed abnormal signals in the soft tissue of the left upper femur and oedema of the subcutaneous soft tissue. In addition, MRI revealed a chronic abscess with sinus tract formation (Figure 1C-E). Computed tomography of the chest showed scattered nodules in both lungs (Figure 1F). But the symptoms of tuberculosis are not obvious.

**Further diagnostic work-up**

Considering that the abscess was large, we performed abscess resection of the left thigh and vacuum sealing drainage therapy. We observed inflammation and degeneration in subcutaneous tissue and cystic infected tissue wrapped in the deep layer, which had tough capsule walls and a size of approximately 8 cm × 6 cm (Figure 2A and B). After incision of the purulent cyst, gelatinous necrotic tissue which was grey and white, was observed. Furthermore, we performed histological examination, bacterial culture, and NGS testing of the specimen.

Histological examination revealed fibrous connective tissue hyperplasia with necrosis, acute and chronic inflammatory cell infiltration, and focal granulomatous inflammation with multinucleated giant cell formation (Figure 2C). Bacterial culture of the surgically excised specimen was negative on day seven after admission. However, MTB was detected by NGS simultaneously. The distribution of bacteria and fungi identified by NGS revealed that MTB was the main pathogen (Figure 3A), and 24 sequence reads were identified (Figure 3B).

The pathology department was then contacted for an additional acid-fast bacillus staining test of the intraoperative specimen, and scattered suspicious antacid staining positive rods were observed microscopically (Figure 2D). Further, the T-SPOT. TB test results were positive.

---

**FINAL DIAGNOSIS**

Combined with the patient's medical history and outcome of NGS, the patient was finally diagnosed with soft tissue tuberculosis.

---

**TREATMENT**

We planned a standardized anti-tuberculosis treatment with four drugs, isoniazid, rifampicin, ethambutol, and pyrazinamide, for 2 mo. Further isoniazid and rifampicin were given for four months. But the patient stopped the drug because of gastrointestinal discomfort during the 3rd month of treatment and suspended for 2 wk, then he continued to take the medicine again for 3 mo.

---

**OUTCOME AND FOLLOW-UP**

Currently, the wound has healed adequately and the patient is undergoing follow-up. A summary of the timeline is shown in Figure 4.

A: Intraoperative photograph; B: Excised specimen (8 cm × 6 cm); C: Granulomas are embedded among the muscle fibers with lymphocyte infiltration and multinucleated giant cell aggregation (× 40); D: The acid-fast bacilli staining test showed scattered, suspicious antacid staining-positive rods (× 1000).

## DISCUSSION

According to a global TB report published by WHO, TB deaths have increased because of reduced access to TB diagnosis and treatment in the face of the COVID-19 pandemic for the first time in over a decade[14]. China has the second-highest number of TB cases worldwide, accounting for approximately 9% of the global TB incidence. One study indicated that the prevalence of smear-positive TB in China decreased from 170/100 000 population in 1990 to 59 /100 000 population in 2010, a reduction of more than 50 percent[15]. Despite past success in controlling TB, the limited epidemiologic information

**Figure 3** Next-generation sequencing results of surgically resected specimen. A: Distribution of the sequences detected by next-generation sequencing of surgically excised specimens; B: Twenty-four sequence reads of mycobacterium tuberculosis are observed, with a coverage rate of 0.005%.

available suggests that the incidence of EPTB may be increasing steadily worldwide, including in China [16,17].

The diagnosis of EPTB can be challenging, especially for TB in rare sites such as soft tissues. A delay in soft tissue TB diagnosis may worsen the disease, increase TB transmission, and accelerate the evolution of drug resistance. The conventional gold standards for TB diagnosis are MTB culture and drug sensitivity tests. However, it is tedious and can take 6-8 wk because of slow growth of MTB[18]. Molecular diagnostic techniques, such as Xpert MTB/RIF, loop-mediated isothermal amplification (LAMP), and line probe assay (LPA), can effectively reduce turnaround time and improve diagnostic performance. However, these techniques have limited diagnostic sensitivity for specimens with low bacterial content, such as EPTB[19,20]. For example, a meta-analysis found that the pooled sensitivity of Xpert MTB/RIF for diagnosing abdominal TB was only 23%[21]. Another meta-analysis reported that the pooled sensitivity of LAMP for detecting EPTB was 77%[22]. Only a few studies have evaluated the role of LPA in EPTB specimens. A study from India reported a sensitivity of 46.1% with a specificity of 91% in EPTB specimens, with liquid culture as the reference standard[23].

Soft tissue TB is rare and easily misdiagnosed. Therefore, rapid, efficient, and accurate diagnosis of soft tissue TB is an urgent clinical problem. NGS is a revolutionary development of first-generation sequencing methods that can sequence millions of DNA fragments simultaneously with high throughput and short detection cycles. A study found that the positivity rate of NGS is approximately 15% higher than that of traditional pathogen culture in a pairwise manner for infectious diseases[24]. Xpert MTB/RIF and NGS tests were performed on various samples of sputum, cerebrospinal fluid, and pus from patients with suspected active TB infection. Compared with Xpert MTB/RIF, NGS showed better sensitivity in all clinical (76.9% vs 61.5%), pulmonary (87.5% vs 75.0%), and extrapulmonary samples (60.0% vs 40.0%)[13]. In this case, NGS rapidly detected the sequence of MTB in the sample, which was important for us to confirm the diagnosis of soft tissue TB early and to treat it with anti-tuberculosis drugs in time. Below, we review the relevant literature on soft tissue TB.

Recent case reports on soft tissue TB published in the past 10 years were identified by searching PubMed (Table 1). We found 17 case reports including 10 males and 7 females. The ages of the patients ranged from 7 to 79 years. There were 12 cases distributed in Asian countries, four cases in African countries and one case in America. No underlying diseases were reported in 10 patients. In 13 patients, the lesions were located on the extremities, including the thigh, calf, forearm, and wrist. The other four patients had lesions in the gluteus, back, thorax, and iliopsoas.

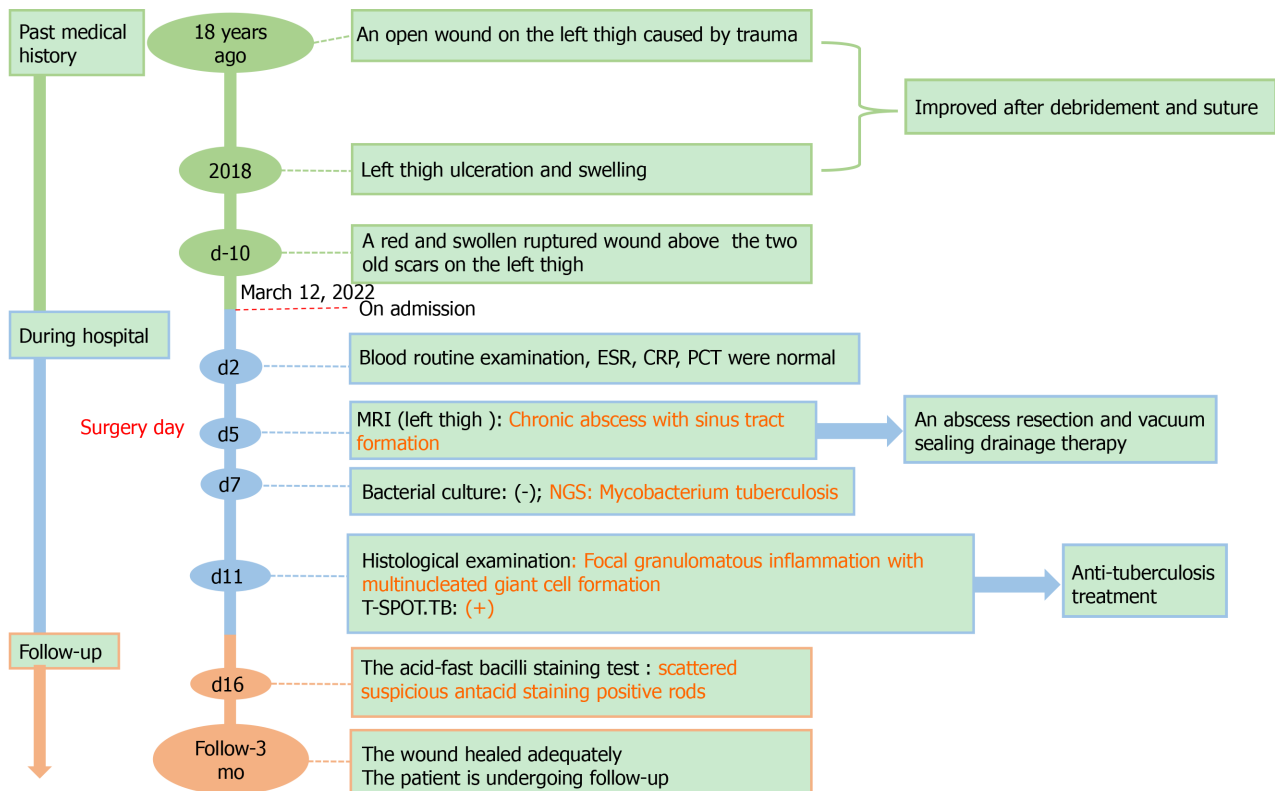

**Table 1** Main features of reported cases of soft tissue tuberculosis

Ref.	Gender/age (yr)	Country	Underlying disease	Main clinical manifestations	Involved sites	Diagnostic methods
Arora <i>et al</i> [38], 2012	Male/15	India	None	Swelling, anorexia, weight loss	Left thigh	Mycobacterium tuberculosis culture
Lee <i>et al</i> [39], 2013	Male/62	Korea	Right total hip arthroplasty	Mass	Right thigh	Histological examination, and culture
Elshafie <i>et al</i> [40], 2013	Male/25	Oman	Exposed to suspected tuberculosis, diarrhea	Enlarging swelling	Right gluteus	Histological examination, and culture
Neogi <i>et al</i> [41], 2013	Female/11	India	None	Swelling	Right thigh, right calf, and left arm	Histological examination, and culture
Meena <i>et al</i> [42], 2015	Male/25	India	None	Swelling, fatigue, weight loss	Right triceps	Mycobacterium tuberculosis PCR
Dhakal <i>et al</i> [43], 2015	Female/9	Nepal	None	Swelling	Forearm, right calf	Histological examination
Sbai <i>et al</i> [44], 2016	Male/45	Tunisia	None	Pain, swelling	Right wrist	Tissue biopsy and culture
Al-khazraji <i>et al</i> [45], 2017	Female/33	America	Lupus nephritis, hormonal therapy	Pain, weakness, swelling, redness	Right calf	Fluid culture
Alaya <i>et al</i> [46], 2017	Female/23	Tunisia	None	Swelling, pain	Left thigh	Mycobacterium tuberculosis PCR
Manicketh <i>et al</i> [25], 2018	Female/55	India	Pulmonary tuberculosis	Swelling, fever	Left wrist and right calf	A Ziehl-Nielsen stain
Hashimoto <i>et al</i> [27], 2018	Male/79	Japan	None	Swelling, erythema	Left wrist	Histological examination
Zeng <i>et al</i> [4], 2019	Male/49	China	Pulmonary tuberculosis; steroid treatment	Pain, mass, swelling	Both thighs and calves	Mycobacterium tuberculosis PCR, Tissue biopsy and culture
Zitouna <i>et al</i> [47], 2019	Female/42	Tunisia	None	Mass, swelling	Right mid-back	Tissue biopsy and culture
Moyano <i>et al</i> [48], 2019	Male/29	Senegal	None	Pain, increase in size of hemithorax	Right hemithorax	Mycobacterium tuberculosis PCR and culture
Fahad <i>et al</i> [28], 2020	Female/45	Pakistan	None	Swelling, pain	Right forearm	Histological examination
Murugesha <i>et al</i> [49], 2020	Male/31	India	Renal transplant with immuno-suppressants	Fever, pain, swollen erythematous	Right foot and calf	Nucleic acid amplification test
Tone <i>et al</i> [26], 2021	Male/29	Japan	Right tuberculous pleurisy	Fever, pain	Right iliopsoas	Mycobacterium tuberculosis PCR

PCR: Polymerase chain reaction.

Soft tissue TB occurs mostly in the extremities, and patients present with local masses, swelling, and weakness. Only a small percentage of patients present with constitutional symptoms such as fever and weight loss[25,26]. Most cases of soft tissue TB reported in the literature were diagnosed by histological examination and MTB culture, whereas some were confirmed by rapid PCR. Although the culture and gene Xpert were negative, two patients recovered after empirical anti-TB therapy[27,28]. Empirical treatment for TB was initiated without a confirmed bacterial diagnosis. Moreover, factors contributing to the probability of a patient developing TB and experiencing adverse outcomes were weighed against the threshold for initiating anti-TB therapy. This threshold is subjective and may vary among the clinicians. Factors considered in empirical anti-TB treatment include the background TB epidemiology in the geographic area, exposure to TB patients, clinical manifestations suggestive of TB disease, comorbidities such as HIV co-infection, and the results of other diagnostic methods such as imaging outcomes if available[29].

There are many traditional tests for TB, including smear, culture, pathological biopsy, imaging, purified protein derivative testing, interferon-gamma release assay, and TB antibody testing[30,31]. Confirmation of TB over the past few decades often requires a combination of these tests. Over the last decade, advances have been made in the field of TB diagnostics in the form of new molecular tests. Often referred to as nucleic acid amplification tests, these assays rely on amplification of a targeted genetic region of the MTB complex, typically by PCR[32]. GeneXpert MTB/RIF is a fully automated

closed system that performs sample preparation and real-time PCR and produces results within 2 h. This system can detect RIF resistance (targeting the *rpoB* gene). In 2011, the WHO recommended GeneXpert MTB/RIF for the early diagnosis of drug-resistant TB, which was further expanded in 2013 to replace smear and culture for the rapid diagnosis of EPTB[33]. The new version of Xpert MTB Ultra improved overall sensitivity and was endorsed by the WHO in 2017[34]. In 2017, the UK used NGS for TB diagnosis, drug resistance detection, and MTB typing for the first time[35]. Several studies have shown its advantages in the diagnosis and treatment of EPTB[36,37]. However, the value of NGS in the rapid diagnosis of TB has not been verified in large samples, and there is a lack of unified standards and procedures. Guidelines for the clinical interpretation of NGS reports need to be improved.

## CONCLUSION

We reported the case of a patient who was immunocompetent and had no history of TB and was diagnosed with soft tissue TB by NGS. The patient received timely anti-TB treatment, which improved. Clinicians should consider atypical pathogens such as MTB in the diagnosis of patients with local masses or swelling. NGS may be a useful method for identifying the pathogens responsible for soft tissue infections without typical clinical manifestations.
