TO THE EDITOR

More than 80% of cirrhotic patients who have been treated successfully for spontaneous bacterial peritonitis (SBP) experience a recurrence[1,2]. Long-term prophylaxis with single daily oral antibiotic has been shown to be cost effective in delaying a recurrence but only for a short time[3]. What has never been tested in this population is the cycling of antibiotics. We report the beneficial use of antibiotic cycling for 36 weeks in a 74-year-old woman with cryptogenic cirrhosis and recurrent SBP.

The patient was admitted because of abdominal pain. Physical examination revealed a malnourished woman with mild jaundice. Blood pressure was 100/60 mmHg, pulse 110 beats /min and temperature 37.4 °C. There was moderate ascites, splenomegaly and multiple signs of chronic liver disease. Plasma levels of urea, creatinine, and electrolytes were within normal limits. Blood platelets were 80 000 per mm³; prothrombin time by international normalized ratio (INR) was1.4; serum albumin, 3.0 g per deciliter; bilirubin, 2.5 mg per deciliter; alanine aminotransferase, 28 U per liter, ascitic protein, 1.0 gr per deciliter and ascitic white blood cells 1500 cell per mm³ with 75% neurophils. Ascitic culture was positive for Escherichia coli bacteria. Blood culture was negative. Abdominal ultrasonography revealed signs of portal hypertension. The patient was on prophylactic therapy with trimethoprim-sulphamethoxazole 160/800 mg daily during the last 3 mo. On admission the patient was treated with intravenous ceftriaxone 1 gr bid for 5 d with good response (ascitic neurophil decreased bellow 200 cell /mm^3). The patient was discharged with a recommendation to be on a prophylactic oral cefuroxime 500 mg qd for 6 wk followed by oral ofloxacin 200 mg qd for 6 wk, followed further by amoxicillin-clavulanic acid 875/125 mg qd for another 6 wk and finally trimethoprim-sulphamethoxazole 160/800 mg for an additional 6 wk (four cycles). The regimen was repeated. Gradually the patient's condition improved, the number of SBP episodes decreased and her ascitic neutrophil count returned to baseline levels (<100 cell/mm^3). Repeated ascitic cultures during follow up of 36 wk was negative for bacteria.

Several strategies have been suggested to prevent or reduce bacterial resistance to antimicrobials, including cycling[4]. This strategy has been studied recently in intensive care units and has resulted in fewer infections and in lower mortality[5]. The basic principle of cycling antibiotics is that a bacterium that becomes resistant (by plasmids, bacteriophages, transposons or integrons) to the first course of treatment would remain susceptible to the second regimen. If it is resistant to the second regimen, the third regimen should cope with the resistance. The selection of antibiotic cycling schedule in this case was arbitrary. Amoxicillin-clavulanic acid eliminates both aerobic and the anaerobic bacteria which could contribute to the development of multi-resistant organism. However, repeated ascites and blood culture were negative for bacteria, so the antibiotic resistance profile and the molecular evidence of bacterial translocation were not performed. Our report suggests the need for a randomized, prospective study of cycling of antibiotic prophylaxis in patients with recurrent SBP. The timing, number and order of cycles directed to prevent selection pressure of bacterial resistance remain to be determined.

TO THE EDITOR

With great interest we read the recent retrospectice study by Barta *et al* (1) dealing with the clinical presentation of patients with microscopic colitis. They investigated in a cohort of 53 patients with microscopic colitis (46 with collagenous colitis, 7 with lymphocytic colitis) the relationship between microscopic colitis and both constipation and diarrhea. One of their mean finding was that abdominal pain, diarrhea and constipation was a common symptom complex of patients with microscopic colitis, thus the face of microcopic colitis resembles the subgroups of irritable bowel syndrome (IBS).

Irritable bowel syndrome is highly prevalent disorder. Consensus diagnostic criteria (Rome II) based on symptoms have been established to aid the diagnosis of IBS. Microscopic colitis, encompassing collagenous and lymphocytic colitis, is diagnosed by histologic criteria. Since symptoms of microscopic colitis and both diarrhea predominant irritable bowel syndrome or functional diarrhea are similar, a considerable number of patients with micoscopic colitis may be misdiagnosed as IBS or functional diarrhea or a disease overlap could be present in a subgroup of patients.

We would like to confirm the data by Barta *et al*[1] presenting a subgroup analysis of placebo-controlled trials, in which we evaluate the possible symptom overlap between microscopic colitis and IBS. We aimed to assess the proportion of patients with histologically confirmed microscopic colitis who fulfill the Rom-II-criteria for IBS and functional diarrhea[2] .

We selected a large patient cohort with histologically confirmed symptomatic microscopic colitis, who participated in placebo-controlled trials of our group. Baseline gastrointestinal symptoms were assessed by standardized questionnaires and ascertained consistent with Rome-II-criteria (chronic abdominal pain and/or stool abnormalities for at least 12 wk in the preceding 12 mo, no alarm symptoms such as weight loss, no findings in the routine procedures including colonoscopy).

Eighty-two cases of microscopic colitis (74 collagenous, 8 lymphocytic) were included in this analysis. The mean age was 57 years (30-80). Seventy-three % were women. The mean stool frequency per day was 6 (range 3-15). The duration of symptoms prior to histological diagnosis of microscopic colitis ranged between 1 and 156 mo with a mean of 28 mo. Forty-seven patients (57.3%) had concomitant abdominal pain.

Twenty-three patients (28.1%) met the Rome-II-criteria for diarrhea-predominant IBS. Six patients (7.3%) fulfilled the criteria for functional diarrhea. If the criteria for duration of symptoms were excluded from our analysis, the corresponding rates were 65% and 13.4%, respectively These data clearly demonstrate that a considerable group of patients with microscopic colitis have diarrhea-predominant IBS- or functional diarrhea-like symptoms. Thus, patients with microscopic colitis could be misdiagnosed as IBS or functional diarrhea. Additionally, because of the high frequency of IBS, a disease overlap could be present in a subgroup of patients as it was shown between IBS and celiac disease[3]. We conclude that the clinical symptom-based criteria of IBS are not specific enough to rule out the diagnosis of microscopic colitis. Therefore, patients with diarrhea-predominance of IBS-like symptoms should undergo matrix biopsies from the entire colon to investigate for possible microscopic colitis especially biopsies from the right colon are of importance because the left colon sometimes is less involved.

Abstract

AIM: To determine the distribution of Hepatitis B virus (HBV) genotypes in Benin, and to clarify the virological characteristics of the dominant genotype.

METHODS: Among 500 blood donors in Benin, 21 HBsAg-positive donors were enrolled in the study. HBV genotypes were determined by enzyme immunoassay and restriction fragment length polymorphism. Complete genome sequences were determined by PCR and direct sequencing.

RESULTS: HBV genotype E (HBV/E) was detected in 20/21 (95.2%), and HBV/A in 1/21 (4.8%). From the age-specific prevalence of HBeAg to anti-HBe seroconversion (SC) in 19 HBV/E subjects, SC was estimated to occur frequently in late teens in HBV/E. The comparison of four complete HBV/E genomes from HBeAg-positive subjects in this study and five HBV/E sequences recruited from the database revealed that HBV/E was distributed throughout West Africa with very low genetic diversity (nucleotide homology 96.7-99.2%). Based on the sequences in the basic core promoter (BCP) to precore region of the nine HBV/E isolates compared to those of the other genotypes, a nucleotide substitution in the BCP, G1757A, was observed in HBV/E.

CONCLUSION: HBV/E is predominant in the Republic of Benin, and SC is estimated to occur in late teens in HBV/E. The specific nucleotide substitution G1757A in BCP, which might influence the virological characteristics, is observed in HBV/E.

INTRODUCTION

Hepatitis B virus(HBV) is a member of the family *Hepadnaviridae*. This virus is a small DNA virus with a partially double-stranded 3.2-kb genome. HBV has been classified into seven genotypes based on the sequence divergence over the entire genome exceeding 8%[1,2]. The seven genotypes show a distinctive geographical distribution. HBV genotype A (HBV/A) is prevalent in Northwestern Europe, North America, and Africa[3]. HBV/B and HBV/C are characteristics of Asia. HBV/D is predominant in the Mediterranean area, HBV/E in West Africa, and HBV/F in South America.

Recently, virological and clinical differences in genotypes have been reported[4,5]. In addition, subtypes of HBV/B, HBV/Ba, 'a' indicating Asia, and HBV/Bj, 'j' indicating Japan, have been reported[6]. The former has

recombination with HBV/C, but the latter does not, and clinical differences have been shown between them[7]. Furthermore, HBV/A is phylogenetically classified into subtypes, namely HBV/Aa, 'a' indicating Asia/Africa, which is distributed in Asia and Africa, and HBV/Ae, 'e' indicating Europe, which is distributed in Europe[8].

It is now recognized that mutations in basic core promoter (BCP) and precore region regulate hepatitis B e antigen (HBeAg) expression. It was shown in an *in vitro* study that the double mutations in BCP, A1762T and G1764A, downregulate precore mRNA and slightly increase the efficiency of pregenome mRNA and core mRNA[9]. Additionally, the mechanism of HBeAg reduction through subtype-specific nucleotide substitutions just prior to the start of the precore open reading frame (ORF), known as "Kozak sequence" in the African subtype of HBV/A, has been shown in an *in vitro* study[10].

In Africa, the distribution of HBV genotypes is HBV/A in the South, HBV/D in the North, and HBV/E in the West. For HBV/E, only four human HBV/E full genomes have been reported so far, and the virological and clinical characteristics have not yet been sufficiently clarified.

In this study, the distribution of HBV genotypes in the Republic of Benin was investigated for the first time, and the virological and clinical characteristics of the dominant genotype were analyzed.

MATERIALS AND METHODS

Patients

Five hundred blood donors, who visited the National Blood Transfusion Center in the Republic of Benin in 2002, were screened for hepatitis B surface antigen (HBsAg). Twenty-four were positive for HBsAg (4.8%). Sera from 21 donors were available in this study (17 males, 3 females, unknown in 1; mean age, 23.1±6.7 years). All the donors were negative for the antibody to HIV-1 (anti-HIV) and the antibody to human adult leukemia virus 1 (anti-HTLV-1). The antibody to hepatitis C virus (anti-HCV) was positive in one donor. Informed consent was obtained from each patient.

Serological testing

HBsAg, anti-HCV, and anti-HTLV-1 were tested by counting immunoassay (PAMIA, Sysmex, Kobe, Japan). HBeAg and the antibody to HBeAg (anti-HBe) were determined using a commercially available chemiluminescent enzyme immunoassay (EIA, Lumipulse f, Fujirebio Inc., Tokyo, Japan). Aspartate aminotransferase (AST), alanine aminotransferase (ALT), and total bilirubin (T-Bil) were measured in all the samples.

Genotyping

The HBV genotypes were determined in the sera using an EIA with pre-S2 specific mAb[12,13]. When the result of the EIA method was indeterminate, HBV genotypes were detected by restriction fragment length polymorphism, as previously described[14].

PCR amplification and sequencing of HBV

The serum samples were stored at -80 °C until use. Total DNA was extracted from 100 μL of serum using microspin columns (QIAamp Blood kit, Qiagen KK, Tokyo, Japan). Purified DNA was resuspended in 80 μL of distilled water. PCR was carried out by the same protocol as described previously[15]. Nucleotide sequences of the amplified products were determined directly by the dideoxy method, using the ABI Prism BigDye Terminator Cycle Sequencing Ready Reaction kit with a fluorescent 3100 DNA Sequencer (Applied Biosystems, Foster City, CA, USA).

Real-time detection polymerase chain reaction (RTD-PCR)

serum HBV DNA was quantitatively detected by RTD-PCR based on Taqman chemistry as reported previously[16]. Amplification was performed using primers corresponding to conserved sequences of the surface region. A 10-μL aliquot of DNA solution was used for RTD-PCR. A portion of the HBV surface region was amplified using primers: a forward primer HBSF2 (5'-CTTCATCCTGCTGCTATGCCT-3', nucleotide position (nt) 406-426) and a reverse primer HBSR2 (5'-AAAGCCCAGGATGGGAT-3', nt 646-627). A taqman probe was designed as HBSP2 (5'-ATGTTGCCCTTTGTCCTCCTCTAATTCCAG-3', nt 461-488), with an additional G at the 3'-end of HBSP2 in the original method, the detection limit of this system was as low as five DNA copies/assay, and linear standard curve was obtained from 5 to 10^6 DNA copies/assay.

Phylogenetic analysis

Complete sequences of 21 HBV isolates were aligned with the CLUSTAL W software program[17], and the alignment was confirmed by visual inspection. Genetic distances were estimated by the six-parameter method, and phylogenetic trees were constructed by the neighbor-joining method using ODEN program of the National Institutes of Genetics (Mishima, Japan)[18]. To confirm the reliability of the phylogenetic trees, bootstrap resampling tests were performed 1 000 times.

RESULTS

HBV genotypes

Distribution of HBV genotypes among 21 HBV carriers in the Republic of Benin was 20/21 (95.2%) for HBV/E, and 1/21 (4.8%) for HBV/A. HBV/B, C, D, F, and G were not found. HBV/E was the predominant genotype in the Republic of Benin.

Clinical characteristics of asymptomatic HBV carriers in the Republic of Benin

HBeAg was positive for 4/21 (19.0%) subjects, and anti-HBe was positive for 17/21 (81.0%) subjects. The titers of four HBeAg-positive subjects were beyond the upper detection limit. In order to clarify the clinical characteristics of asymptomatic HBV carriers in this country, the clinical and laboratory data between HBeAg-positive patients

Table 1 Comparison of clinical characteristics between HBeAg-positive and anti-HBe-positive subjects

	HBeAg-positive (n = 4)	Anti-HBe-positive (n = 17)	P
Age (yr)	21.25±2.21	23.5±7.42[1]	NS[2]

[1]Sex and age unknown in one subject. [2]P values were calculated by Welch's t-test. [3]P values were calculated by Fisher's exact test. AST, aspartate aminotransferase; ALT, alanine aminotransferase; T-Bil, total bilirubin.

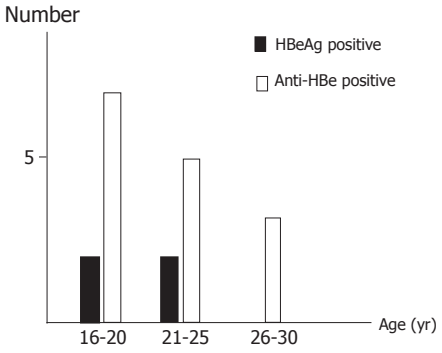

Figure 1 Age-specific prevalence of HBeAg/anti-HBe status in 19 HBV genotype E strains.

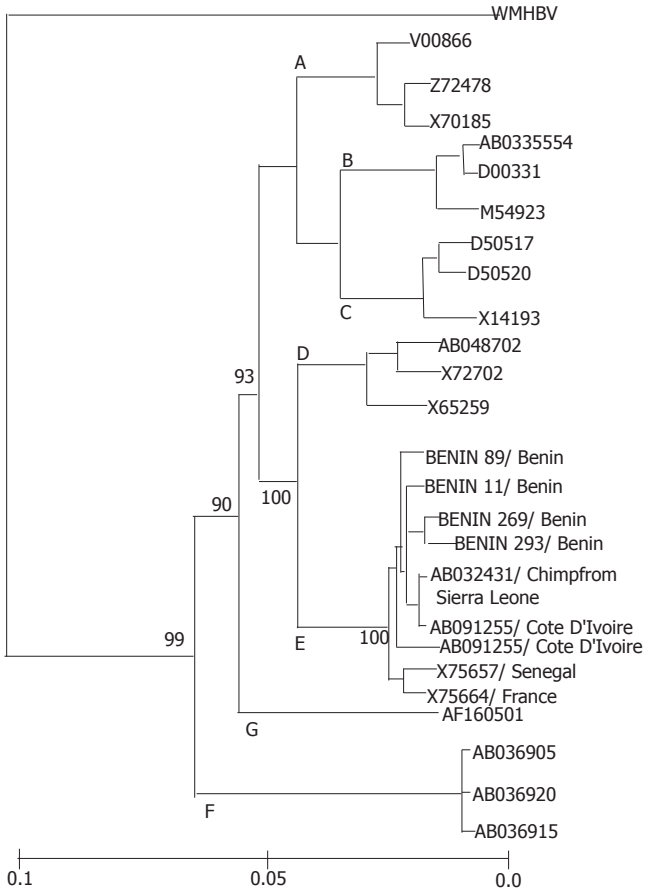

Figure 2 Phylogenetic tree constructed on complete nucleotide sequences of 26 HBV isolates. The nine HBV genotype E isolates were compared along with 16 HBV isolates representative of the other six genotypes **(A–D,** F and **G**), along with woolly monkey hepatitis virus (WMHBV) as an outgroup. The four HBV genotype E isolates determined in this study are indicated in boldface, and the other 22 HBV isolates are specified by accession numbers. The country of origin is indicated after the slash for each HBV isolate of genotype **E.**

and anti-HBe-positive patients were compared (Table 1). The mean age of the HBeAg-positive group was not lower than that of the anti-HBe-positive group. As a matter of course, the difference in the mean HBV DNA titer between the two groups was statistically significant (P<0.0005). HBV DNA titers in anti-HBe-positive subjects were quite low. To examine the correlation between age and HBeAg/anti-HBe status in detail, the age-specific prevalence of the HBeAg/anti-HBe status in 19 HBV/E subjects was analyzed. Seroconversion (SC) during the late teens occurred in 7 of 19 subjects (36.8%, Figure 1). This was the reason why the comparison of age between the two groups was not statistically significant.

Phylogenetic analysis of four strains

HBV full genomes of four HBeAg-positive patients were determined to have a nucleotide length of 3 212 bp. Phylogenetic analysis of the complete genome sequences of these four strains compared to those of 22 HBV strains from the DDBJ/GenBank/EMBL database showed that four strains clustered with five other HBV/E strains (accession numbers: X75657, X75664[2]; and AB032431[19]; AB091255, AB091256[11]) (Figure 2). The nucleotide homology within the HBV/E cluster ranged from 96.7% to 99.2%. In addition, the phylogenetic analysis of four ORFs showed no recombination of HBV/E strains in the Republic of Benin (Figure 3). Genetic diversity among HBV/E strains was very low compared to the other genotypes, excluding HBV/G. The nucleotide sequence data reported in this article will appear in the DDBJ/GenBank/EMBL nucleotide sequence databases with the accession numbers AB201287-90.

Characteristics of nucleotide substitutions in BCP and precore region

In order to find out the HBV/E-specific nucleotide substitution associated with HBe protein production, the BCP to the precore region of nine HBV/E strains and the strains of six genotypes were compared (Figure 4). The representative nucleotide sequences of HBV/A (Aa-Ae), B, C, D, F, and G were determined by aligning five sequences of each genotype, and the consensus nucleotide was deduced, if the identical nucleotide was detected in 60% or more of the sequences. In the BCP, the nucleotide substitution at A1757 was observed in all the strains of HBV/E. This substitution was not found in HBV/A-C, HBV/F, and HBV/G, but was found in more than half of HBV/D[20]. BCP double mutation (T1762/A1764) was not found in the HBV/E strains; however, T1772C substitution was found in all the HBV/E strains as well

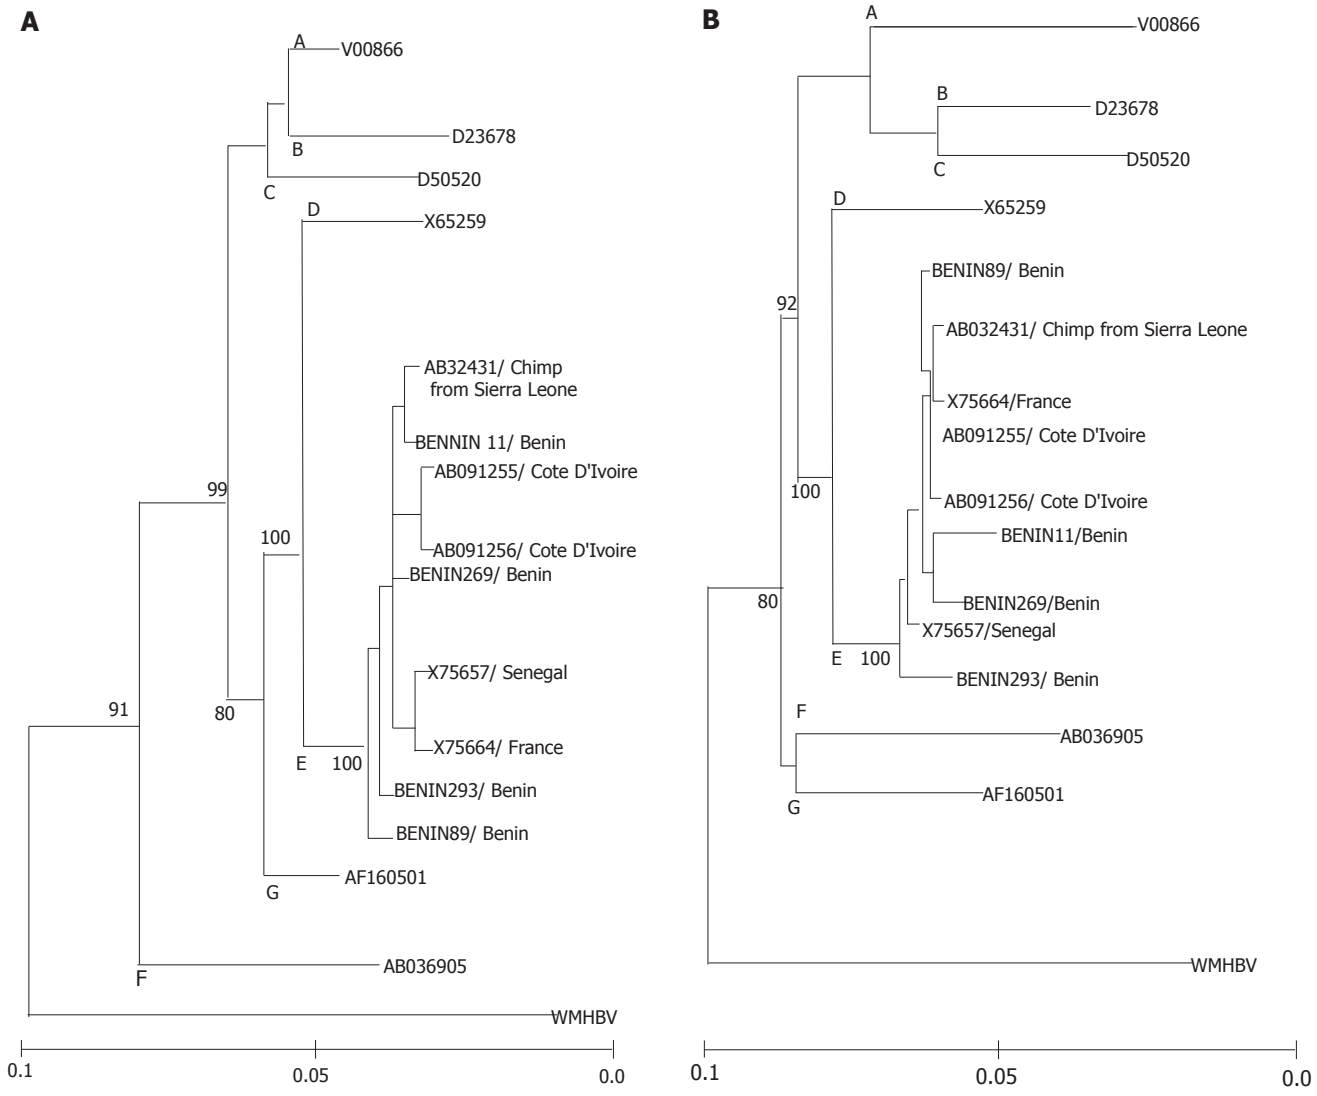

Figure 3 Phylogenetic trees representing the large S gene (**A**), and precore region plus core gene (**B**) along with the strains of the other six genotypes and WMHBV.

as in HBV/B, C and F. Other sequences in the BCP were conserved irrespective of genotypes, except for the above mutations. One HBV/E isolate had T1809 substitution prior to the start of precore ORF, which is recognized as the Kozak sequence frequently found in HBV/Aa. Precore stop mutation (A1896) was not found in the HBV/E.

DISCUSSION

In this study, the distribution of HBV genotypes among blood donors in the Republic of Benin was analyzed for the first time. In Africa, HBV/D is dominant in the Northern region[21], with HBV/A found in South Africa. HBV/E is the major genotype in the Republic of Benin. This agrees with previous reports that HBV/E is prevalent mainly in West Africa[2,11,22]. In addition, the distribution of HBV/E is restricted to West Africa, unlike other genotypes. Though slaves have migrated from West Africa to North America, HBV/E is not found in USA, suggesting that genotype E emerged from the mid to late 19th century[22,23].

East Asia and Sub-Saharan Africa are the two most HBV endemic areas; however, clinical differences have been shown between the two areas. Vertical transmission is the main route in Asia, whereas horizontal transmission is the main route in Africa, and SC occurs much earlier in Africa than in Asia[24,25]. It is important to examine the clinical characteristics of asymptomatic HBV carriers in Benin, which reflect the characteristics of HBV/E, because there are only a few reports concerning the clinical characteristics of HBV/E. As shown in Figure 1, SC is thought to occur at a young age in subjects with HBV/E in Benin. These data might explain one of the reasons why vertical transmission does not occur in West Africa. Recently, the difference in SC between HBV/B and HBV/C in Taiwan was reported[5]. SC occurs a decade earlier in HBV/B patients[26,27] and the mean SC age in HBV/B is approximately 30 years. In comparison with HBV/B, the mean SC age in HBV/E occurs even earlier. These data lead us to speculate that HBV/E has a better prognosis than other genotypes in terms of chronic liver disease.

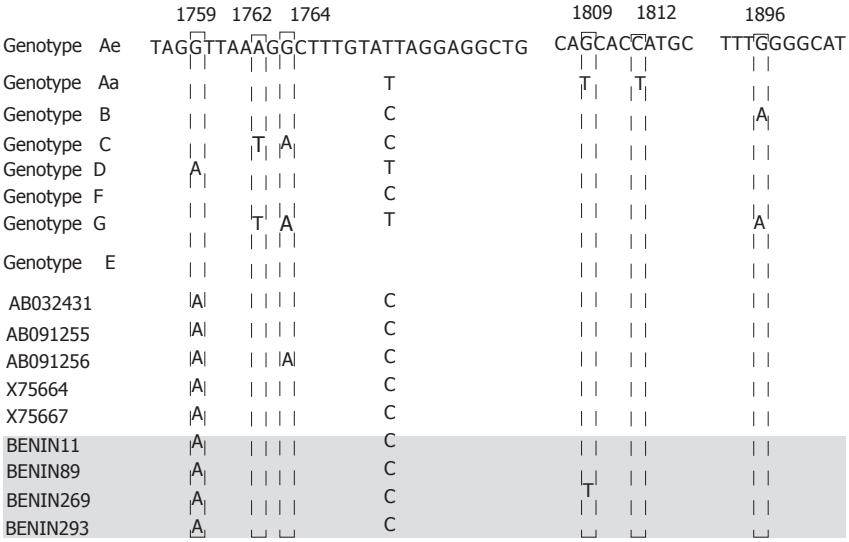

Figure 4 Nucleotide sequences constituting parts of the BCP to the precore of nine HBV genotype E isolates with the consensus sequences of the other six genotypes. The four Benin isolates determined in this study are shaded in gray.

Regarding hepatocellular carcinoma (HCC), a report from Gambia, where HBV/E is the most prevalent, revealed that chronic HBV infection is associated with HCC development at a younger age[28]. Infection with HBV/B is associated with HCC development at a young age in Taiwan[5]. In this sense, HBV/E in West Africa is clinically more similar to HBV/B than HBV/C, and virologically, HBV/E and HBV/B have a high frequency of a precore mutation, G1896A, in common[11,29]. Further information about the clinical characteristics of HBV genotypes might reveal the reason why the age of SC and the age-related HCC incidence differ among genotypes.

So far, only five complete genomes of HBV/E (one from a chimpanzee) have been reported. By adding the four complete genomes reported here, phylogenetic analyses of the full genome and ORFs show much more clearly that HBV/E has a low genetic diversity, as previously reported[11,22,23]. Although subtypes of HBV/B, which have recombination in the BCP to the core region[7] and subtypes of HBV/A[8,30] have been reported, the analysis of nine HBV/E genomes shows neither the possibility of subtypes nor the possibility of recombination.

As mentioned above, HBV/A is divided into two subtypes: HBV/Aa, 'Aa' indicates Asia and Africa, and HBV/Ae, 'Ae' indicates Europe[8,30]. Subtype HBV/Aa has subtype-specific substitutions just before precore start codons, known as the "Kozak sequence". Substitutions reduce the HBeAg expression[10,31]. Hence, genotype- and subtype-specific nucleotide substitutions in the BCP region are crucial, not only in viral replication but also in HBe SC. In this study, we identified the mutation in the BCP, $A^{1757,}$ in HBV/E. Other genotypes have G^{1757} except for HBV/D, in which A^{1757} is observed in about 70%[20]. BCP has been identified as a sequence that regulates both precore and pregenomic messages[32]. The core promoter A1762T and G1764A double mutation is known to downregulate precore mRNA but does not seriously affect pregenome mRNA[33]. The double mutation (1762/1764) occurs over time, as the viral load and HBeAg/anti-HBe status change, and the sequences around the double mutations are conserved irrespective of the genotype so far. However, HBV/E seems to possess 1757A from the early stage of the infection, similar to Kozak sequence substitutions in genotype Aa. Thus, the different functions in relation to nuclear receptor binding between 1757G and 1757A was shown in an *in vitro* study, when the mechanism of suppression of HBV precore RNA transcription by core promoter double mutation was sought. The double mutation in 1762 and 1764 changes the nucleotide sequences of the nuclear-factor binding site of BCP. When the mutation occurs, the nuclear factor known as COUP TF I cannot bind to BCP. Instead, a different nuclear factor, HNF1, binds, and this alters the efficiency of precore and core mRNA transcription. The artificial mutation was created with the intention to create a sequence that neither COUP TF I nor HNF-1 can bind. This mutation is G1757A, and the mutation abolishes both the nuclear factors (COUP TFI and HNF1) binding to BCP in the *in vitro* experiment[34]. This unique mutation and its alteration of nuclear factor binding capacity to the BCP region might influence the clinical characteristics of HBV/E. Further studies, including *in vitro* studies, are expected.

Abstract

AIM: To examine the serum from black African patients with acute hepatitis B to ascertain if integrants of viral DNA can be detected in fragments of cellular DNA leaking from damaged hepatocytes into the circulation.

METHODS: DNA was extracted from the sera of five patients with uncomplicated acute hepatitis B and one with fulminant disease. Two subgenomic PCRs designed to amplify the complete genome of HBV were used and the resulting amplicons were cloned and sequenced.

RESULTS: HBV and chromosomal DNA were amplified from the sera of all the patients. In one patient with uncomplicated disease, HBV DNA was integrated into host chromosome 7 q11.23 in the WBSCR1 gene. The viral DNA comprised 200 nucleotides covering the S and X genes in opposite orientation, with a 1 169 nucleotide deletion. The right virus/host junction was situated at nucleotide 1 774 in the cohesive overlap region of the viral genome, at a preferred topoisomerase I cleavage motif. The chromosomal DNA was not rearranged. The patient made a full recovery and seroconverted to anti-HBs- and anti-HBe-positivity. Neither HBV nor chromosomal DNA could be amplified from his serum at that time.

CONCLUSION: Integration of viral DNA into chromosomal DNA may occur rarely during acute hepatitis B and, with clonal propagation of the integrant, might play a role in hepatocarcinogenesis.

Key words: Hepatocellular; Chronic hepatitis B infection; Clonal propagation

INTRODUCTION

Hepatitis B Virus (HBV), the prototype member of the family Hepadnaviridae, belongs to the genus Orthohepadnavirus. Compelling evidence supports a causal role for chronic HBV infection in hepatocellular carcinoma (HCC)[1,2]. Less certain is the pathogenesis of HBV-induced HCC. Direct and indirect carcinogenic mechanisms have been implicated, the latter mainly by the frequency with which this tumor co-exists with cirrhosis[3,4]. Evidence for a direct effect is provided by the development of HCC in an otherwise normal liver (in as many as 40% or more of black African patients[5]) and by observations in a variety of animal models. The latter include the development of HCC in the absence of cirrhosis, both in animals that were chronically infected with other members of the family Hepadnaviridae[6-8] and in transgenic mice with HBV DNA incorporated into the germline[9]. Further support comes from the finding of integrated hepadnaviral DNA in cellular DNA in HCCs in animal and human hosts[10-14]. The latter does not, however, prove that insertion of viral DNA is essential for hepatocarcinogenesis. If clonal expansion of integrated HBV DNA proves to be a pivotal step in hepatocarcinogenesis, the timing of integration becomes important. Because HCC typically develops in patients chronically infected with HBV, it has been assumed that DNA insertion occurs at some point during persistent infection. Integration during the short period of viral replication in acute hepatitis B had not been conclusively demonstrated[15-17]. However, in a recent study, integration of HBV DNA was demonstrated in 3 of 19 liver specimens from patients with acute hepatitis B, one of whom had subacute fulminant hepatitis[18]. Moreover, a study in acutely infected ducks showed that insertion of duck HBV (DHBV) DNA into host DNA may occur as early as d 6 after the infection[12]. HCC does not, however, develop in ducks chronically infected with DHBV. The time at which integration occurred was studied in the liver tissue and a similar study could not, for obvious ethical reasons, be performed in human beings with acute hepatitis B.

In a previous study, primers used to amplify the complete genome of HBV were found to amplify

chromosomal DNA also. Taking advantage of this phenomenon and the leakage into the bloodstream of fragments of cellular DNA from damaged hepatocytes during acute liver injury[19,20], we examined the serum of patients with acute hepatitis B for integrated HBV DNA.

MATERIALS AND METHODS

Patients studied

Blood samples were drawn, with informed consent, from six South African blacks suffering from acute hepatitis B during the peak of the disease or shortly thereafter. Permission to undertake this study was given by the Human Ethics Committee of the University of Witwatersrand. In five patients, the illness was uncomplicated, and all recovered completely; the remaining patient had fulminant hepatitis B and died of liver failure. Alanine aminotransferase levels in the early stages of the illness ranged between 799 and 4 747 IU/L. The patients varied in age from 18 to 32 years: 3 were males and 3 females. Serum known to be HBsAg-positive and HBsAg-negative was used as positive- and negative-extraction controls, respectively. The sera were stored at -70 °C until analyzed.

DNA extraction, amplification, cloning, and sequencing

Total DNA was extracted from the sera using the QIAamp DNA Mini Kit (QIAGEN GmbH, Hilden, Germany), according to the manufacturer's instructions. Two subgenomic PCRs designed to amplify the complete genome of HBV were used and the resulting amplicons were cloned and sequenced. A modification of the method of Takahashi K *et al*[21] was used, which involved the amplification of two overlapping fragments of HBV, fragment A (1.35 kb) and fragment B (2.2 kb). However, this amplification designed for amplification of viral DNA also fortuitously, randomly recognized chromosomal DNA, leading to the amplification of genomic DNA in addition to HBV DNA. The sequence of the primers is given in Table 1. The reaction mix for the amplification consisted of 2.25 μL 10× Ex Taq buffer with 20 mmol/L $MgCl_2$ set as subscript, 2 μL 2.5 mmol/L dNTP mix, 1.25 μL each of the appropriate primers (Table 1), 2.5 μL DNA, made up to 22.5 μL with water (SABAX water for injection, Adcock Ingram, Johannesburg, South Africa). The enzyme mix was made up of 1.875 μL water, 0.25 μL 10× Ex Taq and 0.375 μL TaKaRa Ex Taq polymerase [TaKaRa Biotechnology (Dalian) Co., Ltd., Shiga, Japan]. The 22.5μL reaction mix was preheated to 94 °C for 2 min and 2.25 μL TaKaRa Ex Taq enzyme mix was added at the first annealing step. This was followed by 40 cycles of amplification with the cycling profile shown in Table 1. Both HBV-positive and HBV-negative controls were included. The latter consisted of water instead of DNA in the PCR mixture. To avoid cross-contamination and false-positive results, the precautions and procedures suggested by Kwok and Higuchi[22] were strictly adhered to. DNA extraction, PCR amplification, and electrophoresis were performed in physically separated venues.

Amplicons were cloned into a pPCR-ScriptTM Amp SK+ vector (Stratagene, La Jolla, CA, USA) according to the protocol provided by the manufacturer. The positive clones containing either inserts of the correct or shorter size were prepared for direct sequencing using the BigDye Terminator v3.0 Cycle Sequencing Ready Reaction Kit (Applied Biosystems, Foster City, USA) and sequenced on a 377 DNA automated sequencer (Applied Biosystems, Inc.) using primers T3 (5'-AATTAACCCTCACTAAAGG G-3') and T7 (5'-GTAATACGACTCACTATAGGGC-3'). All sequences were analyzed in both forward and reverse directions.

RESULTS

In addition to yielding amplicons of the expected size, i.e., 1.35 kb for fragment A and 2.2 kb for fragment B, the two subgenomic PCRs designed to amplify the complete genome of HBV gave rise to smaller amplicons ranging in size from 100 to 750 bp. These amplicons were successfully cloned into a pPCR-Script^{TM} Amp SK^{+} vector (Figure 1) and a number of clones from each of the six patients were sequenced (Table 2).

The majority of the clones contained HBV DNA only and the detailed analysis of these sequences will be published elsewhere. Fortuitously, the primers designed for the amplification of viral DNA amplified Chromosomal DNA was amplified in 5 patients using primers designed to amplify fragment A (Table 1) and in the remaining patient with primers designed to amplify fragment B. As shown in Table 2, the chromosome number and the lengths

[1]Fragment A amplified with primers 455 (+) and 1 800 (–); fragment B amplified with primers 1 687 (+) and 685 (–).[2] yr, years; bp, base pairs; [3]Patient with fulminant hepatitis.

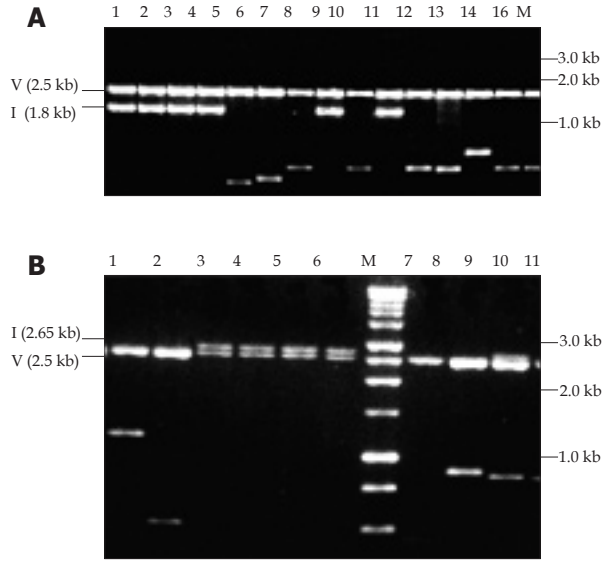

Figure 1 Ethidium bromide stained with 1% agarose gel showing pPCR-Script Amp SK(+) plasmid containing amplicons restricted with PvuII. In panel A, the fragments cloned were amplified with primers 455(+) and 1 800(–). Lanes 1-4, 8, and 10 show the expected size insert of -1.8 kb for fragment A amplicon (1.3 kb) whereas lanes 5-7, 9, and 11-16 show shorter inserts ranging in size 0.6-1.1 kb. In panel B, the fragments cloned were amplified with primers 1 687(+) and 685(–). Lanes 3-6 and 9 show the expected size insert of -2.65 kb for fragment B amplicon (2.2 kb), lane 7 is vector alone and lanes 1, 2, 8-11 show shorter inserts ranging in size 0.5-1.2 kb. M: Promega 1 kb molecular weight marker, V: vector, I: insert of expected size (A and B).

of the fragments varied, although in three cases the fragment amplified corresponded to the sequences from chromosome 1.

In one patient with uncomplicated hepatitis B, HBV DNA was found to be integrated into host chromosome 7q11.23 in the WBSCR1 gene using primers for fragment A. WBSCR1 corresponds to the eukaryotic initiation factor 4H identified in rabbits[23,24] and is within the region encompassing the elastin gene. This region is commonly deleted in patients with Williams–Beuren syndrome, giving rise to loss of heterozygosity[24,25]. The viral DNA comprised 200 nucleotides covering the S and X genes in opposite orientation, with an 1 169 nucleotide deletion (Figure 2). The right virus/host junction was situated at nucleotide 1 774 in the cohesive overlap region of the viral genome, at a preferred topoisomerase I cleavage motif (TAA). The left virus/host junction of the integrant was not identified and, therefore, the length of the integrant could not be determined. Following phylogenetic analysis of the 175 nucleotides of the S region (nucleotides 4-630), the sequence clustered with subgenotype A1 of genotype A, which is the predominant genotype in southern Africa[26-28]. When the 175 nucleotides of the insert covering the S region were translated, starting at nucleotide 3 of the fragment, the amino acid at position 122 was K, which is characteristic of serotype ad. Amino acid 160, which encodes for the w/r determinant, was not included in this fragment and, therefore, we cannot conclusively determine the serotype, although we can probably assume that the determinant is w because the predominant serotype in southern Africa is adw. The nucleotide sequence of the chromosomal DNA (262 bp) was completely conserved and not rearranged. The 3' end was amplified by primer 1 800 (-) (Table 1). A BLAST search[29] revealed that in addition to binding to chromosome 7, the primer 1 800 (–)

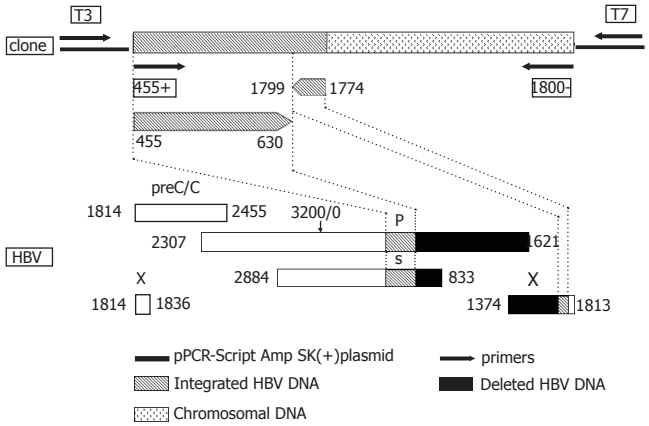

Figure 2 Schematic representation of the HBV DNA integrant amplified from the serum of acute hepatitis patient (#0962) using primers 455 (+) and 1 800 (–) and cloned into pPCR-Script Amp SK (+) plasmid relative to the HBV genome. The lower part of the figure represents the genetic organization of the four open reading frames of HBV, preC/C: precore/core, P: polymerase gene, S: surface gene and X: X gene. Numbering according to nucleotide position of HBV GenBank accession no. V00866 where the EcoRI cleavage site is position 1.

(Table 1) has identical sequences on human chromosomes 2, 3, 12, 13, 20, 22, and Y. The sequence of the integrated HBV DNA and flanking the chromosomal DNA has been deposited in GenBank (accession no. AY223548).

The patient with the integrant was a 27-year-old Xhosa gold-mine laborer, who was previously healthy and presented with the typical clinical features of uncomplicated acute viral hepatitis. When he was first tested, the tests of liver function showed a serum bilirubin concentration of 257 μmol/L (conjugated bilirubin 228 μmol/L), alkaline phosphatase 91 IU/L, γ-glutamyl transferase 94 IU/L, alanine aminotransferase 3 238 IU/L, aspartate aminotransferase 2 781 IU/L, and albumin 4 g/L. HBV surface antigen, e antigen, and IgM core antibody were present in the serum. The patient made an uneventful and complete recovery, with return of biochemical tests to normal and disappearance of surface and e antigens and the appearance of IgG core antibody and antibody to surface and e antigens in his serum. HBV DNA could not be detected in the serum. after he had recovered and cloning and whole genome sequencing were not attempted at that time.

DISCUSSION

Unlike retroviruses, in which insertion of viral DNA into host DNA is integral to the replication cycle, integration does not occur during normal hepadnaviral replication. Integration of hepadnaviral DNA may, however, take place as a result of an illegitimate recombination mechanism mediated by cellular enzymes[12,30]. Clonally propagated integrations have been detected in the majority of HCCs that develop in the presence of chronic hepadnaviral infection[6-10] and have been incriminated in the hepatocarcinogenesis that often complicates persistent infection. HBV DNA insertions are found at random sites in human cellular DNA, although some chromosomes are affected more often than others[31]. In the present study, we detected an integrant in chromosome 7 of an acute hepatitis B patient.

Although we cannot exclude the possibility that the HBV integrant amplified was the result of a PCR artefact, there are a number of observations that argue against this interpretation and support our conviction that this integrant was authentic.

Firstly, the site of integration in chromosome 7q11.23 is within the WBSCR1 gene. This gene corresponds to the eukaryotic initiation factor 4H identified in rabbits[23,24] and the integrant is within the region commonly deleted in patients with Williams-Beuren syndrome, giving rise to loss of heterozygosity[24,25]. Moreover, the WBSCR1 gene contains a high abundance of Alu repeats[24], repetitive elements that have been shown to be the preferred sites for recombination and for HBV DNA insertion[32]. Analogously the sites of integration in the three patients with acute hepatitis B reported by Murakami and coworkers[18] were the intronic sequence of the tumor necrosis factor-induced protein gene and a repetitive sequence in the two patients with a single integrant; and the intronic sequence of a hypothetical protein gene (LOC 169443) and a repetitive sequence in the patient with two integrants.

Secondly, the region of HBV integrated (position 1 774-1 799 from EcoRI site) is a highly preferred site of integration of hepadnaviral DNA, that is, close to the 11-bp direct repeat sequence DR1 (position 1 824-1 834) and within the cohesive overlap region between DR1 and DR2[33].

Thirdly, the one viral DNA/chromosomal DNA junction in the single integrant detected in our patient with acute hepatitis B was located at nucleotide 1 774 of the viral genome, a highly preferred topoisomerase I cleavage motif. Linear hepadnaviral DNA is the primary substrate for integration[12,30], and the circular DNA must first be linearized before integration can take place. Insertion is then accomplished by strand invasion of cellular DNA. Thus, integration of viral DNA into chromosomal DNA requires that the linear DNA be imported into the nucleus of the infected cell[30,34,35]. Wang and Rogler[30] have produced experimental evidence for a key role for the cellular enzyme topoisomerase I in the illegitimate recombination between hepadnaviral and host DNA. A role for this enzyme in illegitimate recombination is supported both by the finding of highly preferred topoisomerase I cleavage motifs in the immediate vicinity of almost all crossover sites in mammalian DNA, and by the observation that integrants in WHV-induced HCC in woodchucks occurred at preferred topoisomerase I cleavage sites[30].Fourthly, the integrated HBV DNA covered the S and X regions, the open reading frames most commonly integrated into chromosomal DNA[36].

Finally, the integrant detected in the serum of our patient with acute hepatitis B conformed in general to the integrants described in HCC developing in the

presence of chronic HBV infection[31]. It contained a long deletion (1 169 nucleotides in length), and the viral DNA between the right end of the deletion and the right virus/chromosome junction was inverted X sequence (Figure 1). One or more deletions or other more complex rearrangements are invariably found in inserted hepadnaviral DNA[10,31], indicating that specific mechanisms for integration of functional viral DNA into chromosomal DNA are not encoded by the virus. Simple microdeletions are most common, probably because the single-stranded ends of viral DNA resulting from topoisomerase I cleavage are sensitive to cellular nucleases. The larger deletions and complex rearrangements of the viral DNA are generally believed to occur after the integration[37], although WHV with extensive rearrangements of DNA has been described in hepatocyte nuclei in woodchucks[38] and there is some evidence in these animals that DNA rearranged in this way may be preferentially integrated[39]. Similarly, Yaginuma *et al*[40] observed features of HBV integration to be common to HCC and patients with chronic active hepatitis and an analogous integrant to the one detected in this study has been described in a 9-year-old child with HCC[41].

Integration of hepadnaviral DNA into host DNA is normally rare, perhaps because recycling of viral DNA into the nucleus is at a low level during productive infection[12]. The frequency of integration of DHBV in experimentally infected ducklings was estimated to be one viral genome per 103-104 cells by 6 d after the infection[12]. It is not known if these recombination events occurred in many cells or if a few cells produced many such events. In keeping with the belief that insertion events are uncommon, we found only a single integrant among many clones in only one of 6 patients with acute hepatitis B. Our finding, and that of others[12,18], of integrated viral DNA in early infection is in accordance with the observation, that importation of linear DNA into the nucleus is necessary for insertion of viral DNA into chromosomal DNA, and that such importation is known to occur in the phase of cccDNA amplification during the initiation of infection[42]. Opportunities for viral integration beyond the early phase of infection would require continued importation of viral DNA into the nucleus, depend on new rounds of infection or loss and replacement of cccDNA by cell turnover[12]. Thus, insertion of linear forms of viral DNA may occur preferentially during early phases of infection or during periods of extensive hepatocyte turnover and/or re-infection, at times when linear viral DNA is imported into the nuclei. Integration may be enhanced during these periods by the availability of DNA ends resulting from DNA replication or damage[43]. Alternatively, interference with the normal replication cycle at some stage in chronic infection may result in the accumulation of linear forms of DNA, and there is some evidence for defective replication of HBV and accumulation of replicative intermediates in patients with HBV-associated HCC[44].

The clinical, biochemical, and serological features of the acute hepatitis B in the patient with the integrant did not differ obviously from those in the other patients with uncomplicated disease. He made a complete clinical and biochemical recovery, and seroconverted to anti-HBs and IgG anti-HBc. At this stage, HBV DNA could no longer be detected in his serum by PCR amplification and further cloning was not attempted. Even if the integrated HBV DNA was still present in hepatocytes, it would not be detected in peripheral blood once healing of hepatocyte cell membranes had taken place. Thus, persistence of the integrated HBV DNA could only have been detected by analysis of liver tissue, and a liver biopsy was not felt to be justified. Although sources other than the liver for the chromosomal DNA amplified in the peripheral blood of the six patients with acute hepatitis B (including the one with fulminant hepatitis) are possible (for example, peripheral blood mononuclear cells), the finding of viral DNA integrated into host DNA in one of the patients favors leakage of chromosomal DNA fragments from damaged hepatocytes during the acute liver injury.

Our finding of an integrant in a patient with acute hepatitis B may have no significance in relation to subsequent HCC development. Clonal expansion of an integrant is required for tumor formation, and the finding of a viral insertion in a tumor may simply reflect the fact that the clonal progenitor of the tumor happened to carry a viral integration[10]. Moreover, integrants may be lost from successive generations of cells[45]. Nevertheless, it is in accordance with the observation made in ducks that hepadnaviral DNA insertion may occur at a very early stage of infection, and raises the possibility that in certain circumstances early integration of HBV DNA might play a role in HBV-induced hepatocarcinogenesis.

Abstract

AIM: To investigate the relationship between certain biochemical parameters of lipid metabolism in the serum and steatosis in the liver.

METHODS: The grade of steatosis (0-3) and histological activity index (HAI, 0-18) in liver biopsy specimens were correlated with serum alanine aminotransferase (ALT), total cholesterol and triglyceride levels in 142 patients with chronic hepatitis C (CH-C), and 28 patients with non-alcoholic fatty liver disease (NAFLD) without hepatitis C virus (HCV) infection. The serum parameters were further correlated with 1 797 age and sex matched control patients without any liver diseases.

RESULTS: Steatosis was detected in 90 out of 142 specimens (63%) with CH-C. The ALT levels correlated with the grade of steatosis, both in patients with CH-C and NAFLD ($P<0.01$). Inserting the score values of steatosis as part of the HAI, correlation with the ALT level ($P<0.00001$) was found. The triglyceride and cholesterol levels were significantly lower in patients with CH-C (with and without steatosis), compared to the NAFLD group and to the virus-free control groups.

CONCLUSION: Our study confirms the importance of liver steatosis in CH-C which correlates with lower lipid levels in the sera. Inclusion of the score of steatosis into HAI, in case of CH-C might reflect the alterations in the liver tissue more precisely, while correlating with the ALT enzyme elevation.

Key words: Lipid metabolism; Chronic hepatitis C; NAFLD

INTRODUCTION

Hepatic steatosis is a frequent and characteristic histological finding in patients with chronic hepatitis C (CH-C) in addition to bile duct damage and lymphoid follicles[1-5]. Fat accumulation in hepatocytes has been reported in 30-70% of liver biopsy specimens obtained from patients infected with hepatitis C virus (HCV)[1-4]. Whether steatosis is mainly related to host factors or to the viral cytopathic effect is still uncertain and a matter of dispute[6-15]. The pathogenesis of development of steatosis in CH-C is complex; host factors including alcohol consumption, exposure to other hepatotoxins, obesity, insulin resistance, type 2 diabetes mellitus, hypertriglyceridaemia, hypobetalipoproteinemia have all been identified as determinants[8,12,16-18].

The most important question concerning the clinical significance of steatosis in CH-C is whether lipid accumulation influences the liver disease progression, affects treatment, or is solely an innocent bystander[5,19]. A role of steatosis in the progression of CH-C is suggested by the finding that the severity of fat accumulation correlates with the stage of fibrosis[20,21] and liver cell apoptosis[5]. Treatment with peginterferon or IFNα-2b and ribavirin has been found to reduce steatosis in HCV genotype 3 patients[1]. On the other hand, no significant association between the stage of fibrosis and liver steatosis has been found by others[22]. *In vitro* studies and transgenic mouse model have both shown the HCV core protein to be capable of inducing steatosis by itself[23,24], which suggests a direct effect of specific viral sequences in the pathogenesis of lipid accumulation. An association of nonstructural protein 5A (NS5A) with lipid droplets and apoA1 has also been observed[11].

The aim of the present work was to study the changes in certain parameters of lipid metabolism in patients with CH-C and compare the findings with the accumulation of fat in liver biopsy specimens and with the histology activity index (HAI). For this reason the serum cholesterol and triglyceride levels of CH-C patients were examined. Patients were selected on the basis of the presence or absence of steatosis in their liver biopsy specimens, as well

as the absence of other risk factors for developing steatosis from a broader HCV-positive group referred to our center for treatment of chronic liver diseases. The results were compared to the lipid levels of patients with non-alcoholic fatty liver disease (NAFLD) verified histologically (NAFL, obesity, diabetes mellitus), and with data of a further control group: outpatients from the praxis without clinical and laboratory signs of liver disease, with or without history of alcohol abuse.

MATERIALS AND METHODS

Study population

A total of 142 patients with chronic HCV infection with no history of alcohol consumption were studied before the treatment with antiviral drugs (Table 1). CH-C was diagnosed on the basis of biochemical (serum aminotransferases greater than or equal to 1.5 times the upper normal value for at least 6 mo), serological (positivity for anti-HCV antibody, detection of HCV-RNA in the sera using the Amplicor HCV assay, Roche, Mannheim) and histological findings in liver biopsy specimens. Among the patients, 90 (63%) had micro- or macro-vesicular steatosis in their hepatocytes. This group comprised 46 females (26 patients younger than 44 years, average 38 years; 20 patients older than 45 years, average 52 years) and 44 males (29 patients younger than 44 years, average 38 years; 15 patients older than 45 years, average 51 years). There were 52 CH-C patients without steatosis, and this group comprised 17 females (10 patients younger than 44 years, average: 29 years; 7 patients older than 45 years, average: 53 years) and 45 males (24 patients younger than 44 years, average: 34 years; 11 patients older than 45 years, average: 49 years).

The control group was made up of 28 (16 males and 12 females) patients with NAFLD without HCV infection (Table 1).

A total of 1 797 patients from the outpatient praxis served as another control group which was matched to the CH-C patients with regard to age (Table 1). The 133 patients younger than 44-year-old female patients included 125 non-alcoholic and 8 alcoholic, the 819 patients older than 45-year-old females included 803 non-alcoholic and 16 alcoholic patients. Among the 146 patients younger than 44-year-old males, 60 were non-alcoholic and 86 were alcoholic patients. Out of the 699 patients older than 45-year-old males, 509 were non-alcoholic and 190 were alcoholic patients (Table 1).

Laboratory, virology assessment

Blood samples for the evaluation of alanine aminotransferase (ALT), total cholesterol and triglyceride were obtained after overnight fasting. Routine biochemical tests were carried out using commercially available kits. The HCV-RNA was determined in the sera using an RT-PCR assay (Amplicor, Roche, Mannheim), with a sensitivity of 70 copies/mL.

Histopathological evaluation

Liver biopsy was performed according to the Menghini technique. The biopsy specimens were formalin-fixed and paraffin-embedded, routinely stained with hematoxylin-eosin, picrosirius red, and a Berliner-blue reaction was carried out for the detection of iron. The slides were evaluated by two independent pathologists. A modified Knodell's histological activity index score[25,26] was applied to semiquantitatively score necroinflammatory activity (grade 0-18) and fibrosis (stage 0-4). Steatosis was graded according to the percentage of hepatocytes containing vacuoles in the cytoplasms (macro- or micro-vesicular steatosis). Steatosis was graded as follows, based on the percentage of fat containing hepatocytes[18]: none (0); mild (1: <10% of hepatocytes); moderate (2: 10-30% of hepatocytes); and severe (3: >30% of hepatocytes).

Statistical analysis

One-way analysis of variance was used to differentiate the data among the groups. Pearson's correlation coefficient was applied to measure the degree of association between the variables. $P < 0.05$ values were corrected according to the Bonferroni method. All values were presented as mean ±SD.

RESULTS

Steatosis was detected in 90 out of the 142 specimens (63%) with CH-C. The ALT levels were significantly higher in patients with grade 3 compared to grade 0 steatosis in the CH-C group ($P < 0.01$) (Figure 1). Significant correlation was found between the ALT level and HAI in the CH-C group without steatosis ($r = 0.556$, $P < 0.0002$) (Figure 2A), while this correlation could not be detected in the CH-C with steatosis subgroup (Figure 2B). Inserting the score values of steatosis (0-3) as part of the activity index (HAI)

Table 1 Study population with or without HCV-infection

	Male			Female			Total
	<44 (yr)	>45 (yr)	total	<44 (yr)	>45 (yr)	Total	
HCV-infection:							
With steatosis	29	15	44	26	20	46	90
Without steatosis	24	11	45	10	7	17	52
No HCV-infection							
NAFLD	10	6	16	5	7	12	28
No liver disease:							
Non alcoholic	60	509	569	125	803	928	1 497
Alcoholic	86	190	276	8	16	24	300

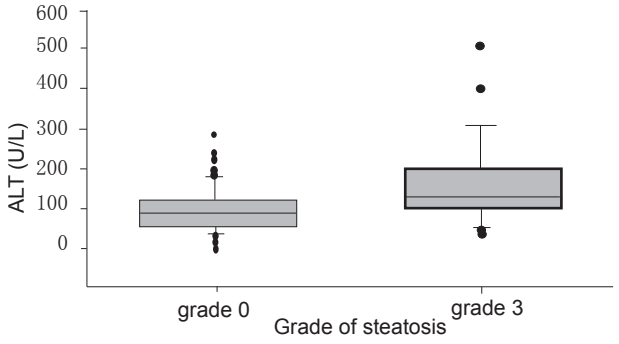

Figure 1 Differences of ALT levels in CH-C patients without steatosis (n = 52, grade 0) and with severe steatosis (n = 28, grade 3) (P < 0.01).

of chronic hepatitis, the correlation between the ALT level and histological scores of inflammatory activity grade was confirmed again in the 142 CH-C patients (r = 0.41, P<0.00001) (Figure 2C). The ALT level also correlated with grade of steatosis in patients without HCV infection (r = 0.533, P<0.005) (Figure 3), similarly to the CH-C patients. Upon comparing the ALT levels in patients with and without steatosis and with steatosis only, the highest ALT level was found in the steatotic CH-C group (Figure 4).

Triglyceride and cholesterol levels of CH-C patients were subgrouped according to age and sex, with and without steatosis. The lipid values of the CH-C groups were compared to the lipid values of the virus-free steatotic patients. The data of these subgroups were further compared based on their average age with the same age and sex group, as well as with the population from the outpatient praxis concerning drinking habits. The lipid levels of CH-C patients with liver steatosis were compared to the levels noted in the drinking outpatients, while these data involving the CH-C patients without liver steatosis were related to the non-drinking outpatients (Figures 5A and B; 6A and B; 7A and B; 8A and B)

The triglyceride levels were low in all the eight separated subgroups with CH-C (with and without steatosis, female, male, young, and elderly patients) (Figures 5A and B; 6A and B). These levels were conspicuously lower compared to the same values of the CH-C virus-free steatotic patients as well as to the drinker or nondrinker population.

Among the same groups, the cholesterol levels showed the same pattern as noted for the triglyceride levels. The only difference was that the young steatotic HCV infected male patients failed to show higher cholesterol levels, as was the case in relation to triglyceride (Figures 7A and B; 8A and B).

DISCUSSION

Liver steatosis is an important hallmark of CH-C[1-4,8,10,13,27-29]. The mechanism of HCV-related steatosis, however, is not exactly clear. Both metabolic[8,16-18,29,30] and viral cytopathic effects[7,10,11,13,24] have been suggested to play a role in the pathogenesis. The HCV viral components, especially the HCV-core protein, have been found in association with steatosis. Lipid droplets on which the core accumulated have been found in HCV-core-transfected cell lines strongly expressing this protein[24]. Hepatic overexpression of the HCV-core protein has been shown to interfere with the hepatic assembly and secretion of triglyceride-rich very low density lipoproteins (VLDL)[31]. Fatty change was detected *in vivo* in core-expressing transgenic mice too[23]. Chimpanzees chronically infected with HCV developed steatosis similarly to human beings[24]. The degree of steatosis in chimpanzees correlated with the amount of viral load and ALT[32].

More recently the NS5A of HCV has been shown in association with lipid droplets and apoA1, suggesting that NS5A may contribute to the pathogenesis of steatosis commonly observed in HCV-infected livers[11]. It has, however, been demonstrated that neither HCV viral load nor HCV genotype is associated with the severity of steatosis in certain studies[29,33].

HCV is a lipid-containing virus which binds to low density lipoprotein, VLDL, IgG and to a minor degree to IgM and high density lipoprotein[34]. This is in correlation with the finding that HCV infection is associated with hypo-β-lipoproteinemia, which occurs in the early stages of HCV infection before the development of cirrhosis[16,35]. The correlation between apo B levels and HCV viral load confirms the interaction between HCV infection and β-lipoprotein metabolism. This suggests that β-lipoproteins competitively inhibit HCV infection, because both HCV and β-lipoprotein use the same LDL receptor[16].

In certain studies, steatosis was found to accelerate the progression of liver disease and correlate with specific HCV genotype[36]. In our study steatosis was detected in 63% of CH-C patients. The ALT-levels were statistically in correlation with the grade of steatosis. Comparing the HAI and ALT levels, a significant correlation was found in the CH-C cases without steatosis, while no difference was found in the group with steatosis. Inserting the score values of steatosis (0-3) into the score of the grade of necroinflammation, a significant correlation was detected for HAI and ALT levels. This suggests that inclusion of the score of steatosis into the grade, for measuring the necroinflammatory reaction in CH-C, might better reflect the alteration in the liver tissue and correlate with ALT enzyme elevation. Our data strongly suggest the importance of steatosis in the virus related necroinflammatory process. Worsening of steatosis was found as an independent factor in fibrosis progression in CH-C[37].

Regarding the different patient subgroups, the triglyceride levels revealed a marked low degree in the C virus-infected patients in comparison to the levels seen in the non-viral steatotic patients and in the relatively large number of outpatients without clinical signs of liver diseases. This detected phenomenon was observable in relation to the age, sex, and drinking habits of the outpatients of the praxis, too.

The behavior of cholesterol levels was the same as in case of the triglyceride levels, while the young steatotic virus-infected male patients failed to show higher elevated levels.

In conclusion, a recent study has found an association

between liver cell apoptosis and steatosis in CH-C patients, which might contribute to the progression of liver injury and fibrosis in CH-C[5]. Our study confirms the importance of the presence of steatosis, which is associated with higher ALT- and lower lipid levels on the periphery in CH-C patients with steatosis. The peripheral lipid levels, however, do not reflect the severity of steatosis or liver damages. Our study suggests that the grade of steatosis in the liver is a substantial part of the determination of the grade of necroinflammation and should be incorporated into the evaluation of liver biopsy materials in CH-C patients.

Abstract

AIM: To investigate the inhibitory effect of VP22 fusion protein-based dominant negative (DN) mutant on Hepatitis Bvrus (HBV) replication.

METHODS: Full-length or truncated fragment of VP22 was fused to C terminal of HBV core protein (HBc), and subcloned into pcDNA3.1 (-) vector, yielding eukaryotic expression plasmids of DN mutant. After transfection into HepG2.2.15 cells, the expression of DN mutant was identified by immunofluorescence staining. The inhibitory effect of DN mutant on HBV replication was indexed as the supernatant HBsAg concentration determined by RIA and HBV-DNA content by fluorescent quantification-PCR (FQ-PCR). Meanwhile, metabolism of HepG2.2.15 cells was evaluated by MTT colorimetry.

RESULTS: VP22-based DN mutants and its truncated fragment were expressed in HepG2.2.15 cells, and had no toxic effect on host cells. DN mutants could inhibit HBV replication and the transduction ability of mutant-bearing protein had a stronger inhibitory effect on HBV replication. DN mutants with full length of VP22 had the strongest inhibitory effect on HBV replication, reducing the HBsAg concentration by 81.94%, and the HBV-DNA content by 72.30%. MTT assay suggested that there were no significant differences in cell metabolic activity between the groups.

CONCLUSION: VP22-based DN mutant can inhibit HBV replication effectively.

Key words: Hepatitis B virus; Dominant negative mutant; VP22

INTRODUCTION

At present, about 3.5 hundred million people are infected with HBV, and about 1 million people die of Hepatitis Bvrus (HBV) infection or related diseases each year, ranking 9th in disease deaths[1-4]. There are no effective therapies for HBV infection. Although about 40% HBV-infected patients responded to interferon, patients in our country have a poorer response to it. Other antiviral agents, such as nucleoside/nucleotide analogs[5], are quite effective inhibitors of HBV replication[6-9]. However, the rapid development of drug resistance remains a growing concern. Gene therapy provides a novel idea for the treatment of HBV infection, can inhibit replication of HBV at gene level and remove HBV from host cells[10-12]. Expression of dominant negative (DN) mutant in liver cells is one of the most important strategies[13-17].

In 1997, Elliott and O'Hare[18] found that VP22, a structural protein (and its fusion protein) of herpes simplex virus type-1 (HSV-1), can enter into the cells from the medium, and translocate between cells in a contact-independent manner. Here, VP22 was fused to HBV core protein (HBc) and a fusion DN mutant was constructed to enhance the antiviral effect of the DN mutant by utilizing the transduction ability of VP22 protein.

MATERIALS AND METHODS

Materials

Plasmids pVP22/*myc*-His2 and pcDNA3.1(-) were purchased from Invitrogen Co. EBO-HBV, in which 1.3-folds of HBV genome was cloned, and stored in our laboratory. Restriction enzymes and ligations were purchased from TaKaRa Biotech Co., Ltd; mouse anti-HBc or c-myc antibodies were purchased from Santa Cruz Co. FITC-labeled sheep anti-mouse IgG was purchased from BioStar Biotech Co., Ltd. DMEM, fetal bovine serum, and Lipofectamine 2000 were purchased from GIBCO Co. Solid phase radio-immunoassay kit was purchased from Beimian Dongya Biotech Institute, Beijing.

Oligonucleotides and primers

All the oligonucleotides and primers were synthesized

by TaKaRa Biotech Co., Ltd. The underlined sequences indicate restriction enzyme (right) sites, respectively, which were added to the oligonucleotide primers for subsequent cloning of amplified DNA. The capital letters indicate start or stop codon.

HBc1: 5'-gcgcggtaccATGgacatcgaccctt-3' (*Kpn*I)

HBc2: 5'-gcgcctcgagTCAggatccacattgaggttccc-3' (*Xho*I, *Bam*HI)

US: 5'-gcccggatccatgacctctcgctccgtg-3' (*Bam*HI)

UR: 5'-ccccagatctatcgggactcgccatacc-3' (*Bgl*II)

DS: 5'-gccgagatctgacgcggccacggcg-3' (*Bgl*II)

DR: 5'-gggcctcgagTTAcagctaatcctcttctgag-3' (*Xho*I)

c-myc1:5'-gcccggatccgaacaaaaactcatctcagaagaggatctgTAActcgaggggc-3' (*Bam*HI, *Xho*I)

c-myc2:5'-gggcctcgagTTAcagatcctcttctgagatgagtttttgttcggatc
cgccc-3' (*Xho*I, *Bam*HI)

Cell culture

HepG2.2.15 cells integrated with full-length HBV gene[19-21] were cultured in DMEM containing 150 mL/L fetal bovine serum at 37 °C, in 50 mL/L CO_2. G418 was added to screen cells at the final concentration of 100 mg/L. The media were freshened once in every two days and the cells were passaged every six days.

Plasmid constructs

PCR products, amplified from EBO-HBV using HBc1/HBc2 as primers, were cloned into pcDNA3.1(-) after being digested by *Kpn*I/*Xho*I, yielding the vector pHBc (Figure 1).

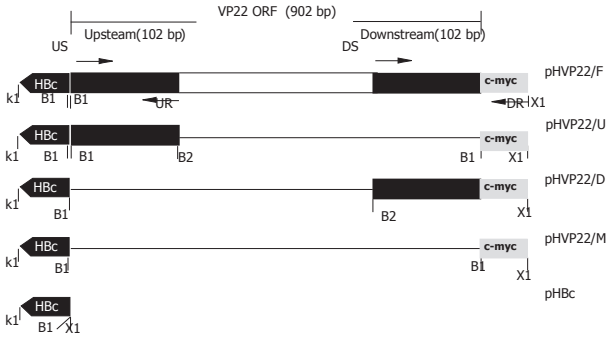

Figure 1 Plasmid constructs used in the experiment. (Dotted lines represent the deleted sequences. The nomenclature of plasmids is listed in the right. The primers, US, UR, DS, and DR, are marked with arrows. Restriction enzymes are expressed in single letters. *K1*, *Kpn*I; *B1*, *Bam*HI; *B2*, *Bgl*II; *X1*, *Xho*I. Downstream sequence of 102 bp is the PTD of VP22).

C-myc1/c-myc2 were dissolved at a concentration of 0.1 g/L and annealed by heating at 100 °C for 5 min, then slowly cooling to room temperature to form double-stranded c-myc digested by *Bam*HI/*Xho*I and cloned into pHBc digested by the same restrictions to produce plasmid pHVP22/M.

The fragment including full-length of VP22 and *c-myc* epitope was amplified from pVP22/*myc*-His2 plasmid (primers US/DR). PCR products were digested by *Bam*HI/*Xho*I and inserted into pHBc to produce pHVP22/F.

The upstream of VP22-coding sequence 102 bp amplified from pVP22/*myc*-His2 (primers US/UR) was digested by *Bam*HI/*Bgl*II and ligated into *Bam*HI site of pHVP22/M restricted with *Bam*HI and dephosphorized. The resulting plasmid bearing directional insertion was called pHVP22/U.

The downstream of VP22-coding sequence 102 bp was amplified from pVP22/*myc*-His2, and PCR products were inserted into pHBc after *Bam*HI/*Xho*I digestion to produce plasmid pHVP22/D.

Transfection

Transfections were performed as described by the provider of Lipofectamine 2000 (Gibco's handbook). Cells (4×10^8 L) were added to a 24-well plate (500 L/well) in which a coverslide was placed in advance. The transfection experiment was divided into seven groups and carried out in triplicate: pHVP22/F, pHVP22/U, pHVP22/D, pHVP22/M, pHBc, pcDNA3.1(-) and MOCK transfection.

Confirmation of transgene expression

After transfection, cells were immediately washed with sterilized PBS (4 °C, pH 8.0), fixed in 20 g/L paraformaldehyde and 1 g/L Triton X-100 diluted in PBS, and put on ice for 30 min. Cells were washed thrice with cold PBS. Non-specific epitopes were blocked with 10 g/L BSA for 10 min at 42 °C. After being washed with cold PBS, cells were incubated with mouse anti-HBc or c-myc mAb (1:500) for 15 min at 42 °C, further incubated with rabbit anti-mouse IgG labeled with FITC (1:1 000). The coverslides were mounted on slides using 50 mL/L glycerol/PBS and observed by fluorescence microscopy.

Antiviral activity

Forty-eight hours after transfection, HBsAg concentration was determined by RIA kit (completed by Nuclear Medicine Department of Xijing Hospital), and HBV-DNA content was quantified by FQ-PCR. The data obtained were analyzed by SPSS software.

MTT assay

The effect of transgene expression on host cells was evaluated by MTT colorimetry.

RESULTS

Plasmid construction

To enhance the antiviral effect of HBc DN mutant, both the full length of VP22 and the truncated version (102 bp upstream or downstream) were fused to C terminals of HBc, respectively (pHVP22/F, pHVP22/U, pHVP22/D), and the effects of anti-HBV replication were detected. All plasmids used here were confirmed by sequencing, which was completed by GeneCore Company (Shanghai, China).

Detection of transgene expression

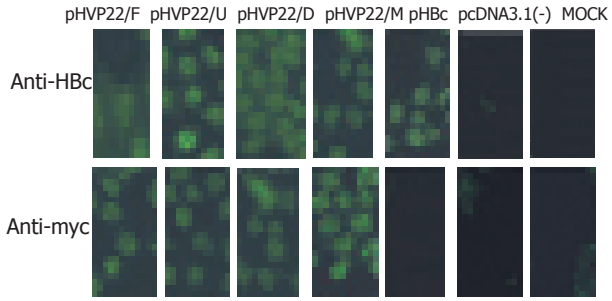

Figure 2 Confirmation of transgene expression in HepG2.2.15 cells.

Table1 MTT results of transfection groups (n=3, mean ±SD)

Group	A_{490}nm	P^1
pHVP22/F	0.425±0.065	>0.05
pHVP22/U	0.465±0.050	>0.05
pHVP22/D	0.410±0.075	>0.05
pHVP22/M	0.438±0.042	>0.05
pHBc	0.413±0.063	>0.05
pcDNA3.1(-)	0.430±0.065	>0.05
MOCK	0.423±0.058	>0.05

[1]*vs* mock.

To identify the expression of transgenes in HepG2.2.15 cells, indirect immunofluorescence was performed using antibody against HBc or c-myc. No fluorescence was found in pcDNA3.1(-) and MOCK transfection, the same results were obtained in pHBc, pcDNA3.1(-) and MOCK transfection. Strong fluorescence was detected in other transfections. The results suggested that transgenes were successfully expressed in HepG2.2.15 cells and recognized by the corresponding antibodies (Figure 2).

Antiviral effect

To investigate the antiviral activity of VP22 fusion DN mutant on HBV replication, the inhibitory effect was determined by HBsAg concentration and HBV-DNA content in the supernatant of HepG2.2.15 cell culture. When compared to MOCK transfection, HBsAg concentrations in pHVP22/F, pHVP22/U, and pHVP22/D transfections decreased by 81.94%, 38.88%, and 63.89%, respectively (Figure 3A, P<0.05), and HBV-DNA content by 72.30%, 29.60%, 46.42%, respectively (Figure 3B, P<0.05), indicating that VP22 fusion DN mutant could inhibit HBV replication effectively. Regardless of taking HBsAg concentration or HBV-DNA content as an index, pHVP22/F, pHVP22/U, and pHVP22/D showed a significant difference between the groups (P<0.05). DN mutant with transduction domains (pHVP22/F and pHVP22/D) had a stronger antiviral activity than that without the domain (pHVP22/U, P<0.05). When compared to DN mutant with full length of VP22 (pHVP22/F), DN mutant with the transduction domain (pHVP22/D) showed a weaker antiviral activity (P<0.05). There was no significant difference between DN mutant based on c-myc epitope (pHVP22/M) and MOCK transfection (P>0.05), suggesting that pHVP22/M could not inhibit HBV replication.

MTT assay

After 48-h incubation, the morphology of cells was observed under inverted microscope and no discernable difference was found between groups. MTT assay showed no significant differences between groups (P>0.05), suggesting that the expression of DN mutants had no effect on the growth of host cells (Table 1).

DISCUSSION

HBV infection is an important health problem worldwide[14], and the investigation about HBV therapy is a long-standing focus. The development of genetic

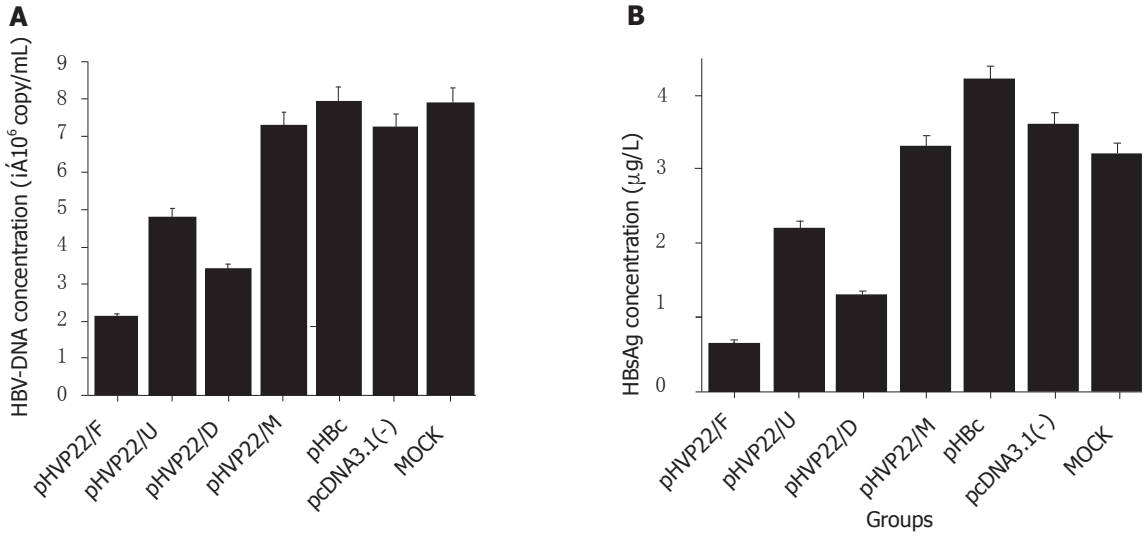

Figure 3 Comparison of HBsAg (**A**) and HBV-DNA (**B**) concentrations between transfection groups.

engineering facilitates the role of gene therapy in anti-HBV therapy[13,14] and DN mutant is one of the important strategies[15-17]. After introduction of mutant gene into the infected cells, the activity of wild-type viral gene is inhibited by the mutant version in a competitive manner, leading to the inhibition of virus replication[22,23]. DN mutant, as a preferential strategy, takes protein as the effector and avoids the problem of HBV mutation, which is one of the obstacles when DNA is used as an effector. But insufficient therapeutic molecules can reach the VP22 protein, bearing protein-transduction ability, to enhance the DN mutant effect and complement the shortage of therapeutic molecules in target cells.

As a structural protein of HSV-1, VP22 (or its fusion protein) has the strong ability to translocate between cells[18]. Proteins fused with the protein transduction domain (PTD), which lies in C terminal of VP22 (34 amino acids), also can translocate into the target cells[24-26]. In this report, HBsAg concentration decreased 63.89% by PTD-HBc fusion based (pHVP22/D) DN mutant, and DN mutant with upstream 34 amino acids of VP22 (pHVP22/U, without PTD) only decreased 38.88%, suggesting that DN mutant with PTD can strongly inhibit the activity of wild-type viral gene than that without PTD, and the transduction domain of VP22 can enhance the antiviral effect of DN mutant. By detecting HBV-DNA concentrations in the supernatant, similar results could be obtained.

DN mutant based on full-length of VP22 (pHVP22/F) decreased HBsAg concentration and HBV-DNA content by 81.94% and 72.30%, respectively (Figures 3A and B), showing a significant difference compared to PTD-based DN mutant (pHVP22/D, $P<0.05$). Due to the different efficiency between the two constructs, the molecular mass of the protein fused to HBc C-terminal is related to the inhibitory effect of DN mutant. The larger the fused molecule, the stronger the antiviral effect of DN mutant. Possible explanations may be related to the stabilization of the larger fusion protein and the steric hindrance is necessary to inhibit proper assembly of the nucleocapsid.

In conclusion, DN mutant-based c-myc epitope (pHVP22/M) cannot inhibit HBV replication. Since c-myc epitope has only 10 amino acids, DN mutant of HBc may mediate antiviral effect through a minimal length of C-terminal. The related experiments are in process.

Abstract

AIM: To study the effects of hepatitis C virus (HCV) core and non-structural 5A (NS5A) proteins on nuclear factor-κB (NF-κB) activity for understanding their biological function on chronic hepatitis caused by HCV infection.

METHODS: Luciferase assay was used to measure the activity of NF-κB in three different cell lines cotransfected with a series of deletion mutants of core protein alone or together with NS5A protein using pNF-κB-Luc as a reporter plasmid. Western blot and indirect immunofluorescence assays were used to confirm the expression of proteins and to detect their subcellular localization, respectively. Furthermore, Western blot was also used to detect the expression levels of NF-κB/p65, NF-κB/p50, and inhibitor κB-a (IκB-a).

RESULTS: The wild-type core protein (C191) and its mutant segments (C173 and C158) could activate NF-κB in Huh7 cells only and activation caused by (C191) could be enhanced by NS5A protein. Moreover, the full-length core protein and its different deletion mutants alone or together with NS5A protein did not enhance the expression level of NF-κB. The NF-κB activity was augmented due to the dissociation of NF-κB-IκB complex and the degradation of IκB-a.

CONCLUSION: NF-κB is the key transcription factor that can activate many genes that are involved in the cellular immune response and inflammation. Coexpression of the full-length core protein along with NS5A can enhance the NF-κB activation, and this activation may play a significant role in chronic liver diseases including hepatocellular carcinoma associated with HCV infection.

Key words: HCV; NS5A; Core protein; NF-κB

INTRODUCTION

Hepatitis C virus (HCV) is a major causative agent for acute and chronic hepatitis, which often leads to liver cirrhosis and hepatocellular carcinoma[1,2]. HCV is an enveloped positive-sense RNA virus of the *Flaviviridae* family. The viral genome encodes a single polyprotein precursor of ~3 010 amino acids, which is cleaved by both host and viral proteases to produce three structural proteins at the amino terminus (Core, E1, and E2) and six nonstructural proteins at the carboxyl terminus (NS2, NS3, NS4A, NS4B, non-structural 5A (NS5A), and NS5B)[3-5].

HCV core protein is the viral nucleocapsid protein that binds to and packages the viral RNA genome. Core protein is a multifunctional protein that can interact with many cellular factors such as lymphotoxin-β receptor, tumor necrosis factor receptor (TNFR), heterogeneous nuclear ribonucleoprotein and LZIP[6-10]. Core protein also can modulate the expression of some genes like interleukin-2 (IL-2), p53 and p21[11-14]. NS5A protein is a phosphoprotein that exists in differentially phosphorylated forms of 56 and 58 ku with modifications of serine residues[15]. NS5A protein can directly interact with double-stranded RNA-dependent kinase and inactivate its function, thus modulating the IFN-stimulated antiviral response[16].

Nuclear factor-κB (NF-κB) belongs to a highly conserved Rel-related protein family, which includes RelA (p65), Rel B, c-Rel, NF-κB1 (p105/p50), and NF-κB2 (p100/p52). Of these, the p50/p65 heterodimer, commonly called NF-κB, is the most abundant and ubiquitous. NF-κB is the key transcription factor activating many genes involved in the cellular immune responses and inflammation, such as interferon-β, TNF-α, IL-2, IL-6, and IL-8[17].

Many researchers have reported that HCV core protein can modulate the activity of NF-κB in mammalian cells[18-21]. This phenomenon has also been found in NS5A protein[22-24]. Core protein can interact with NS5A protein both *in vitro* and *in vivo*[25]. However, whether this interaction has effect on NF-κB activation has not yet been determined. In this study, we investigated the effect of core protein and NS5A protein coexpression on NF-κB activity in three different cell lines. Our results showed that NS5A protein could

enhance the effect of full-length core protein on NF-κB activation in Huh7 cell line only. This activation is associated with the degradation of inhibitor κB-α (IκB-α).

MATERIALS AND METHODS

Plasmid construction

The recombinant plasmids with different deletion mutations of HCV core or NS5A genes were constructed by inserting the corresponding DNA fragments into the eukaryotic expression vector pcDNA3 under the immediate early CMV promoter. The DNA fragments were amplified by PCR from pBRTM/HCV1-3011 plasmid (genotype 1a, a generous gift from Dr. Charles M Rice, University of Washington) using primers in Table 1. Primers 1a and 1b were used to generate pcDNA-core (for C191) containing the full-length core protein, 1a and 1c primers were used to generate pcDNA-Δcore519 (for C173) with a deletion of 54 nt at its 3'-end, 1a and 1d primers were used to generate pcDNA-Δcore474 (for C158) with a deletion of 99 nt at its 3'-end, 2a and 1b primers were used to generate pcDNA-Δcore [76-573, for C(26-191)] with a deletion of 75 nt at its 3'-end, 2a and 1d primers were used to generate pcDNA-Δcore [76-474, for C(26-158)] with a 75 and 99 nt deletion at the 5'-end and 3'-end, respectively, 3a and 3b primers were used for pcNS5A with full-length 5A gene. All the constructed plasmids were confirmed by restricted digestion and sequencing.

Table 1 Primers used in this study

Primers	Oligonucleotides

Italic nucleotides represent the enzymes used for the ligation and the enzymes are also marked in the end of each primer. Bold nucleotides ATG and CTA represent the start and stop codon, respectively.

Cell culture and transfection

Cos-7, HeLa, and Huh7 cell lines were grown in Dulbecco's modified Eagle's medium (Hyclone) with 10% fetal bovine serum (Gibco) at 37 °C in 50 mL/L CO_2. DNA transfection experiment was performed using Lipofectamine™ 2000 (Gibco) according to the manufacturer's instructions.

Luciferase assay

The pNF-κB-Luc (Stratagene) vector containing the *Photinus pyralis* (firefly) luciferase reporter gene driven by a basic promoter element (TATA box) plus five repeats of κB *cis*-enhancer element (TGGGGACTTTCCGC) was used in this experiment. Approximately 5×10^4 cells were seeded into a 24-well tissue culture plate 24 h before transfection. The cells were cotransfected with 0.8 μg plasmids as four kinds of combination: (1) 0.4 μg pNF-κB-Luc and different concentrations (0.1, 0.2, and 0.4 μg) of core mutations or pcNS5A; (2) 0.4 μg pNF-κB-Luc and the same concentration of core mutations (0.2 μg) and pcNS5A (0.2 μg); (3) 0.3 μg pNF-κB-Luc and the same concentration of pcDNA-core (0.2 μg) and different concentrations (0.1, 0.2, and 0.3 μg) of pcNS5A; (4) 0.3 μg pNF-κB-Luc and the same concentration of pcNS5A (0.2 μg) and different concentrations (0.1, 0.2, and 0.3 μg) of pcDNA-core. Cells were cotransfected with pNF-κB-Luc and vector pcDNA3 as a negative control. The total concentration of the transfected plasmids was kept constant with pcDNA3 vector. Cells were harvested at 24 h after transfection and then lysed in the reporter lysis buffer (Promega). The luciferase activity was measured by TD-20/20 luminometer (Turner BioSystems, Sunnyvale, CA, USA), and normalized with respect to the protein concentration of the cell lysates. Each experiment was repeated at least thrice.

Western blot analysis

Twenty-four hours after transfection, the total cell proteins were separated by 15% SDS-polyacrylamide gel electrophoresis (SDS-PAGE) and transferred to a polyvinylidene difluoride membrane. The blots were first blocked with 5% non-fat milk in Tris buffer saline (TBS) containing 1 g/L Tween-20 and then probed with the first antibodies against HCV core protein (ViroStat, Inc., 1851), HCV NS5A protein (a generous gift from Dr. Stephene J Polyak, University of Washington), actin (Santa Cruz Biotechnology, Inc., sc-1616), NF-κB/P65 (Santa Cruz Biotechnology, Inc., sc-800), NF-κB/P50 (Santa Cruz Biotechnology, Inc., sc-114), IκB-α (Santa Cruz Biotechnology, Inc., sc-847) for 1 h at 37 °C After extensive washes, secondary antibodies conjugated with horseradish peroxidase were applied onto the blots for at least 1 h at 37 °C. Blots were washed five times with TBS-1 g/L Tween-20. Reagents for enhanced chemiluminescence were applied to the blots and the light signals were detected by X-ray film.

Indirect immunofluorescence assay

Sterile coverslips were placed in six-well tissue culture plates before the Cos-7 cells were plated on them. Twenty-four hours after transfection, the coverslips were rinsed twice with PBS, and the cells were fixed in methanol-acetone (1:1) at -20 °C for 5 min. After washing thrice with PBS, the fixed cells were covered with anti-core monoclonal or anti-NS5A mAbs for 1 h at 37 °C, and then washed thrice with PBS. Secondary antibodies (FITC-conjugated goat anti-mouse IgG) were then applied on the cells for 1 h at 37 °C in the dark. After washing, the cells were stained with propidium iodide to visualize the nuclear DNA and mounted in antifade mounting medium. The stained cells were visualized under a Leica confocal microscope (TCS NT SN 1500001, Leica Laser Technik, Germany). For the colocalization of full-length core and NS5A proteins, rabbit anti-core polyclonal antibody (produced in our laboratory) and mouse NS5A mAb were used as primary antibodies and TRITC-conjugated goat anti-rabbit IgG and FITC-conjugated goat anti-mouse IgG were used as secondary antibodies, respectively.

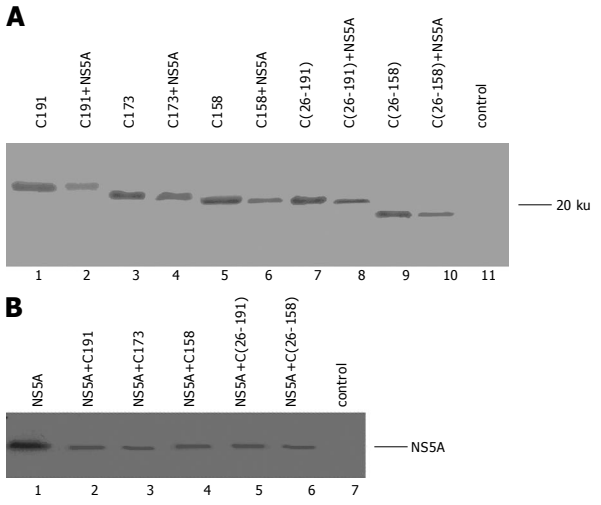

Figure 1 Expression of core mutant fragments **(A)** and NS5A protein **(B)**.

RESULTS

Identification of core mutants and NS5A protein

In this study, four core deletion mutants (C173, C158, C (26-191), C(26-158) were constructed besides the wild-type core protein (C191). C173 is the mature form of core protein with deletion of 18aa at its C-terminus. C158 is a mutant fragment with deletion of the hydrophobic amino acids at its C-terminus. C(26-191) is a mutant fragment without the reported functional domain at its N-terminus. C(26-158) is a mutant fragment without functional and hydrophobic domains at its N- and C-terminus, respectively. The expression of core mutants and NS5A protein in Huh7 was measured by Western blot. As shown in Figure 1A, core mutant fragments were expressed with a correct molecule mass of 21 ku for C191, 19 ku for C173, 18 ku for C158, 18 ku for C(26-191) and 15 ku for C(26-158) in the cells transfected with either core mutation fragments alone (lanes 1, 3, 5, 7, and 9) or together with NS5A protein (lanes 2, 4, 6, 8, and 10). The expression of NS5A protein is shown in Figure 1B. We got the correct band of 56 ku in the cells transfected with NS5A protein alone (lane 1) or together with core mutations (lanes 2-6). This experiment showed that core mutants and NS5A protein were expressed successfully from their respective recombinant plasmids.

HCV core protein activated NF-κB and was enhanced by NS5A protein in Huh7 cells

To study the effect of the coexpression of HCV core and NS5A proteins on NF-κB activity, the expressed plasmids, pcDNA-core, pcDNA-Δcore519, pcDNA-Δcore474, pcDNA-Δcore (75-573), pCDNA-Δcore (75-474), alone or together with pcNS5A were cotransfected with pNF-κB-Luc into three different cell lines Cos-7, HeLa, and Huh7. Luciferase activity was measured 24-h post-transfection. Our results showed a significant change of relative luciferase activity in Huh7 cells (Figure 2A) but not in Cos-7 cells (Figure 2B) or HeLa cells (Figure 2C). In Huh7 cells, the expression of C191 resulted in a significant increase in the NF-κB activity (sevenfold) compared to control cells transfected with vector alone. Expression of C173 and C158 also resulted in an increase in NF-κB activity with about six- and fourfold, respectively, compared to control. Furthermore, the luciferase activity was increased in a dose-dependent manner in core-expressing cells. In contrast, there was no significant change in the relative luciferase activity in the cells transfected with pcDNA-Δcore (75-573) or pcDNA-Δcore (75-474), in which core proteins had 25 amino acids deleted at the N-terminus. This suggested that the N-terminal region (1-25 aa) of core protein is important for its activation on NF-κB, which is consistent with the previous report[20]. The different augmentation of luciferase activity caused by C191, C173, and C158 suggested that

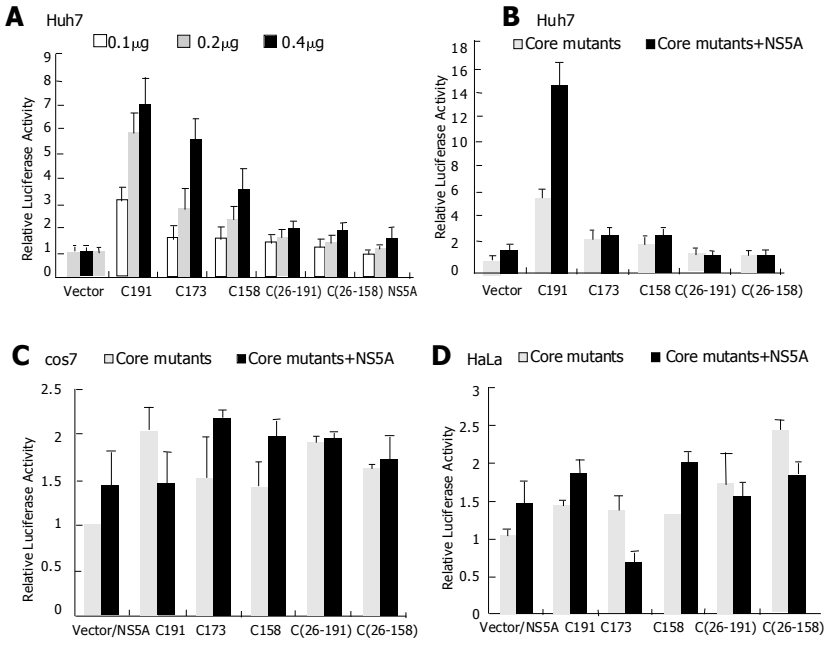

Figure 2 Effect of HCV core and NS5A proteins on NF-κB activity. **A:** NF-κB activation capacity of the core mutant fragments and NS5A protein individually expressing in Huh7 cell line; **B:** NF-κB activation capacity of the core mutants and NS5A protein expressing in Huh7 cells, **C:** Cos-7 cells; **D:** HeLa cells.

the activation of NF-κB by core protein was related to the hydrophobicity of C-terminus of core proteins (C191> C173>C158).

When NS5A protein was expressed alone, it had no effect on NF-κB activation (Figure 2A). But co-expression of C191 and NS5A protein resulted in a significant increase in the luciferase activity with about 15-fold compared to the control and twofold compared to the C191-expressing cells only. However, the relative luciferase activity in the cells co-expressing NS5A protein and other core mutants was not augmented (Figure 2B). These results indicated that NS5A protein could enhance C191-induced NF-κB activation.

NS5A protein enhanced core protein-induced NF-¦ÊB activation in a dose-dependent manner

In order to understand, how NS5A protein affects the NF-κB activation caused by C191 core protein, we designed two kinds of combination between pcNS5A and pcDNA-core expression vectors for luciferase assay. In the first one, 0.2 μg of pcNS5A vector was co-transfected with different concentrations of pcDNA-core (0.1, 0.2, and 0.3 μg), while in the other combination, 0.2 μg of pcDNA-core was co-transfected with different concentrations of pcNS5A (0.1, 0.2, and 0.3 μg). Result is shown in Figure 3. When pcNS5A transfection was certain, more pcDNA-core was transfected, the higher luciferase activity could be detected, while the enhanced increasing of activity in number was almost the same (ninefold) compared to cells expressing C191 alone (Figure 3, right), which meant that the same amount of NS5A protein exerted the same effect on different amounts of C191. When pcDNA-core transfection was certain, more pcNS5A was transfected, higher enhanced increasing of luciferase activity could be detected (Figure 3, left). These results showed that NS5A protein could enhance core protein-induced NF-κB activation in a dose-dependent manner.

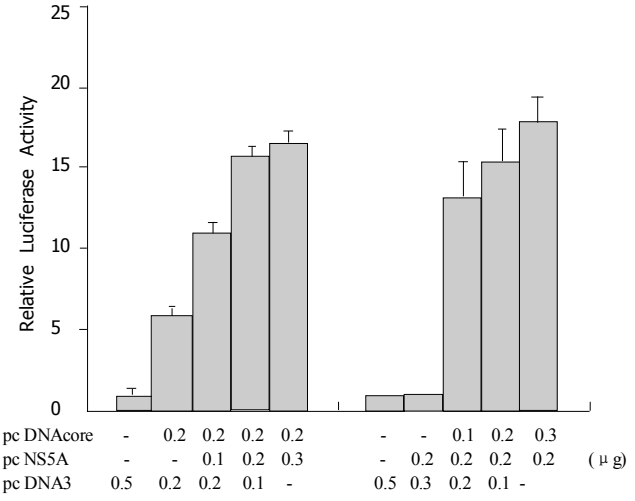

Figure 3 Enhancement of core protein-induced NF-kB activation in a NS5A protein dose-dependent manner.

Activation of NF-κB by core protein and NS5A was associated with IκB−α degradation

We further studied whether NF-κB activation occurred at translational or post-translational levels. To do this, the expression levels of NF-κB/p65, NF-κB/p50, and IκB-α in C191-expressing Huh7 cells either alone or together with NS5A were studied. As shown in Figure 4, at the same concentration of cell lysates as confirmed by actin (Figure 4D), there was no change in the p65 and p50 expression profile (Figures 4A and B). While in case of the IκB-α, the expression level was contrary to the NF-κB activity. In the control, cells transfected with pCDNA3 vector had the highest expression level of IκB-α (Figure 4C, lane 1), while in the cells co-expressing C191 and NS5A with the highest NF-κB activity had the lowest expression of IκB-a (Figure 4C, lane 3). Cells expressing C191 also had a much lower expression of IκB-α (Figure 4C, lane 4), while cells expressing NS5A protein had a much higher expression of IκB-α (Figure 4C, lane 2). It was more likely that when C191 and NS5A protein were co-expressed, they activated IκB kinase (IKK) through some signal pathway, resulted in the phosphorylation and then degradation of IκB, leading to the activation of NF-κB. These results suggested that C191 alone or together with NS5A protein did not enhance the expression of NF-κB. Thus, the NF-κB activity was augmented due to the dissociation of NF-κB¨CIκB complex and IκB degradation.

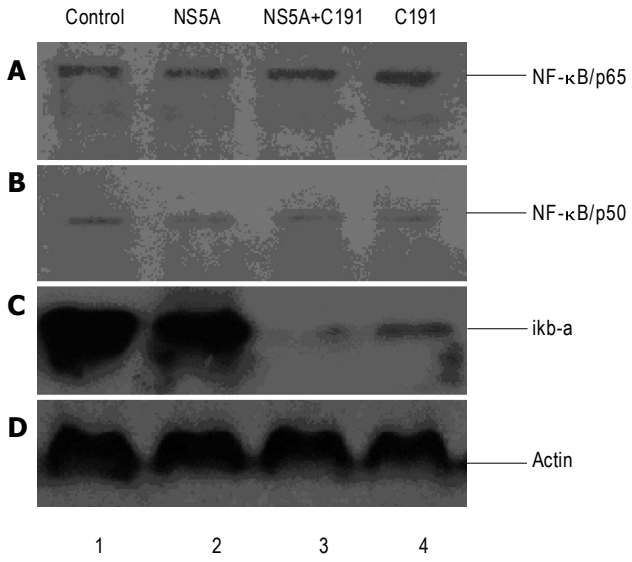

Figure 4 Expression of NF-κB/p65, NF-κB/p50 and IkB-a.

Subcellular localization of C191 and NS5A proteins in Cos-7 cell line

We then analyzed the subcellular localization of C191 and NS5A proteins using indirect immunofluorescence assay in Cos-7 cell line. As shown in Figure 5, C191 was localized predominantly in the cytoplasm (Figures 5A-C). NS5A protein was also localized in the cytoplasm with fluorescence signals surrounded the nuclear membrane (Figures 5D-F). On the other hand, the co-expression of C191 and NS5A proteins did not alter the localization of C191, but redistributed the NS5A protein to the same localization pattern of C191 (Figures 5G-I). All these results are consistent with previous reports[25-27]. Thus, the same

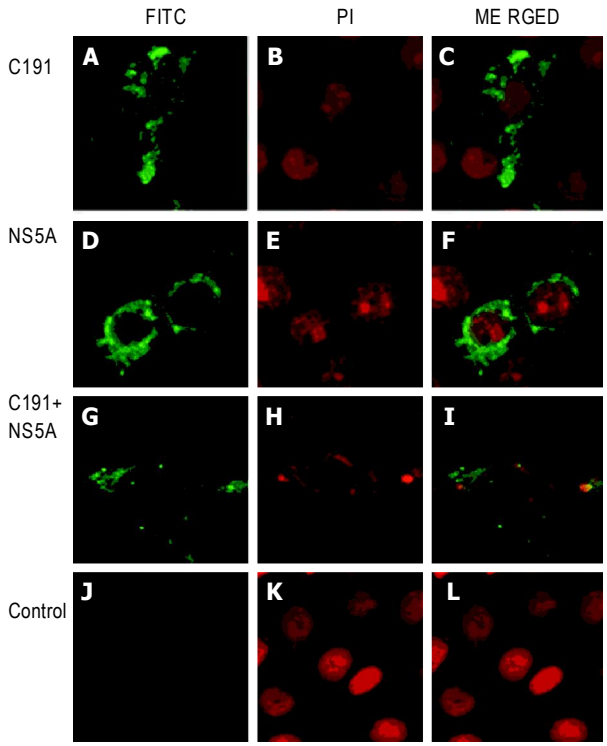

Figure 5 Localization of C191 and NS5A proteins. **A-C:** C191; **D-F**: NS5A protein; **G:** NS5A protein (FITC-labeled); **H:** C191 protein (TRITC-labeled); **I:** merged localization of C191 and NS5A proteins; **J-L:** pcDNA3 vector alone as a negative control.

cytoplasmic localization pattern of C191 and NS5A protein suggested that NF-κB activation caused by co-expression of C191 and NS5A protein was more likely due to a physical interaction between them or the interaction with the same cellular factors.

DISCUSSION

NF-kB is a critical regulator of the immediate early pathogen response, and plays an important role in promoting inflammation and in regulation of cell proliferation and survival[17,28]. NF-κB is highly activated at sites of inflammation in diverse diseases and induces transcription of pro-inflammatory cytokines, chemokines, adhesion molecules, matrix metalloproteinases, cyclooxygenase 2, and inducible nitric oxide synthase[29]. Moreover, NF-κB can also activate the expression of cyclin D1, c-myc, other regulators of the cell cycle and enhance cell survival by switching on genes that inhibit pro-apoptotic signals[30]. Because of the multifunction of NF-κB, many viruses including several human pathogens such as HIV-1, human T-cell leukemia virus, herpes simplex virus, HBV, and Epstein-Barr virus have evolved different strategies to modulate the activity of NF-κB[31-34]. Some of them modulate the NF-κB activity through the binding of the viral particles to their receptor, some of them modulate through viral proteins. The activation of NF-κB may be a strategy of viruses to block apoptosis and prolong survival of the host cells in order to gain time for replication and increase viral progeny production[35].

Since HCV core protein can interact with TNF-α by yeast two-hybrid system[8], NF-κB, the main effective factor in the TNF-α signaling pathway, has become a hot factor in the functional studies of core protein. Core protein can modulate NF-κB at the basal level in many mammalian cell lines, although the modulation is different from HCV genotype and cell lines[19-21].

In this study, we found that core protein could increase the activity of NF-κB only in Huh7 cell line, but not in Cos-7 and HeLa cell lines. This augmentation was in a core protein dose-dependent manner. Core protein can interact with NS5A protein both *in vitro* and *in vivo*[25]. NS5A protein can also modulate the activity of NF-κB[23]. Since this modulation is also different from different cell lines[36], we want to know if this interaction between core and NS5A proteins has certain effect on the regulation of NF-κB. Our results showed that when C191 and NS5A proteins were co-expressed in Huh7 cell line, they activated NF-κB and this activation was in a NS5A protein dose-dependent manner. Moreover, the full-length core protein was required for the interaction between core and NS5A proteins, because no increase in the NF-κB activity was observed in the cells co-expressing any of the core mutant fragments and NS5A protein. Further experiments have confirmed that this activation is associated with the NF-κB-IκB complex dissociation and IκB degradation but not with the change in the expression level of NF-κB.

There are two signaling pathways leading to NF-κB activation. The classical NF-κB pathway, based on IKK-β-dependent IκB degradation, is essential for innate immunity. The alternative NF-κB pathway, based on IKK-α processing of NF-κB2/p100 into NF-κB2/p50, is related to lymphoid organ development and adaptive immunity[29]. The activation of NF-κB caused by co-expression of core and NS5A proteins may occur in the classical NF-κB pathway. Proinflammatory cytokines and pathogen-associated molecular patterns, working through different receptors belonging to the TNFR and Toll-like receptor-IL-1 receptor superfamilies, cause activation of IKK. The activated IKKs, predominantly acting through IKK-β in an IKK-γ-dependent manner, catalyze the phosphorylation of IκBs, polyubiquitination and subsequent degradation by the 26S proteasome[29]. As previously reported, core protein can activate NF-κB through TNF receptor-associated factor 2-IKK-β-dependent pathway[37]. The phosphorylation of I κB-α by IKK-β can be significantly enhanced by HCV core protein expression in a dose-dependent manner. NS5A protein can activate NF-κB by altering intracellular calcium levels and then inducing oxidative stress, through tyrosine phosphorylation of IκB-α at Tyr^{42} and Tyr^{305} residues instead of $Ser^{32,36}$ phosphorylation of IκB-α caused by IKK, thus inducing IκB-α degradation[24]. We found that expression of core protein could activate NF-κB, while this did not happen in case of NS5A protein expression in Huh7 cells. These results of NS5A protein are consistent with one report[38] but inconsistent with other reports[22,24]. This may be due to the different cell lines and/or experimental methods used in their studies. Interestingly, co-expression of C191 and NS5A proteins activated NF-κB significantly.

When NS5A and C191 proteins were co-expressed, this interaction caused the change in the conformation of NS5A protein, which leads to the tyrosine phosphorylation of Iκ B-α, and resulted in core protein-induced NF-κB activation. Further experiments need to be done to elucidate this idea.

HCV causes persistent infection and chronic hepatitis in most infected individuals. Spontaneous recovery following HCV infection is a relatively rare event. The mechanisms responsible for HCV-mediated chronicity and disease progression remain unclear[39]. The activation of NF-κB has been found in both subgenomic replicon and full-length HCV-transfected cells and HCV-infected livers [24,36,39]. This may provide the possible mechanism for HCV pathogenesis.

C191 is produced in the early stage of HCV infection and then cleavaged to its mature form C173 to assist virus assembly[40]. In this study, we found that NS5A protein could enhance C191-induced NF-κB activation but not C173, when NS5A and core proteins were co-expressed in Huh7 cells. Activation of NF-κB always leads to inhibition of apoptosis. In the early stage of HCV infection, NS5A protein functions synergically with C191 on NF-κB activation and this may inhibit apoptosis of host cells; while in late stage of HCV infection, NS5A protein does not function synergically with C173 on NF-κB activation and decreases their ability to inhibit apoptosis of host cells. This may play an important role in the establishment of chronic and persistent liver disease during HCV infection.

ACKNOWLEDGMENTS

The authors thank Dr. Charles M Rice (University of Washington) for providing pBRTM/HCV1-3011 and Dr. Stephene J Polyak (University of Washington) for providing HCV NS5A mAb. The authors thank Jingrong Gao and Changlu Liu for helpful suggestions, and also thank Wei Peng for his technical help in confocal microscopy.

Abstract

AIM: To develop the epitope-based vaccines to prevent Hepatitis C virus (HCV)/Hepatitis B virus (HBV) infections.

METHODS: The HCV core epitopes C1 STNPKPQRKTKRNTNRRPQD (residuals aa2-21) and C2 VKFPGGGQIVGGVYLLPRR (residuals aa22-40), envelope epitope E GHRMAWDMMMNWSP (residuals aa315-328) and HBsAg epitope S CTTPAQGNSMFPSCCCTKPTDGNC (residuals aa124-147) were displayed in five different sites of the flock house virus capsid protein as a vector, and expressed in *E. coli* cells (pET-3 system). Immunoreactivity of the epitopes with anti-HCV and anti-HBV antibodies in the serum from hepatitis C and hepatitis B patients were determined.

RESULTS: The expressed chimeric protein carrying the HCV epitopes C1, C2, E (two times), L3C1-I2E-L1C2-L2E could react with anti-HCV antibodies. The expressed chimeric protein carrying the HBV epitopes S, I3S could react with anti-HBs antibodies. The expressed chimeric proteins carrying the HCV epitopes C1, C2, E plus HBV epitope S, L3C1-I2E-L1C2-L2E-I3S could react with anti-HCV and anti-HBs antibodies.

CONCLUSION: These epitopes have highly specific and sensitive immunoreaction and are useful in the development of epitope-based vaccines.

Key words: HCV; HBV; Epitope-based vaccine; Recombinant; Immunoreactivity

INTRODUCTION

hepatitis C virus (HCV) and Hepatitis B virus (HBV) are the causative agents of hepatitis C and B. Exposure to HCV or HBV causes acute hepatitis, leading to chronic hepatitis, liver cirrhosis, hepatocellular carcinoma and even death. The worldwide prevalence is estimated to be around 170 million individuals (3%) infected with HCV and 350 million individuals (7%) infected with HBV[1,2]. HCV and HBV infections are social and economic issues.

HCV is a member of the Flaviviridae family, possessing a linear single-stranded RNA genome of 9.4 kb[3]. The HCV genome contains a single open reading frame (ORF) encoding a polyprotein that is cleaved into the mature viral core, envelope and non-structural proteins[4]. The core protein is the most conserved and contains highly conserved epitopes[5]. The envelope protein E1 is the most variant region and contains the major neutralizing epitopes[6-11]. HBV is a double-stranded circular DNA virus[12]. The surface antigen of HBV (HBsAg), the major antigen protein, consists of large, middle and small proteins encoded by ORF S and preS, and have been successfully used as a hepatitis B vaccine. Since HCV and HBV infections share a similar route, i.e., mainly infected individuals through serum or seral products, it is very important to develop HCV/HBV covalent vaccines to simultaneously protect individuals from HCV and HBV infections.

It has been previously demonstrated that the epitope-presenting system based on the flock house virus (FHV) capsid protein is useful in displaying foreign epitopes[13]. In the present study, epitopes derived from the HCV core, envelope protein and HBsAg were displayed in this system, immunoreactivities were determined, and the possibility to develop epitope-based vaccines was discussed.

MATERIALS AND METHODS

Epitopes and epitope-presenting system

The epitopes studied in this study were derived from the HCV core region residues aa2-21C1 STNPKPQRKTKRNTNRRPQD (C1) and aa22-40, VKFPGGGQIVGGVYLLPRR (C2), the envelope region residues aa315-328, GHRMAWDMMMNWSP (E), and the HBsAg residues aa124-147 CTTPAQGNSMFPSCCCTKPTDGNC (S).

The epitope-presenting system was developed using the

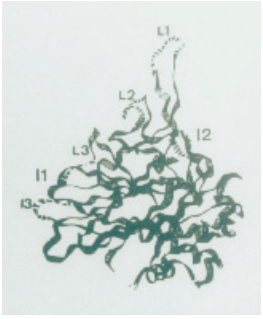

Figure 1 Three-dimensional structure of FHV capsid protein.

FHV capsid protein as a vector (FHV-RNA2 system)[13]. The FHV capsid protein expressed in the recombinant system could self-assemble into virus-like particles (VLPs). Six sites on the vector protein outer surface could be chosen for insertion of foreign epitopes which have little influence on the protein structure (Figure 1). The epitopes were inserted into L3 (C1), I2 (E), L1 (C2), L2 (E) and I3 (S), by means of genetic recombination engineering on plasmid pET-3. Four recombinant plasmids were constructed, pET-Wt carrying the bare vector protein gene, pET-I3S carrying the vector gene and the epitope S, pET-L3C1-I2E-L1C2-L2E carrying the vector gene and the epitopes C1, C2, E, and pET-L3C1-I2E-L1C2-L2E-I3S carrying the vector gene and the epitopes C1, C2, E and S.

Expression of chimeric proteins carrying epitopes

The recombinant plasmids were transformed into *E. coli* BL21(DE3) cells. The chimeric proteins carrying the epitopes were expressed under the control of T7 promotor[14] in TB/ampicillin media at 37 ℃. Cells were harvested by centrifugation at 3 000 r/min for 10 min at 4 ℃ (Beckman rotor type J-20). Cell lysis was accomplished by ultrasonication and centrifuged at 10 000*g* for 30 min. The chimeric proteins in the deposit were dissolved in 8 mol/L urea and analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). To purify the expressed chimeric proteins, the band containing the chimeric proteins was cut-off from the gel and the proteins were recovered by further electrophoresis procedures. The purified chimeric proteins were stored at -20 ℃ and used as an antigen in ELISA and Western blot tests.

Serum samples

Serum samples used in this study were collected from patients with hepatitis C (anti-HCV positive or HCV-RNA positive) or hepatitis B (anti-HBs positive), from the Kunming Infectious Disease Hospital, Kunming, China.

ELISA

Recombinant chimeric proteins carrying HCV/HBV epitopes purified by PAGE were diluted to 5 mg/L in carbonate/bicarbonate buffer (pH 9.6) and used as coating antigens in ELISA test. One hundred microliters of the protein solution was added to each well of 96-well microtiter plates. The plates were incubated overnight at 4 ℃ and then blocked with 2.5 g/L bovine serum albumin in 10 mmol/L of phosphate-buffered saline containing 0.01% Tween 20 (PBS-T), at 37 ℃ for 1 h and washed five times with (PBS-T). Sera from hepatitis C or B patients were diluted to the ratio 1:10 and 100 μL was added to each well of the blocked plates. The mixture was incubated at 37 ℃ for 1 h. After washing, 100 μL of horseradish peroxidase-conjugated rabbit anti-human immunoglobulin G (Sigma BioSciences, St. Louis, MO, USA) was added to each well, and the plates were incubated for 1 h at 37 ℃. After incubation and washing, ortho-phenylenediamine dihydrochloride (OPD, Sigma BioSciences, St. Louis, MO, USA) was added, and the color was measured at 455 nm with a Titertek plate reader.

When the cut-off value was (SS-NC)/NC ≧ 2, it was defined as positive. In the formula, SS is the OD value of the serum sample, NC is the value of the negative control.

Western blot

In the Western blot test, the expressed chimeric proteins were separated in 10% SDS-PAGE and transferred onto the nitrocellulose membrane. After incubation with the patient's serum (in 1∶400 dilution) and horseradish peroxidase-conjugated rabbit anti-human immunoglobulin G, the immobilized antigens (epitopes) were detected with 3,3-diaminobenzidine tetrahydrochloride (DAB, Sigma BioSciences, St. Louis, MO, USA).

RESULTS

Expression and purification of chimeric proteins

The chimeric proteins Wt, I3S, L3C1-I2E-L1C2-L2E and L3C1-I2E-L1C2-L2E-I3S were expressed in inclusion body form in transformed cells with the corresponding recombinant plasmids pET-Wt, pET-I3S, pET-L3C1-I2E-L1C2-L2E-I3S or pET-L3C1-I2E-L1C2-L2E-I3S, and analyzed by 10% SDS-PAGE (Figure 2). The results showed that the chimeric proteins were highly expressed.

Table 1 Detection of immunoreaction of expressed proteins as antigen with anti-HCV antibodies in serum from hepatitis C patients by ELISA

Protein	Patients	
	Anti-HCV$^+$/HCV-RNA$^+$ (%)	Anti-HCV$^-$/HCV-RNA$^+$ (%)
Wt	0	0
13S	2/66 (3.1)	1/24 (4.1)
L3C1-12E-L1C2-L2E	63/66 (95.5)	7/24 (29.2)
L3C1-12E-L1C2-L2E-I3S	63/66 (95.5)	9/24 (37.5)

The contents of chimeric proteins were estimated possessing about 35.1% (Wt), 35.5% (I3S), 34.2% (L3C1-I2E-L1C2-L2E), and 39.7% (L3C1-I2E-L1C2-L2E-I3S) of the full cell proteins. After purification, the chimeric proteins possessed about 43.8 kD (Wt), 46.5 kD (I3S), 49.7 kD (L3C1-I2E-L1C2-L2E) and 52.5 kD (L3C1-I2E-L1C2-L2E-I3S) of molecular weight, respectively as expected (Figure 3).

ELISA test

Using purified chimeric proteins as a coating antigen, 66 anti-HCV$^+$/HCV-RNA$^+$ and 24 anti-HCV$^+$/HCV-RNA$^-$ serum samples from hepatitis C patients were determined (Table 1). The results showed that the chimeric proteins carrying HCV epitopes, L3C1-I2E-L1C2-L2E and L3C1-I2E-L1C2-L2E-I3S could react with ant-HCV antibodies with a high specificity and susceptibility. The reactivity rates of chimeric proteins L3C1-I2E-L1C2-L2E and L3C1-I2E-L1C2-L2E-I3S were 95.5% and 95.5% with anti-HCV$^+$/HCV-RNA$^+$ sera, 29.2% and 37.5% with anti-HCV$^+$/HCV-RNA$^-$ sera, respectively. No serum samples reacted with the expressed vector protein Wt. Few serum samples reacted with chimeric protein I3S, implying that the patients were co-infected with HBV

Western blot test

Using sera from patients with hepatitis C (anti-HCV positive by ELISA kit) or B (anti-HBs positive by ELISA kit) as detecting antibody, the chimeric proteins carrying HCV epitopes L3C1-I2E-L1C2-L2E and L3C1-I2E-L1C2-L2E-I3S could be recognized by anti-HCV antibody (Figure 4A), and the chimeric protein carrying HBV epitopes S, I3S and L3C1-I2E-L1C2-L2E-I3S could be recognized by anti-HBV antibody on Western blot (Figure 4B). Ten serum samples from hepatitis C or B patients were detected respectively and the results in each group were similar.

DISCUSSION

Due to the host defense mechanism and virus genome RNA instability, HCV seems to escape immune pressure by mutation and results in high genetic heterogeneity[15,16]. The humoral immune response to neutralizing antibodies appears to be restricted and isolate-specific. HCV isolates obtained can be classified into at least six major clades (clades 1 to 6) and more than 70 subtypes[3]. Development of HCV vaccines is largely hampered for these characteristics of the virus.

Recent studies indicate that when a virus epitope is present in an appropriate vector system, the epitope can be displayed on the exposed surface of the vector protein with high immunogenicity[17]. Sequencing and immunological analysis showed that the residues aa1-40 in HCV core region are the most conserved and the residues aa315-328 in E1 region are highly conserved too[18]. HBsAg is the major antigenic protein of HBV. Mature HBsAg can self-assemble into VLPs and induce effective immune response. The residues aa120-160 of the large protein S exposed on the outer surface of VLPs are defined as a determinant. This determinant induces cross neutralizing antibodies which protect infections against different HBV subtypes[19-21]. Further studies indicate that the "a" determinant is mainly located within a double-looped structure formed by disulfide bridges between cysteines at 124, 137 and at 139-147[22,23]. The epitope S (aa124-147) studied in this report contains the key residues of the "a"

determinant. The epitopes displayed in the FHV-RNA2 system in this study had a high reactivity to specific anti-HCV or anti-HBV antibodies, indicating the importance of these HCV and HBV epitopes.

HCV/HBV epitopes, multiple-presented in a fusion form, cross react with HCV and HBV antibodies[24]. DNA immunization with fusion genes encoding different regions of the HCV E2 fused to the HBsAg gene elicits immune responses to both HCV and HBV. The antibody responses induced by the same epitopes are also demonstrated[25]. These results suggest that these epitopes contribute to the development of epitope-based vaccines.

Since HCV and HBV have a similar infection route with a high co-infection rate, development of HCV/HBV covalent vaccines is of great importance. Previous studies on HIV-1[13], HCV[26] and rotavirus[27-29] single epitopes and the present study demonstrated that the FHV-RNA2 system can be used to study the foreign epitope characteristics and to develop epitope-based vaccines. Since no sustainable cell culture system can be used, whether the antibodies elicited by these epitopes neutralize HCV and HBV infectivity or protect individuals against HCV and HBV infection remains to be studied.

Abstract

AIM: To investigate a possible role for a recently identified polymorphism in the gene of cytochrome P450 2E1, the presence of which is associated with high activity of the enzyme.

METHODS: Two hundred and thirty-nine alcohol consumers, ICD 10.1/.2 (ALC), and 208 normal controls were studied. PCR amplification of the CYP2E1 gene region was performed to assess polymorphic variation. Fisher's exact test was used to assess the data.

RESULTS: Twelve normal controls (5.8%) possessed the insertion. Five ALC (2.1%) had the insertion; of these 2 of 144 with alcohol induced chronic pancreatitis, none of 28 with alcoholic liver disease and 3 of 67 without end-organ disease had the polymorphism. A significantly Lower frequency of subjects possessed the insertion than normal controls [$P = 0.049$ (genotype analysis $P = 0.03$)]. To further assess, if there was a relationship to alcohol problems *per se* or end-organ disease, we compared patients with alcohol induced end-organ disease *vs* alcoholic controls without end-organ disease *vs* normal controls which again showed a significant difference [$P = 0.045$ (genotype analysis, $P = 0.011$)], further sub-group analysis did not identify which group(s) accounted for these differences.

CONCLUSION: We have shown the frequencies of this high-activity polymorphism in alcohol related patient groups for the first time. The frequency is significantly less in alcoholics than normal controls, as with high activity polymorphisms of alcohol dehydrogenase. The biological significance, and whether the relevance is solely for alcoholism or is there a relationship to end-organ disease, would benefit from the assessment in the populations with a greater frequency of this polymorphism.

Key words: CYP2E1; Alcohol; Chronic pancreatitis; Liver disease; Polymorphism

INTRODUCTION

Cytochrome P450 2E1 (CYP2E1) is the major component of the microsomal enzyme oxidizing system, which is one of the major pathways of oxidative metabolism of ethanol[1,2] as well as a large number of xenobiotics[3]. CYP2E1 is induced to greater activity by its substrate ethanol, probably *via a* number of mechanisms, including transcriptional, post-transcriptional and post-translational[2,4,5].

CYP2E1 activity is expressed in the liver, at sites of maximal alcohol induced damage[6], and in the pancreas, where it is also induced by chronic alcohol consumption[7,8]. These two are the major sites of damage following chronic consumption of ethanol. In addition, it is found in the brain[9], also a site of ethanol induced damage.

The genetic predisposition to both alcoholism and alcohol induced end-organ damage is an area of debate. Alcohol-induced pancreatitis occurs in approximately 5% of alcoholics[10] while no, or minimal, fibrosis is found in 32% of pancreata of alcoholics[11]. Alcoholic cirrhosis occurs in around 10% and hepatitis in 10-35%[12].

The heterogeneity of the response to alcohol implicates genetic factors. Family and twin studies suggest a genetic component to alcoholism[13,14]. Some evidence suggests that the majority of genetic predisposition to psychosis and liver disease may be accounted for by disposition to alcoholism[14].

Recently, an insertion polymorphism in the promoter

region of the gene coding for the enzyme CYP2E1 has been described; sequencing has shown a 96-bp insertion as a series of eight repeats, as opposed to six in the wild type[15,16]. This corresponds to the restriction fragment length polymorphism, between positions -2270 and -1672. Presence of which is associated with higher CYP2E1 metabolic activity (employing an *in vivo* chlorazoxazone 6-hydroxylation test) in the presence of recently consumed alcohol or obesity[17]. We have therefore analyzed the frequency of this polymorphism in patients with a history of excessive alcohol consumption, with and without end-organ damage, and normal controls.

The 96-bp insertion, previously described, is a 729-bp fragment employing the PCR based analysis of Fritsche *et al*[16]. The wild type allele is 633 bp in length. In addition, a GenBank record also exists for a 48-bp deletion (accession no. J02843), corresponding to 585 bp.

MATERIALS AND METHODS

Subjects

Venous blood samples were drawn from patients giving informed consent and local research ethics committee approval was obtained. We collected samples on 239 Caucasoid subjects (ALC) fulfilling the ICD 10 criteria 10.1 and 10.2, that is harmful use and/or alcohol dependence syndrome. Cut-off for minimal consumption was 80 g alcohol per day (UK patients range 56-400 U/week; median 106 U/week) over a minimum of 2 years (UK range 2-45 years; median 10 years). Age range was 25-73 years, median 47 years. The subjects were sub-divided as follows:

Sixty-seven (36 British and 31 German) subjects without known end-organ disease, AC, collected from clients at alcohol rehabilitation centers.

One hundred and seventy-two with alcohol-related end-organ disease (AEOD). Of which, one hundred and forty-four (39 British and 105 German) patients had alcohol-induced chronic pancreatitis (AICP); all fulfilled the criteria for late- or end-stage AICP, as defined by the Zurich criteria[18]. The twenty-eight patients with alcoholic liver disease (ALD) had biopsy proven cirrhosis or a history, consistent with alcoholic hepatitis, including jaundice associated with excess alcohol consumption without other evident cause.

Two hundred and eight samples of cord blood from Caucasoids with a normal, healthy delivery taken in Derriford Hospital, Plymouth, UK were employed as normal controls.

Laboratory analysis

DNA samples were extracted from peripheral and cord blood samples employing the commercially available Nucleon II DNA extraction kits (Nucleon Biosciences, Lanarkshire, Scotland, UK) or QIAmp DNA Blood Minikits (Qiagen, Hilden, Germany).

DNA amplification was performed for the promoter region of CYP2E1 as previously described[16], employing amplimers 5'-GTG ATG GAA GCC TGA AGA ACA- and 5'-CTT TGG TGG GGT GAG AAC AG-. Reactions were carried out in a volume of 25 μ L employing 100-200 ng of genomic DNA. Following a hot start for 4 min at 94 °C, thirty cycles of: 94 °C (denaturing) for 30 s; 66 °C (annealing) for 2 min and 72 °C (extension) for 2 min were performed. This was followed by 10-min extension at 72 °C.

Products were analyzed on a 1.5% agarose gel stained with 0.01% v/v ethidium bromide, viewed under ultraviolet light and compared to 50 and 100 bp molecular weight ladders (Roche Diagnostics, Lewes, East Sussex, UK).

Statistical analysis

Two-sided Fisher's exact tests were used throughout (SPSS 9.0, SPSS Inc., Chicago, IL, USA). A P value of <0.05 was taken as significant. Where appropriate, multisided contingency tables were employed initially for comparisons, with sub-group analysis only when a statistically significant result was seen in the initial comparison. Individual sub-group analyses for end-organ disease(s) only involved comparison with AC controls. Chi square values, where expected cell numbers are greater than 5, are shown in brackets in tables. A comparison is made for the presence of the insertion polymorphism, which has the functional association[17], and for the genotype of that polymorphism.

RESULTS

Results are displayed in Table 1. of 208 normal controls 12 (5.8%) had the insertion polymorphism, and all were heterozygotes (Figure 1A). In contrast, 5 of 239 ALC subjects (2.1%) had the insertion. In the AICP group two subjects had the insertion and one of these was homozygous for the insertion. In the AC group, three subjects had the insertion. In addition, one AICP and one AC had a band which would correspond to the 48-bp deletion found in GenBank (Figure 1B), as did two normal controls. Results from the British and German groups, all European Caucasoids, were similar: three of the 136 German subjects (2.2%) and 2 of the 103 British (2%) had the insertion; two of the 31 German AC, 1 of the 36 British AC, 1 of the 105 German AICP and 1 of the 39 British AICP.

Comparing ALC to NC for the presence of the insertion polymorphism, showed that it was less abundant in the former than the latter ($P = 0.049$) (Table 2). The same comparison for genotype of the insertion was comparable ($P = 0.030$) (Table 2).

To delineate whether the difference may have been for alcohol problems *per se* or end organ disease we initially employed Fisher's exact test for the presence of the insertion using a three by two contingency table of normal controls, AC and AEOD. This revealed a statistically significant difference ($P = 0.045$), and analysis for insertion genotypes was comparable ($P = 0.011$) (Table 3). Thus, we further analyzed the sub-groups. Comparing AC with NC and comparisons within alcoholic (ALC) subgroups analysis did not reveal any significant differences, as might be expected with such a low frequency in the patient

Table 1 Full genotype data on all subjects

	Normal controls (n = 208)	ALC (n = 239)	Of ALC		Of AEOD	
			AC (n = 67)	AEOD (n = 172)	AICP (n = 144)	ALD (n = 28)
Homozygote wildtype	194	232	63	169	141	28
Heterozygote for insertion	12	4	3	1	1	0
Homozygote for insertion	0	1	0	1	1	0
Heterozygote for deletion	2	2	1	1	1	0

ALC, ICD 10.1/10.2; AC, alcoholic controls; AEOD, alcohol-related end-organ disease; AICP, alcohol induced chronic pancreatitis; ALD, alcoholic liver disease.

Table 2 Normal control and alcoholic figures and comparisons

	Normal controls n = 208 (%)	ALC n = 239 (%)	Fisher's exact test
Presence of insertion polymorphism	12 (5.8)	5 (2.1)	$P = 0.049$ ($\chi^2 = 4.110$, $P = 0.043$)
Genotype for insertion polymorphism			
Heterozygote	12 (5.8)	4 (1.7)	$P = 0.030$
Homozygote	0 (0.0)	1 (0.4)	

ALC, ICD 10.1/10.2.

	Normal controls n = 208 (%)	Alcoholic controls n = 67 (%)	Alcoholic end organ disease n = 172 (%)	Fisher's exact test
Presence of insertion polymorphism	12 (5.8)	3 (4.5)	2 (1.2)	$P = 0.045$
Genotype for insertion polymorphism				
Heterozygote	12 (5.8)	3 (4.5)	1 (0.6)	$P = 0.011$
Homozygote	0 (0.0)	0 (0.0)	1 (0.6)	

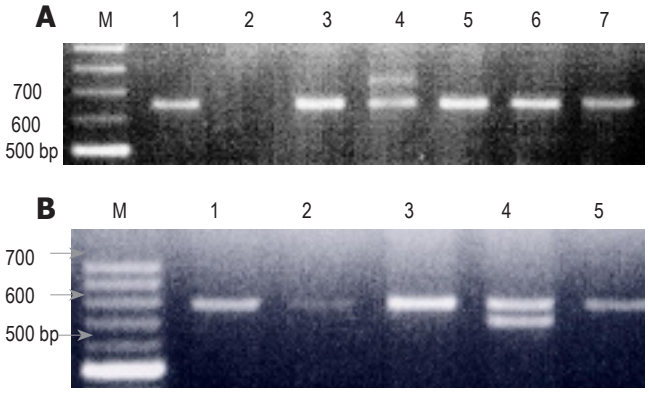

Figure 1 A: Agarose gel showing wild type homozygotes (633 bp, lanes 1, 3, 5–7) and a heterozygote for the insertion polymorphism (729 bp, lane 4). Run alongside a molecular weight marker (M); **B**:Agarose gel showing wild type homozygotes (633 bp, lanes 1–3 and 5) and a heterozygote for the deletion polymorphism (585 bp, lane 4). Run alongside a molecular weight marker (M).

groups. Although genotype analysis for AEOD compared with AC approached significance with $P = 0.068$.

DISCUSSION

Polymorphisms in CYP2E1, other than that studied here, have been looked at in previous studies, though some have used small numbers. Their association with alcoholism has been studied: no association was found for the c1/c2 alleles in most studies[19-23]. A positive association for the D form of the C/D polymorphism was found in Japanese subjects[24]. Although some studies used non-alcoholic controls, in alcohol induced end-organ disease association for these polymorphisms has been found: for ALD and the c2 allele[25-27] and fatty liver and the c2 allele[28]. However, the positive association with end-organ disease has not been found in a number of studies[19,21,29-31] and two studies found an association with the c1 allele[32,33].

The original study describing the polymorphism assessed in this study, showed greater CYP2E1 metabolic activity associated with the 96 bp insertion. In that study chlorazoxazone hydroxylation was higher in the patients with the presence of the polymorphism and who were obese or recent consumers of alcohol[17]; both circumstances when CYP2E1 is induced. The two later descriptions[15,16] delineate the pattern of 8 repeats of 42-60 bp, as opposed to 6 in the wild type. The first sequencing data showed a run of five repeats[34] (accession no. J02843), which had not been seen in the two further studies[15,16], this form would correspond to the smaller band seen in four of our 447 samples (Figure 1B).

Hu *et al*[15] did not find an increased constitutive

expression in luciferase transfection experiments, for the insertion polymorphism, which would agree with McCarver et al[17] findings of increased enzymatic activity only in the induced state (obese subjects and recent alcohol consumers).

To our knowledge, this is the first study to look at this polymorphism in patient groups. In previous studies of healthy groups of American Caucasoids, frequencies of 6.9%[17] and 4.2%[16] are seen. Another previous study found the insertion in only 2.1% of healthy Swedish subjects[15].

At low frequencies these results, on Caucasoid subjects, could all be consistent with the frequencies found in our patient, as well as our control, groups; of 5.8% controls (British), 2.2% German ALC and 2% British ALC. However, in the large numbers in our study our results do indicate a statistically significant difference, which remains when isolating the smaller numbers of only British subjects for insertion genotype between NC and ALC ($P = 0.03$). Population stratification is a confounding factor in all genetic association studies and the possibility of this is recognized, raising the question as to whether our results are biologically as well as statistically significant.

We have shown a significantly lower frequency of this polymorphism, which is associated with increased activity, in the gene coding for the enzyme CYP2E1 when comparing those with alcohol dependence or abuse and normal controls. This could be explained and be analogous to the association found in the functional variations in ADH. It has been shown that high activity forms of ADH (and low activity forms of ALDH) are associated with the protection against alcoholism in a number of studies, as previously reviewed[35]. This is believed to be due to the increased production (or decreased metabolism) of the ethanol metabolite acetaldehyde (and possibly other toxic metabolites), to which associated unpleasant side effects such as flushing are ascribed[35].

Due to the low frequency in our patient populations it was not possible to delineate whether there was only a relationship to alcohol misuse *per se*, or a relationship to end-organ disease. If a lower frequency existed in alcoholics, it could then be expected to be increased in those with end-organ disease compared to alcoholic controls. The sole homozygote was a patient with AICP and genotype analysis of those with end-organ disease *vs* AC approached significance, with $P = 0.068$. However, to infer a finding from such a result would not be justified.

Further analysis in ethnic populations with a frequency of this polymorphism which is sufficiently common to a more likely impact on susceptibility to CYP2E1-related diseases would be useful (e.g. Chinese[15], Taiwanese or African American[16] populations). This would be useful both to confirm or refute the association found here and to delineate any association with end-organ disease, rather than alcoholism *per se*.

In conclusion, the debate regarding a role for CYP2E1 in alcohol misuse and end-organ disease and a genetic component of this is further assessed. We have shown for the first time frequencies of this functional polymorphism in patient groups and there appears to be an association with this high activity polymorphism in the gene coding for cytochrome P450 2E1 and genetic protection against alcohol consumption. However, further studies are required in other populations.

Abstract

AIM: Grapefruit-seed extract (GSE) containing flavonoids, possesses antibacterial and antioxidative properties but whether it influences the gastric defense mechanism and gastroprotection against ethanol- and stress-induced gastric lesions remains unknown.

METHODS: We compared the effects of GSE on gastric mucosal lesions induced in rats by topical application of 100% ethanol or 3.5 h of water immersion and restraint stress (WRS) with or without (A) inhibition of cyclooxygenase (COX)-1 activity by indomethacin and rofecoxib, the selective COX-2 inhibitor, (B) suppression of NO-synthase with L-NNA (20 mg/kg ip), and (C) inactivation by capsaicin (125 mg/kg sc) of sensory nerves with or without intragastric (ig) pretreatment with GSE applied 30 min prior to ethanol or WRS. One hour after ethanol and 3.5 h after the end of WRS, the number and area of gastric lesions were measured by planimetry, the gastric blood flow (GBF) was assessed by H_2-gas clearance technique and plasma gastrin levels and the gastric mucosal generation of PGE2, superoxide dismutase (SOD) activity and malonyldialdehyde (MDA) concentration, as an index of lipid peroxidation were determined.

RESULTS: Ethanol and WRS caused gastric lesions accompanied by the significant fall in the GBF and SOD activity and the rise in the mucosal MDA content. Pretreatment with GSE (8-64 mg/kg i g) dose-dependently attenuated gastric lesions induced by 100% ethanol and WRS; the dose reducing these lesions by 50% (ID_{50}) was 25 and 36 mg/kg, respectively, and this protective effect was similar to that obtained with methyl PGE2 analog (5 μg/kg i g). GSE significantly raised the GBF, mucosal generation of PGE_2, SOD activity and plasma gastrin levels while attenuating MDA content. Inhibition of PGE_2 generation with indomethacin or rofecoxib and suppression of NO synthase by L-NNA or capsaicin denervation reversed the GSE-induced protection and the accompanying hyperemia. Co-treatment of exogenous calcitonine gene-related peptide (CGRP) with GSE restored the protection and accompanying hyperemic effects of GSE in rats with capsaicin denervation.

CONCLUSION: GSE exerts a potent gastroprotective activity against ethanol and WRS-induced gastric lesions via an increase in endogenous PG generation, suppression of lipid peroxidation and hyperemia possibly mediated by NO and CGRP released from sensory nerves.

INTRODUCTION

Grapefruit-seed extract (GSE) containing flavonoids, possesses antibacterial, antiviral and antifungal properties[1-3]. These beneficial actions of GSE have been attributed to the antioxidative activity of grapefruit containing citrous flavonoids such as naringenin[4]. Moreover, grapefruit juice and its major flavonoid exhibited the potent anti-*H pylori* activity *in vitro*[5] and was also recently found to exert the cytoprotection against hepatocyte injury induced by algal toxins[6]. In another study, naringenin showed anti-cancer

activity against human breast cancers[7]. Therapeutic efficacy of citrous fruits such as grapefruits and red grapes has been explained by the content of different classes of polyphenolic flavonoids, that were shown to inhibit platelet aggregation, thus decreasing the risk of coronary thrombosis and myocardial infarction[8]. However, the involvement of grapefruit extracts containing various flavonoids in the mechanism of gastric mucosal defense has been little studied.

Our group demonstrated previously that other flavonoids, namely, meciadanol, a synthetic flavonoid inhibiting histidine decarboxylase (HDC) and decreasing histamine content in the stomach, attenuated gastric mucosal lesions produced by ethanol and aspirin *via* the mechanism unrelated to gastric acid secretion and endogenous prostaglandins (PG)[9]. Furthermore, naringenin, a major citrous flavonoid, was reported to exhibit gastroprotection against the gastric injury induced by absolute ethanol due to the increase in the mucus secretion and that this gastroprotective effect of naringenin and accompanying increase in the mucus secretion, were, in part, attenuated by indomethacin suggesting the involvement of endogenous PG in the mechanism of this flavonoid-induced gastroprotection[10]. It remains unknown, to what extent GSE influences the gastric mucosal injury induced by topical (ethanol) and non-topical ulcerogens (stress) and, if so, what is the mechanism of gastroprotection induced by GSE. Therefore, using animal models of gastric lesions induced by 100% ethanol and water immersion and restraint stress (WRS), we determined the influence of GSE on gastric lesions and the accompanying changes in the gastric blood flow (GBF) in the rat stomach. An attempt was also made to assess the contribution of gastric acid secretion, plasma gastrin levels, PG/cyclooxygenase (COX)-system, nitric oxide (NO) and sensory nerves in the gastroprotective effect of GSE. Finally, we evaluated the effect of pretreatment with GSE on the gene expression and activity of superoxide dismutase (SOD) and lipid peroxidation, as expressed by malonyldialdehyde (MDA) concentration, in rats with or without the pretreatment with GSE.

MATERIALS AND METHODS

Male Wistar rats, weighing 180-220 g and fasted for 24 h before the study were employed in all the studies. This study was approved by the Institutional Animal Care and Use Committee of Jagellonian University School of Medicine in Cracow and run in accordance to the statements of European Union regarding handling of experimental animals.

Gastric secretory studies

The effects of GSE purchased from Herb-Pharma, Welke Dudince, Slovakia on gastric acid secretion were examined in 40 conscious rats equipped about 1 mo earlier with a gastric fistula (GF) as described previously[11]. The animals were fasted overnight but had free access to water 24 h before the experiment and they were placed in individual Bollman type cages to maintain the minimum restraint necessary. The GF was opened; the stomach was rinsed gently with about 5 mL of tap water at 37 ℃. The basal gastric secretion was collected for 60 min and GSE was administered i.g. in gradual doses ranging from 8 to 64mg/kg, each dose being administered on a separate test day. In control tests, vehicle (1 mL of saline, i g) was given in the same volume as in tests with GSE and the collection of gastric juice was continued for the final 120 min. The volume and acid concentration of each collected sample of gastric juice were measured and acid outputs was calculated and expressed in terms of micromoles of acid per 30 min[12].

Induction of ethanol and stress lesions and determination of gastric blood flow (GBF)

Acute gastric lesions were induced by an intragastric (ig) application of 100% ethanol similarly to the method described previously[11,12]. Briefly, 100% ethanol in a volume of 1.5 mL was administered ig to rats by means of a metal orogastric tube. After 60 min, the animals were lightly anesthetized with ether, their abdomen was opened by the midline incision and stomach exposed for the measurement of GBF by means of using the H_2-gas clearance technique as described previously[13]. For this purpose double electrodes of electrolytic regional blood flowmeter (Biotechnical Science, Model RBF-2, Osaka, Japan) were inserted into the gastric mucosa. One of these electrodes was used for the local generation of gaseous H_2 and another for the measurement of tissue H_2. With this method, the H_2 generated locally was carried out by flow of blood, while the polarographic current detector reads out decreasing tissue H_2. The tissue H_2 clearance curve was used to calculate an absolute flow rate (mL/100 g/min) in the oxyntic area as described previously[13]. The measurements were made in three areas of the mucosa and the mean values of the measurements were calculated and expressed as percent changes of those recorded in the vehicle (saline) treated animals. After the GBF measurement, the stomach was removed, rinsed with water and pinned open for macroscopic examination. The area of necrotic lesions in oxyntic mucosa was determined by computerized planimetry (Morphomat, Carl Zeiss, FRG)[12-14] by the person who did not know to which experimental group the animals belonged.

The WRS was induced in the animals that were placed in restraint cages and immersed vertically to the level of the xiphoid process in a water bath of 23 ℃ for 3.5 h[13,14]. After 3.5 h of WRS, the rats were lightly anesthetized with ether, the abdomen was opened and the stomach was exposed. The GBF was measured in the oxyntic gland area of the stomach by means of local H_2-gas clearance method using an electrolytic regional blood flow meter (Biomedical Science, Model RBF-2, Osaka, Japan) as described above. The stomach was removed, opened along the greater curvature and placed flat to count the number of gastric lesions by two investigators, unaware of the treatment given as described in our previous studies[13,14]. The stress lesions were defined as round or linear mucosal defects of at least 0.1 mm in diameter.

Animals with sensory denervation induced by capsaicin

The role of sensory afferent nerves in mechanism of WRS-induced gastric lesions with or without pretreatment with GSE was determined in rats with or without capsaicin induced deactivation of these nerves. For this purpose the animals were pretreated with capsaicin (Sigma Co., St. Louis, MO, USA) injected s.c. for 3 consecutive days at a dose of 25, 50 and 50 mg/kg for about 2 wk, before the experiment[15,16]. All injections of capsaicin were performed under ether anesthesia to counteract the pain reactions and respiratory impairment associated with injection of this agent. To check the effectiveness of the capsaicin denervation, a drop of 0.1 mg/mL solution of capsaicin was instilled into the eye of each rat and the protective counting movements were counted as described previously[16]. Rats with or without capsaicin-denervation received vehicle or GSE (5-80 mg/kg ig) 30 min prior to exposure to 3.5 h of WRS. At the end of WRS, animals were anesthetized and then the GBF and the number of gastric lesions were measured in a similar manner as mentioned above.

Determination of mucosal generation of PGE_2, lipid peroxidation and SOD activity in gastric mucosa exposed to ethanol and WRS with and without GSE

In groups of rats exposed to standard 3.5 h of WRS without or with pretreatment with GSE, the mucosal samples from the gastric mucosa were taken by biopsy (about 200 mg) from oxyntic gland area without mucosal lesions immediately after the animals were killed to determine the mucosal generation of PGE_2 by radioimmunoassay (RIA) as described previously[17]. The capability of the mucosa to generate PGE_2 was expressed in nanograms of wet tissue weight.

Since lipid peroxidation is a well-established mechanism of cellular injury induced by reactive oxygen metabolites, we measured the changes in the MDA as an indicator of this lipid peroxidation in gastric mucosa[18,19] exposed to WRS without and with the treatment with GSE. For the measurement of lipid peroxidation, the tissue was weighed, transferred to the ice-cooled test tube and homogenized in 400 μL of 20 m mol/L Tris buffer pH 7.4 containing 5 mM butylated hydroxytoluene to prevent new lipid peroxidation that can occur during the homogenization. The homogenate was then centrifuged at 4 °C for 10 min and resulted supernatant (200 μL) was stored in -80 °C until an assay of lipid peroxidation. The content of lipid peroxidation was measured at 37 °C by spectrophotometer at a wave length of 586 nm and compared with the absorbance of purified MDA as the standard.

The activity of SOD was measured in the gastric mucosa of rats exposed to WRS with or without pretreatment with GSE using SOD 525 assay kit (OXIS International, Inc., Portland, USA)[19,20]. The gastric tissue was first washed with 0.9% NaCl containing 0.16 mg/mL heparin to remove red blood cells which may interfere with the SOD activity in the gastric specimens. Then the biopsy sample was blotted on the filter paper, weighed and finally homogenized in 400 μL of PBS buffer pH 7.4 using a tissuemizer Ultra Turax (Janke and Kunkel GmbH and Co., Staufen, Germany). The principle of the SOD measurement is based on the SOD-mediated increase in the rate of auto-oxidation of 5, 6, 6a, 11β-tetrahydro-3,9,10-trihydrobenzoflurene in aqueous solution at 37 °C to yield a chromophore with maximum absorbance at 525 nm. Ethanol-chloroform extraction was employed to inactivate Mn-SOD and Fe-SOD and to ensure that the assay is specific for Cu/Zn-SOD.

Determination of SOD transcripts by reverse transcriptase polymerase chain reaction (RT-PCR)

The expression of SOD was determined by RT-PCR in the gastric mucosa of intact rats or following exposure to WRS with or without GSE. Samples of the gastric oxyntic mucosa (about 500 mg) were scraped off on ice using glass slide and then immediately snap frozen in liquid nitrogen, and stored at -80 °C. Total RNA was isolated from the gastric oxyntic mucosa using a rapid guanidinum isothiocyanate/phenol chloroform single step extraction kit from Stratagene (Stratagene GmbH, Heidelberg, Germany)[21,22]. Following precipitation, the RNA was resuspended in RNase-free TE buffer and the concentration was estimated by absorbance at 260 nm wave length. Samples were frozen at -80 °C until analysis.

First strand cDNA was synthesized from total cellular RNA (5 μg) using 200 U Strata Script TM reverse transcriptase (Stratagene GmbH, Heidelberg, Germany) and oligo (dT) primers (Stratagene GmbH, Heidelberg, Germany). After the reverse transcription, the transcriptase activity was destroyed by heating, and the cDNA was stored at -20 °C until PCR.

A 496-bp fragment of SOD was amplified from single-stranded DNA by PCR using two oligonucleotide primers to SOD. The SOD sense primer was 5' CGAGTTATGGCGACGAAG3' and antisense primer was 5'GTCAGCAGTCACATTGCC3'. The primers for SOD and β-actin were synthesized by Biometra (Gottingen, Germany). Concomitantly, amplification of control rat β-actin (Clon Tech, Palo Alto, CA, USA) (764 bp) was performed on the same samples to verify RNA integrity.

DNA amplification was carried out under the following conditions; denaturation at 94 °C for 1 min, annealing at 60 °C for 45 s, and extension at 72 °C for 45 s. The number of amplification cycles was 29 for SOD. Each PCR-product (8 μL) was electrophoresed on 1.5% agarose gel stained with ethidium bromide, and then visualized under UV light. Location of predicted PCR product was confirmed by using a 100-bp ladder (Gibco BRL/Life Technologies, Eggenstein, Germany) as standard marker.

The intensity of bands was quantified in a semi-quantitative manner using densitometry (LKB Ultrascan, Pharmacia, Sweden) as described in detail in our previous studies[22]. Briefly the gel was photographed under UV transillumination. The intensity of PCR products was measured using video image analysis system (Kodak Digital Science). The SOD mRNA signals were standardized against the β-actin mRNA signal for each sample and results were expressed as SOD mRNA/β-actin mRNA ratio.

Statistical analysis

Results are expressed as means±SE. The significance of the difference between means was evaluated using analysis of variance followed by Duncan's test with a level of significance at $P<0.05$.

RESULTS

Effect of GSE on gastric acid secretion and plasma gastrin levels in rats with chronic GF

As shown in Table 1, gastric acid output reached the value of 134±11 μmol/30 min, while fasting plasma gastrin concentration averaged of 53 ± 4 μmol/L in control rats treated with vehicle (saline). GSE applied ig in a dose of 8 mg/kg ig failed to affect significantly the gastric acid output and plasma gastrin levels as compared to those in control animals. GSE applied ig in a dose of 16 mg/kg and higher, produced a significant decrease in the gastric acid output and significantly raised the plasma gastrin levels (Table 1).

Table 1 Effect of vehicle (saline) and GSE applied ig in graded concentrations ranging from 8 up to 64 mg/kg on the gastric acid secretion and plasma gastrin levels. Results are mean±SE from 6 determinations on 6–8 animals

Type of test	Gastric acid output (μmol/30 min)	Plasma gastrin (pmol/L)
Vehicle	134±11	53±4
GSE (mg/kg ig)		
8	131±9	56±6
16	118±9[a]	69±8[a]
32	89±7[a]	75±9[a]
64	64±5[a]	82±10[a]

[a]$P<0.05$ *vs* vehicle.

Effect of GSE on acute gastric lesions induced by ethanol and WRS

Figure 1 shows the effect of topical pretreatment with GSE applied ig in graded concentrations ranging from 8 to 64 mg/kg on the mean area of gastric lesions induced by 100% ethanol and the accompanying changes in the GBF. Ethanol caused typical widespread gastric lesions with an area of 86±5 mm^2 and reduced the GBF by about 38% as compared to that in intact gastric mucosa. Pretreatment with GSE applied in the lowest dose of 8 mg/kg, failed to influence the ethanol lesions but starting from the dose 16 mg/kg up to dose of 64 mg/kg of GSE, a dose-dependent reduction in gastric lesions was observed; the dose that inhibits ethanol damage by 50% (ID_{50}) being 28 mg/kg. This protective effect of GSE applied in graded doses against ethanol damage was accompanied by the significant rise in the GBF. The gastroprotective effect of GSE and accompanying increase in the GBF were similar to those achieved by the pretreatment with methyl analog of PGE_2 applied 30 min before the application of ethanol.

As shown in Figure 2, the pretreatment with GSE applied topically in a doses ranging from 8 to 64 mg/kg caused a significant attenuation of WRS-induced gastric damage; the ID_{50} being 36 mg/kg. The GBF was significantly decreased in rats exposed to 3.5 h of WRS but GSE given 30 min before the exposure of animals to 3.5 h of WRS resulted in a dose-dependent rise in the GBF as compared to that obtained in vehicle-treated animals (Figure 2).

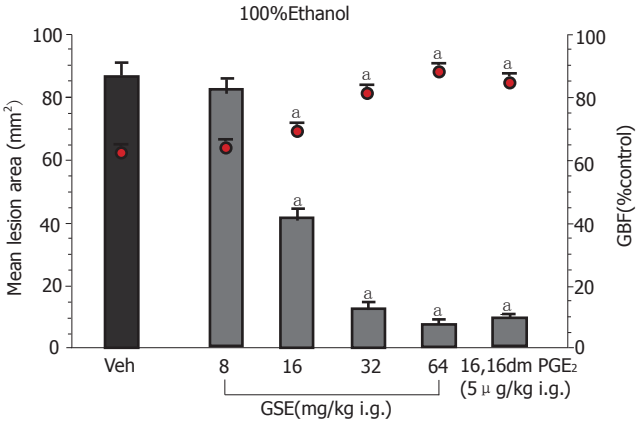

Figure 1 Effect of intragastric (ig) pretreatment with GSE applied in graded doses ranging from 8 mg/kg up to 64 mg/kg or 16,16 dimethyl PGE_2 (5 μg/kg ig) on the mean area of gastric lesions induced by ethanol and accompanying changes in the GBF. Results are mean±SE from 6 to 8 animals per group. [a]$P<0.05$ *vs* vehicle (Veh).

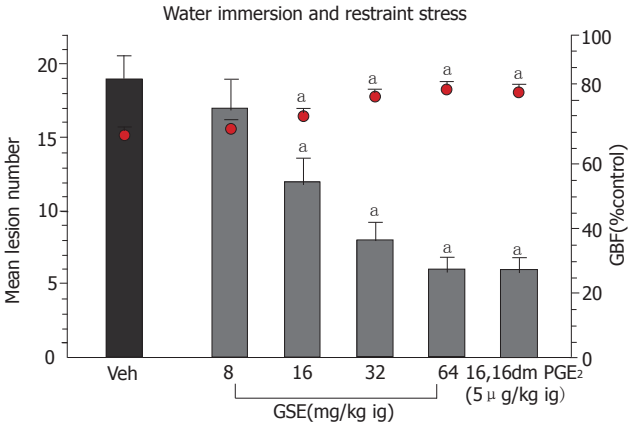

Figure 2 Effect of intragastric (ig) pretreatment with GSE applied in graded doses ranging from 8 mg/kg up to 64 mg/kg or 16,16 dimethyl PGE_2 (5 μg/kg ig) on the mean number of gastric lesions induced by 3.5 h of WRS and accompanying changes in the GBF. Results are mean±SE from 6 to 8 animals per group. [a]$P<0.05$ *vs* vehicle (Veh).

Effect of pretreatment with GSE on the gastric mucosal SOD activity and MDA content in gastric mucosa exposed to ethanol or WRS

Table 2 shows the results of determination of MDA+4HNE as an index of lipid peroxidation in the gastric mucosa or rats exposed to ethanol- or WRS without or with GSE pretreatment. The MDA concentration was significantly increased in vehicle-control gastric mucosa exposed to ethanol or WRS as compared to that in the intact gastric mucosa. Pretreatment with GSE applied ig

in a dose 16 mg/kg or higher, significantly attenuated the MDA concentration in animals exposed to ethanol or WRS (Table 2). The mucosal SOD activity was inhibited in the gastric mucosa of animals exposed to ethanol or WRS as compared to the respective value in intact gastric mucosa (Table 2). In contrast, the pretreatment with GSE applied in i.g. in graded doses ranging from 8 up to 64 mg/kg, which caused a significant attenuation of the damage induced by ethanol or WRS, dose-dependently reversed the deleterious effect of ethanol or WRS on the SOD activity and significantly counteracted the ethanol and WRS-induced rise in the MDA content (Table 2).

Table 2 Effect of vehicle (saline) and GSE applied i.g. in graded concentrations ranging from 8 mg/kg up to 64 mg/kg on the MDA concentration and SOD activity in the gastric mucosa in rats exposed to 100% ethanol or those subjected to 3.5 h of WRS. Results are mean±SE from 6 determinations on 6–8 animals

Type of test	MDA concentration (nmol/g)	SOD activity (unit/g)

Effect of inhibitors of COX and NOS activity on GSE-induced gastroprotection against WRS induced gastric damage and the alterations in GBF

Pretreatment with GSE (32 mg/kg ig) significantly reduced gastric lesions induced by WRS in a manner similar to that presented in Figure 2. The ip administration of indomethacin at a dose of 5 mg/kg which inhibited generation of endogenous PGE_2 by about 85%, aggravated the WRS-induced gastric lesions and significantly decreased GBF as compared to the respective values in animals treated with vehicle. Such pretreatment with indomethacin reversed almost completely the protective effect of GSE against WRS-induced lesions and the accompanying increase in the GBF (Figure 3).

The L-NNA, an inhibitor of NO-synthase by itself failed to affect the area of gastric lesions and the fall in the GBF induced by ethanol or WRS (Table 3, Figure 4). Pretreatment with GSE (32 mg/ kg ig) resulted in a significant reduction of ethanol- or WRS-induced gastric damage and significantly decreased the GBF as compared with the respective values attained in rats without GSE administration. Co-treatment with L-arginine (200 mg/kg ig) but not with D-arginine, added to GSE restored the gastroprotection and the accompanying increase in the GBF induced by this extract in L-NNA treated animals.

Capsaicin-denervation which by themselves aggravated ethanol- and WRS-induced gastric damage significantly attenuated the GSE-induced protection and hyperemia against lesions induced by ethanol or WRS (Table 4, Figure 5). Co-administration of calcitonine gene-related peptide (CGRP) with GSE in rats with capsaicin-denervation restored the protective and hyperemic effects of this extract against ethanol- and WRS-induced gastric lesions.

Table 3 Effect of GSE with or without pretreatment with NG-nitro-L-arginine (L-NNA 20 mg/kg ip) applied with or without the combination with L-arginine (L-Arg, 200 mg/kg ig) or D-arginine (D-Arg, 200 mg/kg ig) on the area of ethanol-induced gastric lesions and accompanying changes in the GBF. Results are mean± SE of 6–8 rats

DISCUSSION

This study shows that GSE attenuates the lesions in the rat stomach by the intragastric application of noxious agent such as ethanol or those caused by stress and that this protective effect of GSE is accompanied by the increase in the GBF and SOD expression and its activity and reduction of MDA concentration, that is widely considered as an index of lipid peroxidation. The inhibition of acid-dependent lesions caused by WRS can be attributed to the inhibition of acid secretion by this compound as observed in this study using well-conditioned and fully adapted GF rats. This protective and hyperemic activity of GSE against WRS ulcerogenesis was abolished by COX inhibitors such as indomethacin and rofecoxib and significantly reduced by L-NNA. Thus, we conclude that GSE containing citrous flavonoids exerts a potent gastroprotective activity against ethanol- and WRS-induced gastric lesions and this protective effect in the stomach may involve endogenous PG derived from COX-1 and COX-2 activity, suppression of lipid peroxidation and gastric hyperemia mediated by NO and neuropeptides released from afferent sensory nerves.

Previous studies documented that grapefruit seeds are the major depository for limonoids (triterpenoid dilactones chemically related to limonin) of these 77% are neutral while 2% are acidic limonoids[1-3]. Grapefruit contains also many flavonoids that includes glycosides, naringenin, quercetin, kaempferol, hesperetin and apigenin being the most abundant among their aglycones[4]. GSE, containing flavonoids, has been shown to possess antibacterial, antiviral and antifungal properties[2,3]. This beneficial action of GSE was attributed to the antioxidative activity of grapefruit containing citrus flavonoids[4,23], since, for instance, these flavonoids were found to exhibit the potent

anti-*H pylori* activity *in vitro*[5,24]. Furthermore, grapefruit containing flavonoids were also recently implicated in cytoprotection against injury induced by algal toxins in isolated hepatocytes[6,25]. Interestingly, GSE in a formulation of Citricidal, was demonstrated to be effective against more than 800 bacterial and vital strains, 100 strains of fungus and a large number of single or multicelled parasites[1]. These antimicrobiological properties against a wide range of Gram-negative and Gram-positive organisms were attributed to the disruption by GSE of the bacterial membrane and the subsequent liberation by this extract of the bacterial cytoplasmic contents within a relatively short time (e.g. 15-20 min). In a similar report, it was reported that GSE-induced antimicrobial action is comparable to that of proven antibacterials[2]. Moreover, naringenin, the bioactive component of GSE, showed anti-cancer activity against human breast cancers[7,26]. The underlying mechanism of the therapeutic efficacy of citrus fruits such as grapefruits and red grapes seems to depend upon the presence of different classes of polyphenolic flavonoids that were shown to inhibit platelet aggregation, thus decreasing the risk of coronary thrombosis and myocardial infarction[27-30].

The involvement of GSE in the mechanism of gastric mucosal defense against the formation of gastric lesions caused by obnoxious substances has been little studied. Herein, we provide evidence that GSE applied topically caused dose-dependent diminution of acute gastric lesions induced by both, 100% ethanol and WRS. Previous studies demonstrated that the damaging action of ethanol and WRS could be attributed to the enhancement in the reactive oxygen substances (ROS) and the ROS-dependent increase in the lipid peroxidation and inhibition of antioxidizing enzyme activity[18,19,21]. We found that GSE dose-dependently attenuated the rise in MDA content in the gastric mucosa injured by ethanol or WRS indicating that this extract can attenuate the process of lipid peroxidation implicated in the pathogenesis of ethanol and WRS-induced gastric damage[18,19]. Moreover, we have demonstrated that ethanol decreased the gene expression and activity of SOD in the gastric mucosa suggesting that the suppression of key mucosal antioxidizing enzyme along with the elevation of lipid peroxidation, play an important role in the pathogenesis of these lesions. This increase in the mucosal lipid peroxidation as well as the fall in SOD expression and its activities were attenuated by GSE, suggesting that the reduction in lipid peroxidation by this seed extract may contribute to the attenuation of the deleterious effect of noxious agents on the gastric mucosa. This is supported by the fact that the GBF was elevated and gastric PGE_2 production were enhanced in animals treated with GSE as compared to those treated with vehicle. Our finding is in accordance with observations that some flavonoids stimulated PGE_2 production by isolated gastric mucosal cells while suppressing gastric acid secretion via direct inhibitory effect on H^+/K^+-ATPase activity[24]. It is not concluded that NO/NOS system is also involved in gastroprotection against ethanol and WRS caused by GSE because both, GSE-induced protection and hyperemia were counteracted by L-NNA, a non-specific inhibitor of NO-synthase and this effect was restored in these animals by the combined treatment with L-arginine and GSE. Thus, our study implies that some natural products of the citrous fruits such as GSE, afford protection against ethanol and stress-induced gastric damage due to

endogenous PG and the preservation of expression and activity of a major antioxidizing enzyme such as SOD.

The mechanism of gastroprotective activity of GSE appears to be dependent on endogenous PG and the functional activity of sensory nerves releasing CGRP. This notion is supported by our findings that indomethacin, a non-selective inhibitor of COX-1 and COX-2 activity or functional ablation of sensory afferent nerves by capsaicin reversed GSE-induced protection and accompanying hyperemia. In addition, co-treatment of exogenous CGRP with GSE, administered to replace the deficit of this peptide in capsaicin-treated animals, restored the protective efficacy of GSE. Interestingly, rofecoxib which is a highly selective COX-2 inhibitor[17], also attenuated the gastroprotective and hyperemic activities of GSE suggesting the involvement of COX-2 derived products in the gastroprotection and increase in the GBF induced by this extract. Further studies assessing the mRNA expression of COX-1 and COX-2 in GSE-treated mucosa should reveal which enzymatic pathway is involved in aforementioned effects of this extract.

This gastroprotective activity of the GSE could be attributed to naringenin, a major GSE flavonoid, because this flavonoid was reported to exhibit gastroprotection against the gastric injury induced by absolute ethanol, predominantly due to the increase in the mucus secretion[10]. It is of interest that this gastroprotective effect of naringenin and accompanying increase in the mucus secretion, were, in part, attenuated by indomethacin, supporting the contribution of endogenous PG to the mechanism of gastroprotection by grapefruit products[10]. As shown in our present study, GSE by itself enhanced the gastric mucosa generation of PGE_2 but our unpublished evidence indicates that this extract can be also effective against aspirin-induced gastric lesions under the conditions, where PG generation is completely suppressed. Therefore, it seems likely, that endogenous PG might not be primary mediators of this protection and other gastroprotective factors such as NO and/or neuropeptides released from sensory afferent nerves could be involved. This was the reason for carrying out the study with L-NNA, a potent NO-synthase inhibitor and with capsaicin, applied in a dose that causes functional ablation of sensory nerves releasing vasoactive neuropeptides such as CGRP. We found that L-NNA and capsaicin denervation inhibited the GSE-induced protection against ethanol- and WRS-induced gastric lesions and accompanying gastric mucosal hyperemia. Our study militates against PG as the primary mediator in the mechanism of GSE-induced gastroprotection and this remains in accordance with our previous report that meciadanol, the synthetic flavonoid inhibiting the activity of HDC, prevented the ethanol- and aspirin-induced injury in rat stomach without altering the mucosal generation of prostacyclin (PGI_2)[9].

Another candidate involved in the GSE-induced protection could be gastrin, which is known to exhibit both, gastroprotective and hyperemic activities[11]. Indeed, we addressed this issue by direct determination of the plasma gastrin levels by specific RIA and we found that gastrin is elevated in GSE-treated animals. This effect could be secondary to the inhibition of gastric acid secretion caused by this compound as demonstrated in our study by the administration of GSE to the chronic, well-adapted rats with chronic GF. Suppression of gastric secretion by GSE might contribute to the protective activity of this extract against WRS, because WRS damage depends upon gastric acidity and becomes exaggerated by acidic conditions in the stomach.

In summary, we have demonstrated in this report that the pretreatment with GSE reduces the ethanol and WRS-induced gastric damage through the preservation of the antioxidizing enzyme (SOD) activity, reduction of free radical-dependent lipid peroxidation, enhancement in the GBF and plasma gastrin levels. Endogenous PG appears to be important mediator of this protection, but other mediators such as NO and neuropeptides released from sensory nerves such as CGRP could be also involved in the gastroprotective and hyperemic activities of this extract. No study, so far has been undertaken to examine the ulcer healing efficacy of GSE, but the fact that this grapefruit seed extract exerts a potent anti-*H pylori* in vitro[30] and profound gastroprotective effects in laboratory animals warrants a further approach for its potential application in healing of chronic ulcerations in human beings.

Abstract

AIM: To investigate the influence of neutrophil adhesion molecule blockade with monoclonal antibody (MoAb CD11b) and *E. coli* lipopolysaccharide (LPS) administration on experimental acute pancreatitis (AP).

METHODS: AP was induced by four ip injections of cerulein (Cn) at 1-h intervals. MoAb CD 11b and LPS were administered at the beginning of the experiment.

RESULTS: The neutrophil count and chemiluminescence were diminished at the beginning of AP. The oxidative stress parameters were found within the pancreatic gland. MoAb CD 11b used for AP resulted in a significant reduction of pancreatic infiltration and pancreatitis oxidative stress parameters. Serum interleukin-6 (IL-6) was not detected in AP animals, whereas high serum IL-6 concentration was noted only in animals receiving LPS.

CONCLUSION: Neutrophils are involved in pancreatic damage in the early stage of AP. Neutrophil infiltration reduction protects the pancreatic gland from destruction during AP. LPS does not change the early course of Cn pancreatitis in rats.

Key words: Acute pancreatitis; Polymorphonuclear cells; Immunomodulation; Septic shock

INTRODUCTION

Acute pancreatitis (AP) is an insidious disease. Almost 75% of patients suffer from the mild edematous form of AP. About 25% of patients develop the severe disease with a mortality rate of 30-60%. The reasons of two different courses still remain unclear. One of the discussed reasons of organ dysfunction complicating AP is excessive leukocyte activation. Activation of inflammatory mediators [interleukins, leukotrienes, TNF-α, PAF, and lipopolysaccharide 9LPS)] within the pancreas may result in excessive damage within the pancreas, peripancreatic tissue or even distant organs[1-3]. The suggestion of neutrophil deteriorating role in human AP has largely been suggested. LPS, presented in the Gram-negative bacterial wall, has been studied extensively as an inflammatory stimulating factor contributing to the pathophysiology of conversion from mild to severe form of AP[4-6]. The pathophysiology of inflammatory process in AP leads to the immunomodulation concept. The idea is one of the most promising treatment options in AP nowadays. The early polymorphonuclear (PMN) requirement is well documented in AP.

The aim of this study was to investigate the PMN activation in the early stage of experimental cerulein (Cn) AP and the influence of mAb against adhesion molecule CD 11b on inflammatory response of the disease. Besides, whether LPS aggravated the early experimental AP in rats was also examined. The hypothesis of early aggravation of AP by LPS challenge was investigated.

MATERIALS AND METHODS

The study was performed on male Wistar rats (180-200 g) that were kept on standard rat chow and fasted overnight before the experiment, but with free access to water. AP was induced by four ip injections of Cn at a dose of 15 μg/kg (Sigma Chemical Co., St. Louis, USA) in 1 mL

of saline at 1-h intervals. MoAb CD 11b (POLATOM Świerk, Poland) was given iv once at the beginning of the experiment at a dose of 1 mg/kg. LPS (Sigma Chemical Co., St. Louis, USA) was administered ip at a dose of 10 mg/kg, simultaneously with the first Cn injection. Control animals were injected intravenously with an adequate volume of 0.9% saline solution. Five and nine hours from the beginning of the experiment, rats were anesthetized with sodium pentobarbital (25 mg/kg ip) and thoracolaparotomy was performed. Blood was aspirated into the test tubes on 30 U/mL heparin from left ventricle, the pancreas was excised, and animals were killed by exsanguinations. Pancreas specimen was taken for light microscopy and for determination of malonyldialdehyde (MDA), total sulfhydryl groups (SH) and myeloperoxidase (MPO). The study protocol was approved by The Local Ethic Committee for the Use of Experimental Animals of Medical University (Protocol No. 22/71).

Animals were divided into seven groups: group 1 ($n=14$) control, group 2 ($n=16$) AP, group 3 ($n=11$) AP+MoAb CD 11b, group 4 ($n=11$) AP+LPS, group 5 ($n=8$) AP+MoAb CD 11b+LPS, group 6 ($n=8$) MoAb CD 11b, group 7 ($n=11$) LPS.

Whole blood chemiluminescence (CL) assay

CL assay was performed in 1:200 diluted heparinized whole blood (30 IU/mL) to reduce artefacts. Diluent was prepared with PBS mixed with calcium and magnesium chloride (Biomed, Poland) and glucose (0.1%). Granulocyte CL was started by the phorbol-12-myristate-13-acetate (PMA, ICN Biomedicals Inc., USA). PMA (1 mg) was diluted with 1 mL dimethyl-sulfoxide (DMSO, Sigma) to the final concentration of 1.6×10^{-3} mol/L. PMA solution was diluted with PBS to the final concentration of 1.6×10^{-6} mol/L just before the measurement. Luminol solution was prepared with 1.77 mg dry substance (ICN Biomedicals Inc., USA) combined with 1 mL 0.4% NaOH and filled to 3 mL with PBS to obtain 3×10^{-5} mol/L concentration.

Chemiluminescence measurement

Transparent tubes containing 100 μL heparinized whole blood diluted 1:20 with PBS, 200 μL luminol (3×10^{-5} mol/L), 500 μL PBS and 200 μL PMA (1.6×10^{-5} mol/L) were analyzed in a FB 12 luminometer (Berthold Detection Systems, Germany) at 460-nm light length. The measurement was carried out at 10-s intervals for 20 min. All reagents were kept at 22℃ during the procedure. The CL intensity was calculated in relative light units (RLU) per 2 000 of whole blood PMN cells, per minute (RLU/2 000 PMN ×min).

Serum polymorphonuclear elastase (PMN-E)

The measurement was carried out on the basis of commercial ELISA method (PMN-E, K6840 Immundiagnostic GmbH, Germany). PMN-E serum concentration was expressed as nanogram per milliliter.

Pancreatic myeloperoxidase (MPO)

A part of the pancreatic gland (at least 0.3 g wet mass) was taken during the laparotomy. The tissue was homogenized (Porter-Elvenheim) immediately at 4℃ with PBS (pH 7.4). The volume of PBS was adequate to obtain 5% homogenate solution. Then the sample was centrifuged at 2 400 r/min for 10 min at 4℃. The supernatant was taken for MPO, SH and MDA measurements. Two milliliters of the supernatant was mixed with 0.5 mL of 0.1% phenyl-methyl-sulfo-fluoride (Sigma Chemicals Co.) and 0.5 mL of 0.5% cetrimide (Merck). The mixture was centrifuged again at 2 400 r/min at 4℃. MPO was measured using the ELISA method (Immundiagnostic GmbH, Germany). Pancreatic MPO concentration was expressed as nanogram per one gram of protein.

Sulfhydryl groups (-SH) and malonyldialdehyde (MDA) in pancreatic homogenate

A total of 300 μL of pancreatic homogenate was diluted with sodium phosphate buffer (10 mmol/L) pH 8.0 to obtain 2.5% proteins concentration. Then 300 μL of sodium dodecyl sulfate (10%) was added to the sample to dissolve proteins in order to expose hidden sulfhydryls. Two thousand and four-hundred-microliter PBS was added, mixed and the absorbance was measured at 412 nm (Cecil Super Aquarius CE 9200). Then 300 μL of DTNB was added into the extract or 300 μL of PBS as blank to the reference mixture. Samples were incubated at 37℃ in a water bath for 1 h. The absorbance was measured again. The concentration of SH groups was expressed as nanomole per milliliter.

MDA content was measured by spectrophotometer (LPO-586 Test Kit) assay (OxisResearch, Portland, USA), 600 μL of supernatant was mixed with 1 950 μL of R1 (10.3 nmol/L *N*-methyl-2-phenylindole solved in acetonitrile) and 450 μL 37% HCl. Samples were incubated in a water bath at 45 °C for 1 h, and then centrifuged at 3 500 r/min for 10 min. The absorbance of the supernatant was measured at 586 nm (Cecil Super Aquarius CE 9200).

Plasma α-amylase and lipase activity

The activity of α-amylase was measured using commercial kit RTU 63116 (BioMerieux). Lipase activity was determined using commercial kit Lipase Color 63109 (BioMerieux) in units per liter.

Microscopic findings within the pancreatic gland

Hematoxylin-eosin standard staining was performed. An experienced pathologist performed the light microscopic examination. All samples were estimated with 200× magnification. Edema, vacuolization and necrosis of pancreatic cells were established in modified Spormann scale (0-3 points each parameter). PMN infiltration within the pancreatic parenchyma was calculated as mean number of neutrophils in 10 consecutive microscopic fields by a "blinded" pathologist.

Whole WBC count

Whole WBC and neutrophils were counted in Bürker' s camera following 1∶200 dilution with Türk's solution.

Cells were counted twice by experienced laboratory technician and the mean value was considered as the result.

Interleukin-6 (IL-6) concentration

Serum IL-6 concentration was determined using the commercial ELISA kit Rat-IL-6 (Biosource). The reaction was based on the peroxidation of tetra-methyl-benzydine. The absorbance measurement was made using an automatic reader (Organon Teknika; Reader 200) at 450-nm wave length.

Statistical analysis

Data were expressed as mean±SD. One-way analysis of variance with the *post hoc* analysis was employed to compare the groups. $P<0.05$ was considered statistically significant.

RESULTS

Whole blood chemiluminescence (CL) intensity

CL intensity of peripheral blood neutrophils was significantly lower in Cn AP group after 5 and 9 h of observation than that in control animals. CL was reduced from 1 700 to 1 086 RLU/min ×2 000 PMN in AP group, and from 1 842 to 988 RLU/min ×2 000 PMN after 9 h. MoAb CD 11b given before AP induction did not significantly decrease CL intensity in group 3, but the CL intensity decreased from 1 086 to 1 421 after 5 h and from 988 to 1 408 RLU/2 000 PMN ×min after 9 h of AP induction. No important reduction of CL was observed in AP groups receiving LPS or LPS and MoAb CD 11b. MoAb CD 11b given to healthy animals did not change CL value significantly. LPS given to healthy animals significantly reduced CL from 1 842 to 976 RLU/2 000 PMN ×min after 9 h of experiment (Figure 1).

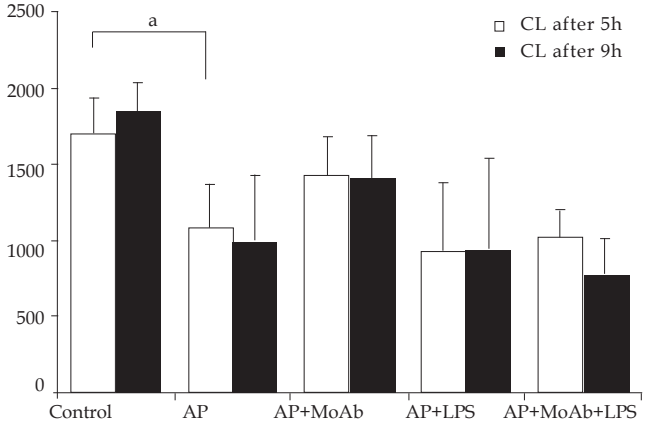

Figure 1 Whole blood CL. [a]$P<0.05$ *vs* control group.

WBC and polymorphonuclear cell (PMN) count

Induction of Cn AP resulted in a significant reduction of peripheral WBC from 5 120 in control group to 2 204 cells/μL in AP group after 5 h of observation. PMN count in peripheral blood reduced from 1 230 to 614 cells/μL during the same period of time. MoAb CD 11b given before AP induction significantly increase WBC/PMN count in peripheral blood (from 2 204/614 to 3 942/2315 after 5 h of observation and from 4 225/1 286 to 4 037/1 120 cells/μL after 9 h of observation). LPS in AP group diminished peripheral WBC count 5 h after AP, while ameliorated their count 9 h after AP induction. LPS given with MoAb CD 11b in AP resulted in a time-dependent decrease of WBC count. MoAb CD 11b given to healthy animals did not change WBC count significantly. LPS given to healthy animals gradually reduced WBC count (Table 1).

Oxidative stress parameters within pancreatic tissue

Sulfhydryl (-SH) compounds and malonyldialdehyde (MDA) concentration in pancreatic homogenate The concentration of (-SH) groups in pancreatic homogenate reduced from 60.3 nmol/mg protein in control group to 40.2 nmol/mg protein in AP group after 5 h of observation. Depletion of (-SH) compounds accompanied the elevation of MDA concentration in pancreatic homogenate from 0.21 nmol/mg protein in control group to 0.38 nmol/mg protein in AP group in the same period of time. After 9 h of observation concentration of (-SH) groups reduced from 64.7 nmol/mg in control group to 43.5 nmol/mg in AP group. LPS and MoAb CD 11b given together or separately in AP did not change the (-SH) group concentration in both periods of observation in comparison to AP group (group 2). MDA concentration in

[a]$P<0.05$ *vs* control group; [c]$P<0.05$ vs AP group.

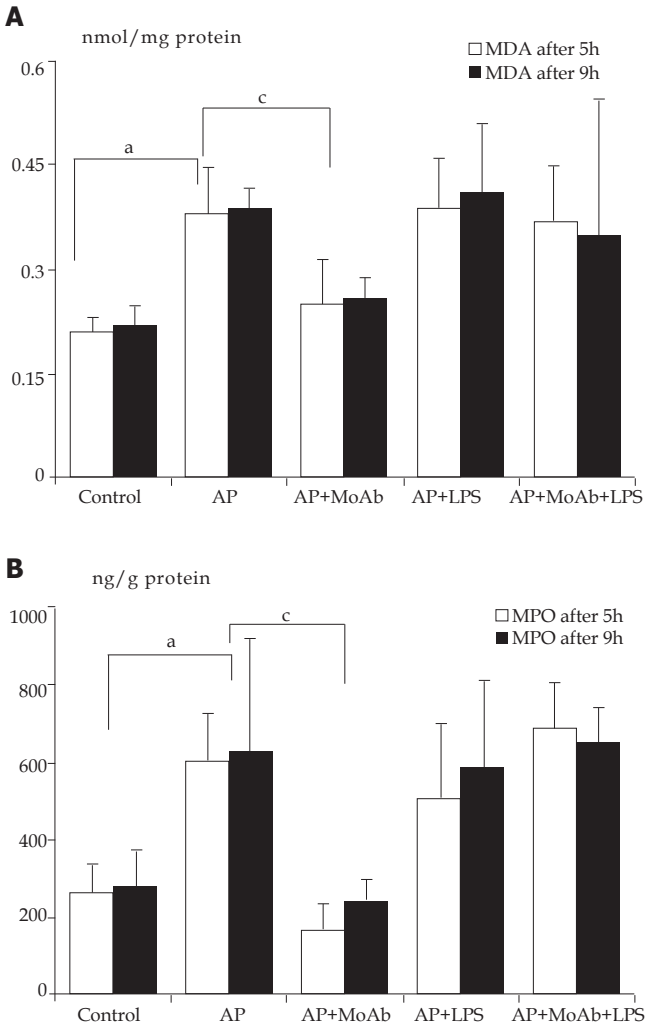

Figure 2 MDA **(A)** and MPO **(B)** level in pancreatic homogenate. [a]*P*<0.05 vs control group; [c]*P*<0.05 *vs* AP group. MDA: malonyldialdehyde; MPO: myeloperoxidase.

AP group treated with MoAb CD 11b reduced significantly from 0.38 to 0.25 after 5 h of observation and from 0.39 to 0.26 nmol/mg protein after 9 h of observation (Figure 2A and Table 2).

Myeloperoxidase (MPO) level in pancreatic homogenate

AP significantly increased pancreatic MPO concentration from 260 in control animals to 602 ng/g protein in AP group after 5 h of observatiozn and from 280 ng/g protein to 626 ng/g protein after 9 h of observation compared to control group. Adhesion molecule blockade with MoAb CD 11b, prior to AP induction, protected the pancreatic gland from MPO elevation after 5 h (from 602 to 168 ng/g protein) and 9 h of observation (626-246 ng/g protein, Figure 2B). LPS or LPS with MoAb CD 11b given to AP groups did not change the course of pancreatic MPO activity (data not shown).

α-Amylase and lipase plasma activity

Cn (15 μg/kg for 4 h) caused transient hyperamylasemia and hyperlipasemia in all AP groups after 5 h of observation (groups 2-5). Animals receiving MoAb CD 11b alone or with LPS in AP (groups 3 and 5) had significantly lower α-amylase and lipase activity after 9 h of experiment compared to other AP groups (groups 2 and 4, Table 3).

Table 3 Plasma α-amylase and lipase activity (U/L, mean±SD)

Polymorphonuclear elastase (PMN-E) plasma activity

Cn-induced AP caused an elevation of plasma PMN-E in all AP groups (groups 2-5). AP animals receiving MoAb CD 11b alone or with LPS had significantly lower PMN-E activity in both periods compared to other AP groups. LPS given to healthy animals elevated plasma PMN-E in a time-dependent manner (3 ng/mL after 5 h and 8 ng/mL after 9 h of observation, Figure 3).

Interleukin-6 plasma concentration

IL-6 was detectable in high concentration only after 5 h of observation in groups 4, 5, and 7 receiving LPS. AP did not correlate with IL-6 plasma level (Table 4).

Microscopic findings within pancreatic gland

Cn-induced AP caused marked pancreatic interstitial edema and acinar cell vacuolization, neutrophil infiltration and foci of necrosis. mAb given in AP reduced significantly interstitial neutrophil infiltration within the pancreas after 5 h of observation. LPS alone given to healthy animals resulted in a significant acceleration of pancreatic infiltration in comparison to control animals. Lipopolysaccharide given in AP did not result in significant

exacerbation of microscopic findings within the pancreatic gland (Table 5).

DISCUSSION

Cn-induced AP is a widely accepted model of acute edematous pancreatitis in rats. The intraperitoneal route of four doses of Cn (15 μg/kg) at 1-h intervals is as effective as the intravenous route[7-9]. Based on the morphologic criteria of acute edematous pancreatitis including acinar cell vacuolization, interlobar and interstitial edema, leukocyte infiltration and foci of acinar cell necrosis, all animals receiving Cn revealed a remarkable hyperamylasemia and hyperlipasemia at the presented study.

The time of observation was established on the basis of preliminary experiments, maximum effect of Cn and $T_{1/2}$ elimination of MoAb CD11b. The production of highly reactive molecules in PMN, as a result of respiratory burst activation, is an essential step in host defense against micro-organisms. The production of these highly reactive molecules can be measured by CL. CL is the process of light emission derived from the chemical reaction in which excited molecules decay the electronic basic state and emit photons. The CL intensity is directly proportional to cell activation and competence. Measurement of CL is a valuable and simple tool in studying PMN activity[10,11]. CL method is used in experimental and clinical medicine to evaluate the function of different cell types. CL detection is used as a label which allows signal amplification due to the enzyme-catalyzed reaction, thus obtaining a higher sensitivity[11]. The whole blood CL assay requires small blood samples and avoids artefacts due to cell isolation. The disadvantage of whole blood CL measurement is light extinguished by erythrocytes. Thus, highly diluted (final sample dilution 1:200) samples of whole blood are used. The diluted whole blood CL corresponds to individual neutrophil activity, because in this case interaction between cells and plasma is minimal[12].

Neutrophil infiltration is the universal feature of acute and chronic inflammatory process. The adhesion to vessel epithelium is followed by interstitial migration and action in the inflammatory focus[13-15]. This phenomenon is well documented. Neutrophil infiltration is the evidence of cell activation[16-20]. Experimental pancreatitis in the present study resulted in early PMN infiltration within the pancreatic gland. Whole blood white cells and neutrophils, in pancreatitis groups, reduced compared to control animals and also whole blood neutrophil CL reduced in AP groups during the same period of time. The phenomenon of low CL activity in pancreatitis group may be due to the migration of activated cells into interstitial space. After 9 h of experiment, the WBC and PMN count of AP group were similar to control one, because peripheral white cells perhaps were supplemented by immature cells from the bone marrow. However, the CL was still significantly lower, parallel to the results obtained in preliminary investigation[21]. The other possible explanation may be

the action of plasma anti-inflammatory agents (cytokines: IL-10, IL-11; soluble receptors: IL-1ra, p75 or prostanoids PGE_2 and PGI)[22].

Some data have confirmed that CL intensity is elevated in AP[23,24]. A different methodology of measurement may be the reason. The majority of investigators have analyzed the isolated neutrophils, whereas any isolation technique can change the neutrophil activity status[15,25]. On the other hand, the CL elevation may occur due to infection complicating AP clinical course.

CD11b is a well-known surface adhesion molecule of neutrophils. The use of mAb against CD11b results in competitive binding of specific adhesion molecules. Administration of MoAb CD11b in the present study significantly reduced the neutrophil infiltration within the pancreatic gland in AP animals. The pancreatic MPO tissue level was correlated to pancreatic neutrophil infiltration. Neutrophil depletion may protect pancreas from damage during AP as was observed by several other authors[16-18]. PAF antagonists reduce adhesion molecule expression and may prevent PMN infiltration of the pancreatic gland during AP. Another known pathomechanism of pancreatic damage during AP is oxidative stress. Several other authors documented that free radicals are generated in experimental AP[17-20]. Oxidative stress and lipid peroxidation debris elevated concentration was observed in animals with AP. MoAb CD11b administration during AP in the present study did not change the (-SH) groups concentration within the pancreatic gland, but the significant reduction of pancreatic MDA concentration was observed. The similar result was noticed in preliminary study group[21].

PMNs are the major source of oxygen radicals. Neutrophil NADPH-oxidase activation leads to the production of superoxide radicals during AP. Thus, MoAb 11b protects lipid peroxidation within pancreatic parenchyma in group 3. Our observations suggest that MoAb 11b induces neutrophil depletion in AP[16-20]. Substances which are thought to be effective in AP treatment (i.e., procaine, dextran, NO or heparin) reduce the aggregation of blood cells[14,26-29]. The role of ischemia-reperfusion and xanthine oxidase reaction is also the source of ROS in AP[26,29,30]. The aggregation of neutrophils and platelets may result in vessel obstruction. Kusterer *et al*[14] found that leukocyte adherence can be observed within the first 30 min from AP induction. The early neutrophil requirement determines the early adhesion molecule blockade necessity.

In our investigation, the IL-6 plasma concentration in AP groups was not elevated in both observation periods in comparison to control animals. IL-6 is a marker cytokine in severe human AP. Edematous AP may not demonstrate cytokinemia during the early stage of the disease[31-34]. On the other hand, some data suggest that IL-6 and other pro-inflammatory cytokines are elevated in Cn-induced AP[8,35]. The difference may be related to the different method of measurement. The biological method is not so specific compared to ELISA technique used in the present experiment[34]. On the other hand, IL-6 may be the marker of complications or SIRS but not AP "*per se*". Numerous data have confirmed the early inflammatory process in the pancreatic parenchyma in early AP. Local cytokine concentration is much higher than the peripheral one[33,36]. The liver plays a cardinal role in cytokine clearance in the early stage of the disease. These facts confirm the local characteristic of AP in the edematous form of the disease.

The pathogenesis of AP is the involvement of bacterial LPS. LPS is the universal stimulator of inflammatory process. Digestive tract bacteria are the major source of LPS in AP. Mucosal damage is the reason of LPS detection in early course of AP. The infected pancreatic necrosis foci are responsible for LPS detection in late stage of AP. In the present work, group 7 was the evidence of LPS action on healthy animals. The LPS administered intraperitoneally worked as a systemic inflammatory agent. There was the elevation in peripheral PMN count, pancreatic infiltration and high plasma IL-6 concentration. AP rats receiving LPS (group 4) revealed slight depletion in circulating neutrophils compared to AP group after 5 h of experiment. It could be the consequence of larger neutrophil sequestration. After 9 h of experiment, elevated peripheral blood PMN count was elevated, but the CL intensity was as low as that in AP group. We observed elevation of circulating PMN count in group 4 after 9 h of observation. But CL intensity was not elevated in the same period. The difference in PMN count after 5 and 9 h of experiment might be the result of bone marrow or spleen release. Edematous AP seems to be the local inflammatory process, whereas LPS administration resulted in huge WBC and PMN count elevation after 9 h of observation.

The data confirm the early neutrophil requirement in AP. But surprisingly, the activation of circulating PMN was lower in AP than in control animals. This phenomenon may result from activated cell sequestration within the inflamed pancreatic gland. The adhesion molecule CD11b blockade and neutrophil infiltration reduction can protect the pancreatic parenchyma from damage. The early PMN involvement of PMN makes it difficult to conduct comparable clinical trials. Most AP patients admitted to the hospital have at least few hours of history. The idea of immunomodulation seems to be attractive but needs further investigations.

In conclusion, the circulating neutrophil and activity are reduced in the early period of Cn-induced AP in rats. Adhesion molecule CD11b blockade can prevent pancreatic infiltration and oxidative stress within the pancreatic gland during AP in rats. Lipopolysaccharide septic challenge does not change the early course of Cn-induced AP in rats.

Abstract

AIM: To investigate the effect of six bile salts: glycocholate (GC), glycochenodeoxycholate (GCDC), glycodeoxycholate (GDC), taurocholate (TC), taurochenodeoxycholate (TCDC), taurodeoxycholate (TDC), and their mixture on cultured human normal esophageal mucosal epithelial cells.

METHODS: Human normal esophageal mucosal epithelial cells were cultured with serum-free keratinocyte medium. 3-[4,5-Dimethylthiaolyl]-2,5-diphenyl-tetrazolium bromide assay was applied to the detection of cell proliferation. Apoptotic morphology was observed by phase-contrast video microscopy and terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling (TUNEL) assay. Sub-G1 DNA fragmentations and early apoptotic cells were assayed by flow cytometry (FCM) with propidium iodide (PI) staining and annexin V-FITC conjugated with PI staining. Apoptotic DNA ladders on agarose gel electrophoresis were observed.

RESULTS: Except for GC, GCDC, GDC, TC, TCDC, TDC and their mixture could initiate growth inhibition of esophageal mucosal epithelial cells in a dose- and time-dependent manner. TUNEL and FCM assays demonstrated that the bile salts at 500 μmol/L and their mixture at 1 500 μmol/L induced apoptosis except for GC. The percentage of sub-G1 detected by FCM with PI staining was 83.5% in cells treated with 500 μmol/L TC for 2 h, and 19.8%, 20.4%, 25.6%, 13.5%, and 75.8% in cells treated with 500 μmol/L GCDC, TCDC, GDC, TDC, and 1 500 μmol/L mixture for 24 h, respectively, which were higher than that of the control (1.5%). The percentage was 1.4% in cells with 500 μmol/L GC for 24 h. DNA ladders on agarose gel electrophoresis were seen in cells treated with 500 μmol/L TC for 2 h and 1 500 μmol/L mixture for 24 h.

CONCLUSION: All GCDC, GDC, TC, TCDC, TDC and their mixture can inhibit growth and induce apoptosis of cultured human normal esophageal mucosal epithelial cells, but GC is well tolerated by the cells.

INTRODUCTION

Duodenogastroesophageal reflux (DGER) causes various gastroesophageal reflux diseases (GERD), and is associated with some complications of GERD, such as reflux esophagitis, Barrett's esophagus, and esophageal carcinoma. It is well known that the incidence of adenocarcinoma of the esophagogastric junction has been increasing during the past decade in Western countries[1]. It was also reported that the incidence of GERD is increasing in the developing countries, such as China[2]. The potential contribution of gastroduodenal components to the development of Barrett's esophagus remains unclear. But bile acids, presenting especially frequently in the refluxate of Barrett's esophagus patients, are likely to influence the development and persistence of metaplasia[3–5]. On the other hand, bile salts can enter mucosal cells in their non-ionized lipophilic form, and cause injuries to cell membranes and tight junctions, thus leading to cell necrosis[6]. It has been reported recently that bile acids upregulate the expression of COX-2 in Barrett's esophagus biopsy explant culture systems[7]. Overexpression of COX-2 inhibits apoptosis[8,9]. However, present studies about bile salt-caused cellular injury performed on hepatocytes[10] and colon cancer cell lines[11,12] showed that different bile salts can induce cell apoptosis. Direct oligomerization of the Fas receptor (CD95/Apo-1) has been suggested as the primary causative mechanism of bile salt-mediated hepatocyte apoptosis[13]. Therefore, it is necessary to investigate the injury mechanism of bile salts on human normal esophageal epithelial cells.

There are no studies about bile salt-induced apoptosis in normal human esophageal epithelial cells. In the present study, normal human esophageal epithelial cells were cultured successfully. We characterized the kinetics of different bile salt-inhibited growth and different bile salt-induced apoptosis in cultured normal human esophageal epithelial cells. The specificity of death induction by toxic bile salts was demonstrated.

MATERIALS AND METHODS

Materials

Serum-free keratinocyte medium for culture of human keratinocytes (K-SFM) and dispase were purchased from GIBCO. DMEM was from Hyclone and trypsin was from Sigma, fetal bovine serum (FBS) from Hangzhou Jiangbin Biotechnology Co., Ltd. Glycocholate (GC), glycochenodeoxycholate (GCDC), glycodeoxycholate (GDC), taurocholate (TC), taurochenodeoxycholate (TCDC), and taurodeoxycholate (TDC) were from Sigma. Terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling (TUNEL) kits were purchased from Beijing Zhongshan Golden Bridge Biotechnology Co., Ltd. Annexin V-FITC apoptosis detection kit I was from BD Biosciences.

Cell culture

Human normal esophageal epithelial cells, cultured from normal esophageal epithelium, were obtained from the resected esophagus of a patient suffering from esophageal carcinoma. Tissue for culture was selected just near the edge of the surgical resection specimens and far away from carcinoma lesions. Tissues were confirmed to contain no macroscopic tumor tissue or histologically detectable metaplastic cells or cancer cells[14,15]. Written informed consent was obtained from the patient for surgery and for the usage of his resected samples. Tunica mucosa was separated from the tissues with forceps, and cut into 0.2 cm × 0.5 cm fragments, then the pieces were transferred to a petri dish containing 25 U/mL dispase[16] and incubated for 18-24 h at 4 °C. Epithelial sheets were separated from the full-thickness mucosa with forceps, pooled in PBS containing 0.25% trypsin/0.02% EDTA, and incubated at 37 °C for 15-20 min with gentle pipetting to dissociate aid cells. Trypsin activity was terminated by the addition of DMEM with 10% FBS. The dissociated cells were collected and grown in K-SFM (pH 7.4) in a humidified atmosphere consisting of 50 mL/L CO_2/95% air at 37 °C. K-SFM contained 3 μL epidermal growth factor, and 0.438 g L-glutamine, 0.9 mL bovine pituitary extract per 500 mL, which was based, but modified on the media of esophageal cells[17] and skin keratinocytes[18,19]. The cells were subcultured and those in passages 3-6 were selected to be used in the study. In the following study, different bile salts were added into the K-SFM (pH 7.1-7.3).

Assessment of cell proliferation

3-[4,5-Dimethylthiaolyl]-2,5-diphenyl-tetrazolium bromide (MTT) assay was conducted to determine the cell proliferation. Cells were treated with six bile salts at the concentrations of 500, 250, and 50 μmol/L, and their mixture at the concentrations of 1 500, 1 000, 500, and 250 μmol/L at the ratio 2:2:1:2:2:1.

Cells were seeded on a 96-well plate (4-6×10^4 cells/well). After 24 h of seeding, cells were treated with different bile salts for 3 d and untreated cells served as a control. Prior to the determination, 10 μL of the 2.5 g/L stock solution of MTT was added to each well. After 4 h of incubation, the culture media were discarded followed by addition of 100 mL of DMSO to each well and vibration for 10 min. The absorbance (*A*) was measured at 492 nm with a microplate reader. The percentage of viable cells was calculated as follows: (*A* of experimental group/*A* of control group)×100%.

Flow cytometry by PI staining

Cells from the medium supernatant and adherent cells treated with bile salts were collected and pelleted at 1 200 U/min. The harvested cells were fixed with 1 mL of 75% cold ethanol at -20 °C for a night, and then washed with PBS. Cell pellets were incubated with 10 μg/mL RNAse and stained with 50 μg/mL propidium iodide (PI) for 30 min in the dark. Samples were analyzed using a FACSCalibur flow cytometer (FCM) with an excitation wavelength of 488 nm. The resulting histograms were analyzed by the program CELLQuest. A total of 2104 cells were detected by FCM in each of the samples.

Flow cytometry by annexin V-FITC conjugated with PI staining[20]

Cells from the medium supernatant and adherent cells treated with bile salts were collected and pelleted at 1 200 U/min. Pellets were washed twice with cold PBS and then resuspended in a binding buffer at a concentration of 1×10^6 cells/mL, and two volumes of the 100 μL solution (1×10^5 cells) were transferred to two 5-mL culture tubes. Five microliters of annexin V-FITC and 5 μL of PI were added into each of the 100 μL solution, and the cells were gently vortexed and incubated for 15 min at room temperature in the dark. The samples, to which 400 μL of 1× binding buffer was added, were analyzed by FACSCalibur FCM within 1 h. A total of 2×10^4 cells were detected by FCM in each of the samples.

TUNEL assay

Apoptosis of cells was analyzed using an *in situ* cell apoptosis detection kit based on the TUNEL technique. Cells were grown on chamber glass culture slides and treated with bile salts. To avoid adherence of the apoptotic cells, the slides were coated with poly-lysine. In brief, after the cells were treated with or without bile salts for the indicated time, they were fixed overnight in 100 g/L formaldehyde, then treated with proteinase K and H_2O_2, labeled with dUTP in a humidified box at 37 °C for 1 h. The cells without addition of TdT enzyme were used as a negative control. The positive cells/the total cells were calculated using an

image-analysis system. A mean of 20 adjacent fields, at a magnification of ×400, was analyzed for each section[21].

DNA fragmentation

A total of 10^6-10^7 cells treated with bile salts were collected and low molecular weight DNA was extracted using a cell apoptosis DNA ladder extraction kit (Beijing Dingguo Biotechnology Co., Ltd). Standard loading buffer was added, 20 μL DNA samples was run on an 1% agarose gel containing 0.1% ethidium bromide in TAE buffer (40 mmol/L Tris, 20 mmol/L sodium acetate, and 1 mmol/L EDTA, pH 8.0).

Statistical analysis

All values were expressed as mean±SD. Statistical differences between means were calculated by the Student's *t*-test and the χ^2 test. $P<0.05$ was considered statistically significant.

RESULTS

Human normal esophageal mucosal epithelial cells were cultured with serum-free keratinocyte medium successfully without contamination of fibroblasts, and could be passaged for more than 20 times without senescence. Cells in passages 3-6 were selected for the following research.

Inhibiting growth

The cell viability was determined by MTT assay (Figure 1). Except for GC, the other five bile salts and their mixture inhibited the growth of normal human esophageal mucosal epithelial cells in a dose- and time-dependent manner. The mixture at 1 500 μmol/L had an inhibitory effect of 79% on esophageal mucosal epithelial cells after 24-h treatment. Cell growth was suppressed by 96% after 24-h treatment with TC at 500 μmol/L, higher than that after being treated with other bile salts at the same concentration ($P<0.01$). Cell growth was suppressed by 51%, 58%, 65%, and 24% after 24-h treatment with GCDC, GDC, TCDC, and TDC at 500 μmol/L, respectively.

Apoptosis induced by the mixture of bile salts

The mixture of bile salts induced apoptosis of cultured human normal mucosal epithelial cells. Morphological criteria of cell apoptosis, such as membrane blebbing, cell shrinkage, and nuclear condensation, were assessed 3 h after the addition of the mixture at the concentrations of 1 500 μmol/L by phase-contrast video microscopy (Figure 2A). FCM assays with only PI staining showed that 27.6% and 75.8% of the cells treated with 1 500 μmol/L bile salt mixture for 12 and 24 h, respectively, were in sub-G1, which were higher than that of the control (1.5%, $P<0.01$), and 13.5% of the cells treated with 1 000 μmol/L bile salt mixture for 12 h were in sub-G1 (Figure 2B). Early apoptotic cells, detected by FCM with annexin-V conjugated with PI staining, reached 8.4%, 6 h after being treated with 1 500 μmol/L bile salt mixture, higher than that of the control (2.3%, $P<0.01$, Figure 2C). TUNEL assay also proved that bile salt mixture induced cell apoptosis, because the number of positively stained nuclei was (30±8)% in cells after being treated with 1 500 μmol/L bile salt mixture for 12 h, which was significantly higher than that of the control (3%±2%, $P<0.01$, Figure 2D). DNA laddering, a typical sign of apoptosis, was detectable after being treated with 1 500 μmol/L bile salt mixture for

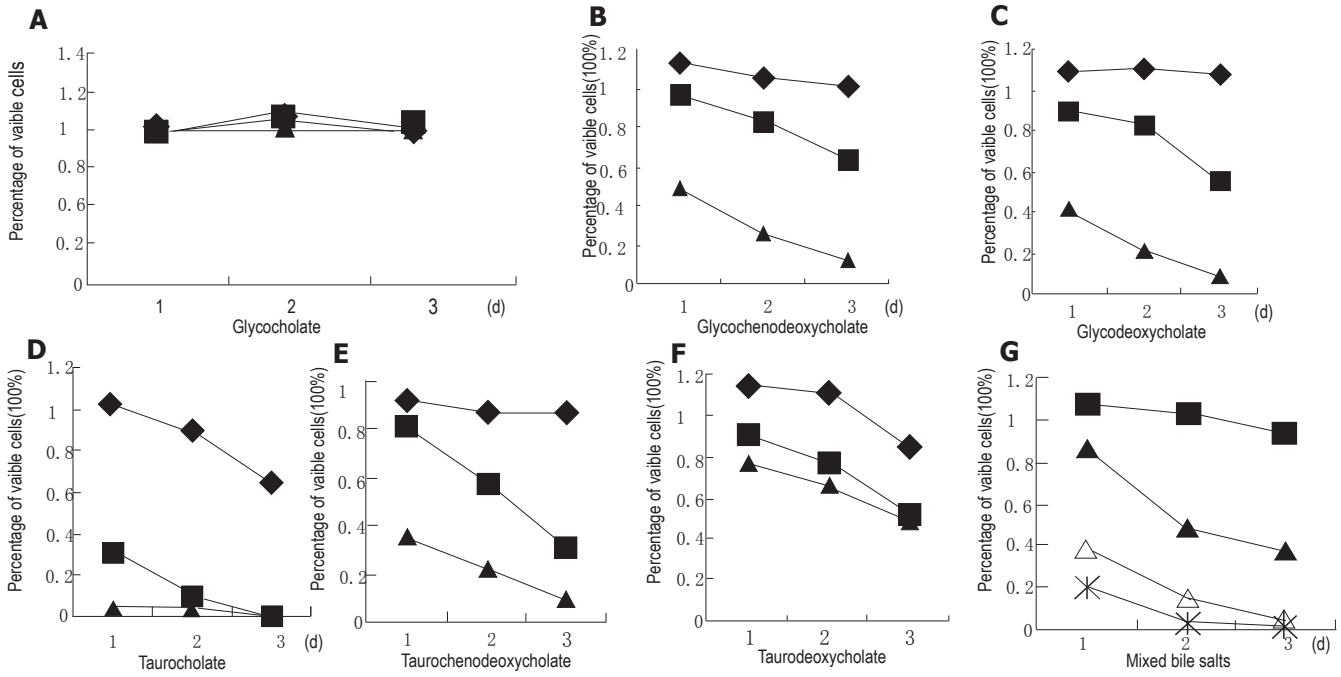

Figure 1 Effect of GC (**A**), GCDC (**B**), GDC (**C**), TC (**D**), TCDC (**E**), TDC (**F**), and mixture (**G**) on the growth of cultured normal human esophageal epithelial cells.◆(at the concentration 50 μmol/L), ■ (250 μmol/L), ▲ (500 μmol/L), △ (1 000 μmol/L), and * (1 500 μmol/L).

24 h (Figure 3).

Effect of GC, GCDC, TCDC, TC, GDC, and TDC

The assays of the six bile salts revealed that the other five bile salts, except for GC, induced apoptosis of esophageal mucosal epithelial cells. The percentages of sub-G1 in cells treated with different bile salts for 24 h are shown in Figure 4. The bile salts induced apoptosis in a time-dependent manner, 83.5% of cells were in sub-G1 treated with 500 μmol/L TC for 2 h, and the percentages were 19.8%, 20.4%, 25.6%, and 13.5% in cells treated with 500 μmol/L GCDC, TCDC, GDC, and TDC for 24 h, respectively. FCM with annexin-V conjugated with PI staining showed that early apoptotic cells reached 24.6% in cells treated with 500 μmol/L TC for 30 min, and 6.8%, 7.6%, 8.3%, and 5.1% in cells treated with 500 μmol/L GCDC, GDC, TCDC, and TDC for 6 h, respectively. They were all higher than that of the control (1.9%, $P<0.05$). The TUNEL assay also revealed that GC did not induce apoptosis, but the other five bile salts did. The positively stained nuclei were (53 ± 8)%, (2 ± 2)%, (20 ± 4)%, (18 ± 3)%, (24 ± 6)%, and (16 ± 3)% in cells treated with 500 μmol/L TC for only 1 h, and 500 μmol/L GC,

GCDC, GDC, TCDC, and TDC for 24 h, respectively. Except for GC, all the others were significantly higher than that of the control (3 ± 2)%, $P < 0.01$). DNA fragments were detected in cells treated with TC at 500 μmol/L for 2 h (Figure 3).

DISCUSSION

The injury mechanism of reflux duodenal components underlying DGER is still controversial. Bile acids and bile salts play a most important role[6]. But the causative mechanism of bile salts has not yet been elucidated in detail.

Bile acids constitute 67% of the normal bile, and are conjugated with glycine or taurine. The normal bile acids consist of 40% cholic acids, 40% chenodeoxycholic acid, and 20% deoxycholic acids, and a minor fraction of lithocholic acid and ursodeoxycholic acid[22]. In the present study, we investigated the effect of GC, GCDC, GDC, TC, TCDC, and TDC in esophageal epithelial cells. In order to speculate the effect of bile in the duodenoesophageal reflux *in vivo*, we also observed the effect of the mixture of these six bile salts. Moreover, the concentrations of bile salts in our study were selected from 25 to 500 μmol/L in the different bile salts and from 50 to 1 500 μmol/L in the mixture. This is because the total bile acid concentration in esophagus of patients suffering from reflux esophagitis is 0.89 mg/mL[23].

MTT assay in this report demonstrated that five bile salts and the mixture, except for GC, could inhibit the growth of cultured human normal esophageal mucosal epithelial cells in a dose- and time-dependent manner. The induced cell death was a major reason for the cell growth inhibition. GCDC, GDC, TC, TCDC, TDC and the mixture caused typical apoptotic alterations including the morphological changes assessed by phase-contrast video microscopy and TUNEL assay, positive cells stained with annexin-V assessed by FCM, apoptotic sub-G1 peak assessed by FCM with PI staining, and DNA fragmentation by agarose gel electrophoresis assay. However, these apoptosis changes were not seen in cells treated with GC.

Differences in the effect of bile salts on cultured normal human esophageal mucosal epithelial cells and hepatocytes and colon cancer cell line death were identified in this study. Studies performed on hepatocytes showed that glycine-conjugated bile acids, such as glycocholic and glycochenodeoxycholic acids, induce hepatocyte apoptosis *in vitro*[24], whereas taurine-conjugated bile acids, such as taurocholic and taurochenodeoxycholic acids, are well tolerated by hepatocytes[25,26]. Cell apoptosis is specifically induced by toxic (hydrophobic) bile salts such as deoxycholate and dihydroxy bile salt, whereas the conjugated bile salt GDC and the trihydroxy bile salt and its conjugate GC do not induce apoptosis of colorectal cancer cell lines[11], which are not in accordance with our results. Conversely, hepatocyte-cytotoxic glycine-conjugated bile acids such as GC, which induce hepatocyte apoptosis *in vitro*[24], do not induce apoptosis in esophageal mucosal epithelial cells. Whereas the hepatocyte-tolerated TC and TCDC[25,26] could induce apoptosis of esophageal mucosal epithelial cells. Our results also showed that TC was the most toxic to esophageal mucosal epithelial cells compared to the other four bile salts. We speculate that the mechanisms of the bile salts-induced apoptosis in human esophageal epithelial cells are different from those in hepatocytes or colorectal cancer cell lines. It was reported that direct oligomerization of the Fas receptor could be suggested as the primary causative mechanism of bile salt-mediated hepatocyte apoptosis[13,27,28]. Some hydrophobic bile acids such as TC could activate PI3K-dependent survival pathways, which prevent their otherwise inherent toxicity in hepatocytes[10,29]. As opposed to hepatocyte death mediated by bile acids, bile salt-induced apoptosis of human colon cancer cell lines involves the mitochondrial transmembrane potential but not the CD95 (Fas/Apo-1) receptor[11,30]. Studies are needed to gain further insight into the effect of bile salts on human esophageal mucosal epithelial cells.

In conclusion, GCDC, GDC, TC, TCDC, and TDC and their mixture inhibit the growth and induce apoptosis of cultured human normal esophageal mucosal epithelial cells in a dose- and time-dependent manner. But GC is not cytotoxic to the esophageal mucosal epithelial cells. Studies are needed to gain further insight into the effect of bile salts on human esophageal mucosal epithelial cells.

ACKNOWLEDGMENTS

Abstract

AIM: To explore the regularity of multi-meridians controlling a same viscus (MMCSV).

METHODS: The rabbit gastric ulcer model was established by ethanol intragastric instillation. Fifty-six rabbits were randomly divided into normal group, model group (MG), model plus acupuncture at Foot Yangming Meridian group (YMG), model plus acupuncture at Foot Taiyin Meridian group (TYG), model plus acupuncture at Foot Shaoyang Meridian group (SYG), model plus acupuncture at Foot Jueyin Meridian group (JYG), model plus acupuncture at Foot Taiyang Meridian group (TYMG), with eight rabbits in each group. Gastric mucosal nitric oxide (NO) and nitric oxide synthase (NOS) were assayed by the nitric acid reductase method, and prostaglandin E2 (PGE2) and epidermal growth factor (EGF) were measured by radioimmunoassay. The comprehensive effects were analyzed by weighing method.

RESULTS: Compared to MG, SYG, JYG and TYMG, the rabbits gastric mucosal injury index (GMII) reduced very significantly in YMG ($P<0.01$). Compared to MG, the GMII also reduced significantly in TYG ($P<0.05$). NO, NOS, PGE2 and EGF increased very significantly in YMG ($P<0.01$). The EGF in YMG also increased significantly than that in TYG compared to those in MG, SYG, JYG and TYMG ($P<0.05$). The PGE2 and EGF also increased very significantly in TYG than those in MG, JYG and TYMG ($P<0.01$). While compared to SYG, the NOS increased significantly in TYG ($P<0.05$). NOS was the highest in YMG ($P<0.01$), and was higher in TYG than in MG ($P<0.01$).

CONCLUSION: MMCSV is common. The Foot Yangming Meridian is most closely related to the stomach, followed by Foot Taiyin Meridian, Foot Shaoyang Meridian and Foot Jueyin Meridian. Foot Taiyang Meridian has no correlation with the stomach.

INTRODUCTION

According to the meridian theory, the meridians in the body connections are sealed. Qi and blood flow recurrently, the meridians connect with each other directly or indirectly. Therefore, it is the underlying theory of multi-meridians controlling a same viscus (MMCSV)[1]. Previous studies are focused on one meridian controlling one viscus[2-4], while MMCSV is seldom referred to. In general, NO, NOS, PGE2 and EGF are regarded as protective factors involved in repairing gastric mucosal injury. Based on our previous research on MMCSV[5,6], in this study, we focused on the Foot Yangming Meridian (FYM) controlling the stomach. The Foot Shaoyang Meridian (FSY), Foot Jueyin Meridian (FJY), Foot Taiyin Meridian (FTY), as well as Foot Taiyang Meridian (FTYM) were selected to explore the regularity of MMCSV and meridian speciality for the Stomach.

MATERIALS AND METHODS

Animals

Fifty-six New Zealand 3-4 mo old pure rabbits, weighing 1.5-2.5 kg, were supplied by the Experimental Animal Center of Hunan College of Traditional Chinese Medicine (Permission number: 20030316).

Animal model and groups

The rabbit gastric ulcer model was established by ethanol intragastric instillation[7]. Fifty-six rabbits were divided into normal group (NG), model group (MG), model plus acupuncture at Foot Yangming Meridian group (YMG), model plus acupuncture at Foot Taiyin Meridian group (TYG), model plus acupuncture at Foot Shaoyang Meridian group (SYG), model plus acupuncture at Foot

Jueyin Meridian group (JYG), and model plus acupuncture at Foot Taiyang Meridian group (TYMG), with eight rabbits in each group. All the animals were fasted for 48 h before ulcer model-making. Rabbits in NG were given normal saline by intragastric instillation (2.35 mL/kg). Rabbits in other groups were given ethanol intragastrically (2.35 mL/kg). Twenty-four hours later, all animals were allowed free access to normal food. Except for rabbits in NG and MG groups, the animals received acupuncture therapy.

Acupuncture method

Acupoints were selected based on the (Modern Acupuncturolgy)[8] and anthropomorphic method[6] as well as on our previous research results[5,6]. In the FYM, Neiting (ST 44), Jiexi (ST 41), Zusanli (ST36), Liangqiu (ST 34), Tianshu (ST 25) and Liangmen (ST 21) were selected for gastric ulcer therapy. The other acupoints of different meridians were almost in the same horizontal level to the FYM. In the FSY, Jiaxi (GB 43), Qiuxu (GB 40), Yanglingquan (GB 34), Xiyangguan (GB 33), Daimai (GB 26) and Jingmen (GB 25) were selected. In the FJY, the selected acupoints were Xingjian (LR 2), Zhongfeng (LR 4), Xiguan (LR 7), Yinbao (LR 9), Zhangmen (LR 13) and Qimen (LR 14). In the FTY, Dadu (SP 2), Shangqiu (SP 5), Yinlingquan (SP 9), Xuehai (SP 10), Dahen (SP 15) and Fu'ai (SP 16) were selected. In the FTYM, Tonggu (BL 66), Shenmai (BL 62), Chengjin (BL 56), Fuxi (BL 38), Beixiadian and Beishangdian were selected.

Consecutive acupoint-stimulation in one meridian was applied by Xuanshou Meridian Dredging Apparatus (China Peace Economy Technology Consultation Company)[6]. Parameters for manipulation were as follows: single way running, six steps, at 0.5 s intervals; double direction narrow impulse and consecutive wave, 50 Hz, 0.5 ms wave width. The apparatus output was connected to the needle (diameter 0.25 mm, length 25 mm) which was inserted into the acupoints. Just mimicking human's obeying meridian to propaganda sense, the excited order was from low leg to trunk, and the output strength was controlled within 2-3 intensity. Acupuncture stimulation was manipulated once a day, for seven days, 30 s each time. All the selected acupoints were in the left lateral body throughout the experiment.

Determination of gastric mucosal injury index (GMII)

After seven days, the animals were killed with their stomachs removed and opened along the greater curvature. The content in the stomach was washed with running water, mucus attached to gastric mucosa was removed by the brusher. Then the mucosa was extended in a flat plate. GMII was calculated by the Guth method[9] with a general magnifier.

Determination of NO, NOS, PGE2 and EGF in gastric mucosa

NO and NOS kit were supplied by Nanjing Jincheng Bioengineering Institute. EGF radioimmunoassay kit was provided by Beijing Huaying Radioimmunoassay Institute. [3H]PGE2 radioimmunoassay kit was obtained from Beijing Furui Bioengineer Co. Gastric mucosal NO and NOS were assayed by the nitric acid reductase method, and PGE2 and EGF were measured by radioimmunoassay. All assays were carried out according to the manufacturer's instructions.

Statistical analysis

All the results were expressed as mean±SD. Comparison between groups was made using one-way analysis of variance (ANOVA). Differences were considered statistically significant, if the *P* value was less than 0.05. Software SPSS 10.0 was used in all statistical tests.

RESULTS

Gastric mucosal injury condition and index (Table1)

There were some dots and strips of injury under the magnifier. The highest GMII was observed in MG and the lowest GMII in NG. There was a very significant difference between them ($P<0.01$), demonstrating that the ulcer model was successful. Compared to MG, GMII in YMG and TYG reduced significantly ($P<0.05$ or $P<0.01$), and the GMII in YMG was better than that in TYG. While the GMII in SYG, JYG and TYMG had no significant difference compared to that in MG ($P>0.05$). The GMII in YMG had a significant difference compared to that in SYG, JYG and TYMG ($P<0.01$). The GMII in TYG also had a significant difference compared to that in TYGM ($P<0.05$).

Table 1 Gastric mucosal injury index comparison (mean±SD)

Groups	*n*	GMII
NG	8	8.50±2.98[b]

YMG	8	10.88±3.23[b]
SYG	8	19.38±3.66[d]
JYG	8	20.38±4.03[d]
TYG	8	14.62±3.20[a]
TYMG	8	24.13±1.64[dc]

[a]$P<0.05$, [b]$P<0.01$ *vs* MG; [d]$P<0.01$ *vs* YMG; [c]$P<0.05$, [f]$P<0.01$ *vs* TYG.

NO and NOS changes in gastric mucosa (Table 2)

Gastric mucosal NO and NOS in NG were both higher than those in MG ($P<0.01$). The highest NO content was found in YMG, than TYG, JYG and TYMG, while the lowest NO content was observed in SYG. The NO was higher in YMG than in MG, SYG, JYG and TYMG, and there was a very significant difference between YMG and MG, SYG, JYG, TYMG, respectively ($P<0.01$). However, no significant difference was found between YMG and TYG ($P>0.05$). The highest NOS content was observed in YMG, the lowest NOS content was found in TYMG. The NOS was higher in YMG and TYG than in

Table 2 NO and NOS changes in gastric mucosa (mean ± SD)

Groups	*n*	NO (μ mot/gprot)	NOS (u/mgprot)
NG	8	1.48±0.54[b]	2081.4±482.6[b]

Summarization of effects of acupuncture at different meridian acupoints (Table 4)

To compare the protective effects of acupuncture at different meridian acupoints on the gastric mucosal injury, we ranked the intensity of effects. From the summarization in Table 4, we could see the comprehensive protection of acupuncture therapy against gastric mucosal injury of experimental rabbits was the best in YMG, followed by TYG, JYG or SYG, and TYMG.

Comprehensive protective effects of acupuncture at different meridian acupoints in gastric mucosa (Table 5)

In order to compare the comprehensive effects of acupuncture at different meridian acupoints on gastric mucosa, weight method was used to analyze the differences.

According to the importance of gastric mucosal protective factors including NO, NOS, PGE2 and EGF, the whole weight was set at 10, NO at 2.5, NOS at 1.25, EGF at 3.75 and PGE2 at 2.5. The comprehensive effect value (CEV) was made in the following process: NO, NOS, EGF and PGE2 content were multiplied with their own weight respectively, then added. ANOVA was used to compare the difference in the acupuncture therapy groups. The highest CEV was found in YMG followed by TYG, SYG, JYG, TYMG, and MG. The statistics showed that there was a very significant difference in CEV between YMG and other groups (*P*<0.01). In addition, CEV was also higher in TYG than in SYG, JYG, TYMG, and MG, respectively (*P*< 0.01).

Table 4 Summarization of effects on items after acupuncture therapy

Items	Order sequence				
	1	2	3	4	5
GMII	YMG	TYG	SYG	JYG	TYMG
NO	YMG	TYG	JYG	TYMG	SYG
NOS	YMG	TYG	SYG	JYG	TYMG
EGF	YMG	SYG	JYG	TYG	TYMG
PGE2	YMG	TYG	SYG	TYMG	JYG

Order sequence refers to the effect intensity from strong to weak.

Table 5 Comprehensive protective effects of different meridian acupuncture on gastric mucosa (mean±SD)

Groups	*n*	WEV

[b]*P* <0.01 *vs* MG; [d]*P* <0.01 *vs* YMG; [f]*P* <0.01 *vs* TYG.

DISCUSSION

Excessive ethanol ingestion can result in gastritis characterized by mucosal edema, subepithelial hemorrhages, cellular exfoliation and inflammatory cell infiltration[6]. Ethanol intragastric instillation breaks the gastric mucosal barrier and increases histamine release and pepsinogen output, thus leading to the damage in the gastric mucosa at least in part via hyperosmolarity[7]. In the present study, after ethanol intragastric instillation, the highest GMII was found in MG, demonstrating that the model of gastric mucosal injury is reliable. It is known that neuronal modulating processes such as release of vasoactive mediators are crucial for the gastric mucosa to resist the continual onslaught of aggressive agents[8,9]. Endothelial cells also release a highly labile humoral vasodilator

substance, now known as NO that mediates the vascular relaxation induced by vagal stimulation[10]. NO could protect the gastric mucosa by increasing gastric mucosal blood flow[11,12], suggesting that gastroprotection can be induced by low level of central vagal stimulation and the consequent release of NO, and that NO plays a role also in ulcer healing by stimulating the formation of growth factors, such as epithelial proliferation and angiogenesis[13]. NOS is a limited enzyme for NO synthesis. Studies have shown that chronic nitric oxide synthase inhibitor L-NAME enhances ulcerogenesis by decreasing mucosal resistance due to reduced mucosal blood perfusion[14–16]. When the specific iNOS inhibitor L-N6-(1-iminoethyl) lysine (L-NIL) is given intravenously to rats, the blood flow increase in response to luminal acid is attenuated[17]. Therefore, NOS is important for maintaining mucosal resistance through increasing the gastric mucosal blood flow. PGE2 is also involved in protecting gastric mucosa. PGE2 inhibits ethanol-induced apoptosis and increases cell viability in a dose-dependent manner in primary cultures of guinea pig gastric mucosal cells. PGE2 also inhibits hydrogen peroxide-induced apoptosis[18]. EGF is also a key to the protection against mucosal injury. Since acute gastric lesions are induced by cold-restraint stress, the ulcer score is significantly reduced after intraperitoneal and intragastric administration of EGF solution[19]. When EGF is added to primary monolayer cultures of guinea pig gastric mucous cells, the cytoprotection induced by EGF can be demonstrated. Mucin biosynthesis and PGE2 release are both significantly increased by EGF[20]. EGF promotes gastric mucosal restitution by activating Na^+/H^+ exchange of epithelial cells[21]. In the present study, the comprehensive effects of different meridian acupuncture on gastric mucosal protective factors including NO, NOS, PGE2 and EGF, the relationship between meridian and viscus were revealed.

MMCSV is common in the theory of meridian and viscus correlation, manifested in two aspects. On the one hand, multiple meridians have different connections with the same viscus, and the function of meridians is complex. For example, there are five meridians connecting the stomach, namely Hand Taiyin Meridian (HTY), FTY, FJY, Hand Taiyang Meridian (HTY), FYM. On the other hand, stimulating different meridian acupoints could regulate the same viscus physical function, which is the underlying theory for treating diseases. For example, moxibustion at Neiguan (PC 6) of Hand Jueyin Meridian, Yangfu (GB 38) of FSY, as well as Shangqiu (SP 5) of FTY, can be selected for stomachache therapy.

Though MMCSV is common, the meridians do have some speciality. It could be explained by the following two reasons. One is that since different meridian acupoints have a relative speciality, and meridian is composed of acupoints, it is no doubt that the meridian has some speciality. In addition, the meridian and viscus match theory also can explain the meridian's speciality. Since FYM is the responsible meridian to stomach, acupuncture at FYM could regulate the stomach physical function and improve pathological conditions. According to viscus-viscus match theory, the stomach is matched with the spleen; since the FTY is responsible for the spleen, acupuncture at FTY also has good effects on the stomach function regulation. Gallbladder's bile secretion from gallbladder could help the stomach to digest, while the secretion depends on the liver dredging function. Since the FSY is responsible for gallbladder, and FJY for the liver, acupuncture at FSY and FJY also has some effects on the stomach function regulation. In the present study, FYM had the best effect on stomach function regulation, followed by FTY, FSY and FJY, while the FTYM had no effect.

MMCSV is the unification for universality and speciality of meridian and viscus theory. In the present study, the protective effects of acupuncture at different meridian acupoints on gastric mucosa were various. For example, except for acupuncture at FTY, GMII decreased in all acupuncture therapy groups, while acupuncture at FYM, FTY and FSY, increased the NOS, suggesting that MMCSV is common. Acupuncture at FYM achieved the best intensity and width of protective effects on gastric mucosa. FJY had almost no effects on NO, NOS, PGE2, and EGF. FTYM has no significant effects on NO, NOS, PGE2, and EGF.

In summary, the FYM is most closely related to the stomach, followed by FTY, FSY, FJY, while FTYM has no correlation with the stomach.

Abstract

AIM: To detect the effects of acid fibroblast growth factor (aFGF) on apoptosis and proliferation of intestinal epithelial cells in differentiation or proliferation status to explore the protective mechanisms of aFGF.

METHODS: Wistar rats were randomly divided into sham-operated control group (C, $n = 6$), intestinal ischemia group (I, $n = 6$), aFGF treatment group (A, $n = 48$) and intestinal ischemia-reperfusion group (R, $n = 48$). Apoptosis of intestinal mucosal cells was determined with terminal deoxynucleotidyl transferase-mediated dUTP-biotin nick-end labeling (TUNEL) technique. Proliferating cell nuclear antigen (PCNA) protein expression and distribution were detected with immunohistochemical method. Plasma levels of D-lactate were determined with modified Brandts method.

RESULTS: In A group, administration of exogenous aFGF could improve intestinal histological structure and decrease plasma D-lactate levels at 2-12 h after the reperfusion compared with R group. The apoptotic rates and PCNA protein expressions were not increased until 2 h after reperfusion and were maximal at 12 h. After reperfusion for 2-12 h, the apoptotic rates were gradually augmented along the length of jejunal crypt-villus units. Administration of aFGF could significantly reduce the apoptotic response at 2-12 h after reperfusion ($P<0.05$). Apoptosis rates in villus and crypt epithelial cells in A group at 12 h after reperfusion were (62.5±5.5)% and (73.2±18.6)% of those in R group, respectively. Treatment of aFGF could apparently induce protein expression of PCNA in intestinal mucosal cells of A group compared with R group during 2-12 h after reperfusion ($P<0.05$). There were approximately 1.3- and 1.5-times increments of PCNA expression levels in villus and crypt cells in A group at 12 h after reperfusion compared with R group, respectively.

CONCLUSION: Intestinal I/R insult could lead to histological structure change and apoptotic rate increment. The protective effects of aFGF against ischemia/reperfusion in rat intestinal mucosa might be partially due to its ability to inhibit ischemia/reperfusion-induced apoptosis and to promote cell proliferation of crypt cells and villus epithelial cells.

INTRODUCTION

An ischemic insult decreases oxygen and nutrient delivery and causes post mitotic cell lineages in the brain, myocardium, muscle and adrenal cortex to undergo apoptosis. Paradoxically, the introduction of oxygen during reperfusion of ischemic tissues exacerbates the damage of these tissues[1-5]. These tissues do not allow evaluation of the effects of proliferative status or state of differentiation on the apoptotic response to this inductive stimulus. The intestinal epithelium provides an excellent system for such an analysis. Renewal of intestinal epithelium takes place continuously in anatomically distinct crypt-villus units. Proliferation is restricted to mucosal invaginations known as crypts. All epithelial cells in each crypt are derived from an uncertain number of multipotent stem cells located at or near the base of the crypt[6-8]. These crypt stem cells divided to produce daughter stem cells as well as more rapidly replicating transit cells, which in turn undergo 4-6 rapid cell divisions in the proliferative zone located in the lower half of each crypt[9,10]. The small intestine is highly sensitive to ischemia-reperfusion (I/R). It has been demonstrated that occlusion of the superior mesenteric artery (SMA) followed by reperfusion can cause apoptosis in the intestinal epithelium[11].

Acid fibroblast growth factor (aFGF) is a mitogen *in vitro* for most of the ectodermal- and mesodermal-derived cell lines. In addition, this factor shows a wide range of endocrine-like activities[12,13]. As a multiple function growth factor, aFGF is involved in embryo development and tissue repair[14-16]. However, the protective mechanisms of aFGF on intestinal I/R injury remain unknown. Given the anatomically well-defined stratification of proliferation and differentiation programs along its crypt-villus axis, the self-renewing intestinal epithelium provides an opportunity to consider, whether aFGF protects intestinal mucosa from I/R injury through inducing proliferation of cells located in crypt or inhibiting apoptosis of epithelial cells distributed in villus or adopting both these two procedures.

In the present article, we have clarified the mechanism of aFGF protection following I/R injury in the small intestinal mucosa of rats by evaluating changes in apoptosis of epithelial cells along gut crypt-villus axis. We evaluated the expression of proliferating cell nuclear antigen (PCNA). The expressive level of this protein is frequently used to evaluate the regenerative ability of epithelial tissue[17]. We also estimated the integrity of small intestinal mucosa by measuring the levels of plasma D-lactate. This study will lead to a better understanding of the repair mechanisms of small intestinal mucosa induced by aFGF treatment after I/R injury.

MATERIALS AND METHODS

Animal model and experimental design

Healthy male Wistar rats weighing 220 ± 20 g (Animal Centre, Academy of Military Medical Science, Beijing) were used in this study. Animals were housed in wire-bottomed cages placed in a room illuminated from 08:00 am to 08:00 pm (12:12 h light-dark cycle) and maintained at 21±1 °C. Rats were allowed to access water and chow *ad libitum*. The animals were anesthetized by using 3% sodium pentobarbital (40 mg/kg), and a laparotomy was performed. The SMA was identified and freed by blunt dissection. A micro-bulldog clamp was placed at the root of SMA to cause complete cessation of blood flow for 45 min, and thereafter the clamp was loosened to form reperfusion injury. The animals were randomly divided into sham-operated control group (C, $n = 6$), intestinal ischemia group (I, $n = 6$), aFGF treatment group (A) and intestinal ischemia-reperfusion group (R). According to the different periods after reperfusion, groups R and A were further divided into 0.25, 0.5, 1, 2, 6, 12, 24 and 48 h subgroups, respectively ($n = 6$, each subgroup). In group I, the animals were killed after 45 min of SMA occlusion, while in groups R and A, the rats sustained 45 min of SMA occlusion and were treated with 0.15 mL normal saline and 0.15 mL saline plus 20 μg/kg aFGF (R&D Systems, Inc.) injected from tail vein, respectively, then sustained 0.25, 0.5, 1, 2, 6, 12, 24 and 48 h of reperfusion, respectively. In C group, SMA was separated, but without occlusion, and the samples were taken after exposure of SMA for 45 min. In groups R and A, rats were killed at different time points after reperfusion. Blood samples and intestinal tissue biopsies were taken. Blood samples were centrifuged and serum was frozen to measure plasma levels of D-lactate. Tissue biopsies were fixed with 10% neutral buffered formalin for detection of intestinal epithelial apoptosis, and protein expression of PCNA.

In situ detection of cell death

The apoptotic cells in intestinal tissues were detected with the terminal deoxynucleotidyl transferase (TdT)-mediated dUTP-biotin nick-end labeling (TUNEL) method. Specimens were dewaxed and immersed in phosphate-buffered saline containing 0.3% hydrogen peroxide for 10 min at room temperature and then incubated with 20 μg/mL proteinase K for 15 min. Seventy-five microliters of the equilibration buffer was applied directly onto the specimens for 10 min at room temperature, followed by 55 μL of TdT enzyme and incubation, which were then incubated at 37 ℃ for 1 h. The reaction was terminated by transferring the slides to prewarmed stop/wash buffer for 30 min at 37 ℃. The specimens were covered with a few drops of rabbit serum and incubated for 20 min at room temperature and then covered with 55 μL of anti-digoxigenin peroxidase and incubated for 30 min at room temperature. Specimens were then soaked in Tris buffer containing 0.02% diaminobenzidine and 0.02% hydrogen peroxide for 1 min to achieve color development. Finally, the specimens were counterstained by immersion in hematoxylin. The cells with clear nuclear labeling were defined as TUNEL-positive cells. The results of positive cells and their distribution were observed under 400 times microscope. Sixty intestinal villi and crypts per time point were required for counting, and then the apoptotic ratios were calculated and analyzed, respectively.

Immunohistochemistry

Immunostaining for PCNA was performed in paraffin sections with a high-temperature antigen-unmasking method in citrate buffer and ABC peroxidase, using monoclonal mouse antibody (Zymed Corp., ZM-0213) against antigen (1 ∶ 100 in PBS). Tissues were fixed overnight in 4% paraformaldehyde, dehydrated, and embedded in paraffin. Sections of 5 μm thickness were deparaffinized and rehydrated using graded alcohol concentrations. Antigen retrieval was performed by incubation in 100 mmol/L sodium citrate, pH 6.0, at 90 ℃ for 20 min. Then, sections were blocked with 5% normal swine serum in PBS for 30 min at 25 ℃, followed by incubation with primary antibodies at a concentration of 5 μg/mL overnight at 4 ℃. Control slides were incubated with PBS without primary antibodies. Tissues sections were then incubated for 60 min with biotinylated secondary antibody. After washing in PBS, the sections were exposed to acidin-biotin complex for 60 min. The sections were reacted with 0.05% (wt/vol) DAB in 50mol/L Tris-HCl (pH 7.4) with 0.1% (vol/vol) hydrogen peroxide for 5 min and counterstained with hematoxylin. The results of positive staining cells and their distribution were observed under 400 times microscope. Sixty intestinal villi and crypts per time point were required for counting,

and then the ratio of positive cells were calculated and analyzed, respectively.

Measurement of plasma D-lactate

The levels of plasma D-lactate were measured with modified Brandts method[18,19]. Briefly, heparinized blood was centrifuged at 3 200 r/min for 10 min and 2 mL of the plasma was deproteinized with 0.2 mL perchloric acid (1/10 vol), mixed and kept in an ice bath for 10 min. The denatured protein solution was centrifuged at 3 200 r/min for 10 min and the supernatant was removed. To 1.4 mL of supernatant, 0.12 mL KON was added and they were mixed for 20 s. Precipitant $KCLO_4$ was removed by centrifugation at 3 200 r/min for 10 min. The supernatant and neutralized-protein-free plasma were used to measure the absorbency at 304 nm. Plasma D-lactate concentrations were expressed as μg/mL.

Statistical analysis

All values were expressed as mean±SD. Differences in mean values were compared using SPSS 11.0 by one-way ANOVA and Student-Newman-Keul (SNK) test. $P<0.05$ as considered as statistically significant.

RESULTS

Change of cellular apoptotic rates

After the SMA was clamped near its origin from the aorta, the damage to the small intestine in the 45-min ischemia group was small. At 2 h after reperfusion, the partial loss of the mucosa could be observed. During 6-12 h after reperfusion, the damage of intestinal epithelial cells, hemorrhage and necrosis could be found, the crypt-villus structure was seriously spoiled. In the period of 24-48 h after reperfusion, the mucosal integrity was partially restored. The protective function of aFGF on intestinal mucosa was the most effective during 2-12 h after reperfusion. The structures of crypt and villus were both guarded, with less damage of the intestinal mucosa (Figure 1). Apoptosis was measured and quantified by TUNEL assay in serial sections prepared from the middle quarter of the small intestine (jejunum). The time animals were killed after a 45 min SMA occlusion followed by reperfusion was varied to further define the apoptotic response. Statistically significant increases in TUNEL-positive cells were not detectable until 2 h after reperfusion and were maximal at 12 h. The augmentation of the cellular apoptotic rates was evident along the length of jejunal crypt-villus units after reperfusion for 2-12 h; i.e., the average increase was 2.3 times for villi [84.0±6.2 (12 h after reperfusion) *vs* 37.3±6.6 (C group $P<0.05$)] and 1.9 times for crypts [28.2±3.9 (12 h after reperfusion) *vs* 14.4±3.8 (C group $P<0.05$; Table 1)]. Highest levels of apoptosis were noted in the upper quarter of the villus. In no matter villus and crypt, the apoptotic rates were restored to the levels of C group after reperfusion for 24 and 48 h. Administration of aFGF could significantly reduce the apoptotic response observed 2-12 h after reperfusion ($P<0.05$). Apoptosis rates in villus and crypt epithelial cells of A group at 12 h after reperfusion were (62.5±5.5)% and (73.2±18.6)% of those in their littermates of R group, respectively (Table 1, Figure 2).

Expression characteristics of PCNA protein

Quantitative immunohistochemical results for PCNA protein were evaluated in Table 2 and Figure 3. PCNA was weakly expressed in the sham-operated intestinal tissues and ischemic tissues, with positive particles mostly

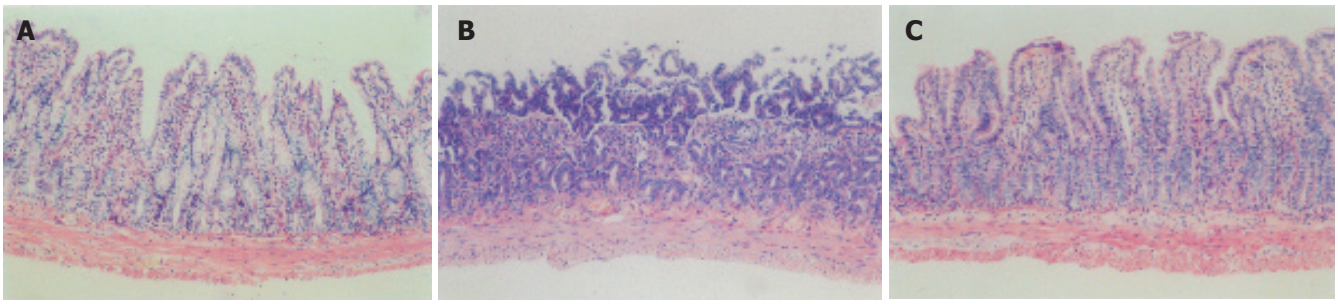

Figure 1 The histological structure of intestine in sham-operated control group **(A)**, 6 h after ischemia-reperfusion in R group **(B)** and 6 h after ischemia-reperfusion in A group **(C)** (100×). Anatomic structures of villi and crypts of intestine in control group were intact. In R group, at 6 h after reperfusion, the crypt-villus structure was seriously spoiled, accompanied by inflammatory cells infiltrating into the intestinal wall. In A group, the structures of crypt and villi were both protected, with less damage of the intestinal mucosa.

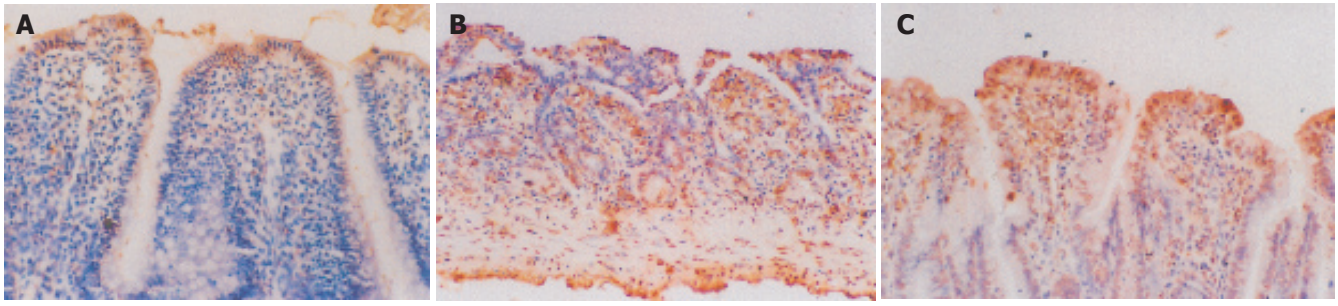

Figure 2 The cellular apoptotic rates in sham-operated control group **(A)**, 6 h after ischemia-reperfusion in R group **(B)** and 6 h after ischemia-reperfusion in A group **(C)** (200×). Cellular apoptotic rates were less in sham-operated control group and were significantly increased in villi and crypts at 6 h after reperfusion. The augmentation of the cellular apoptotic rates was evident along the length of jejunal crypt-villus units. The cellular apoptotic rates both decreased remarkably at 6 h after reperfusion in villi and crypts of A group *vs* those of R group.

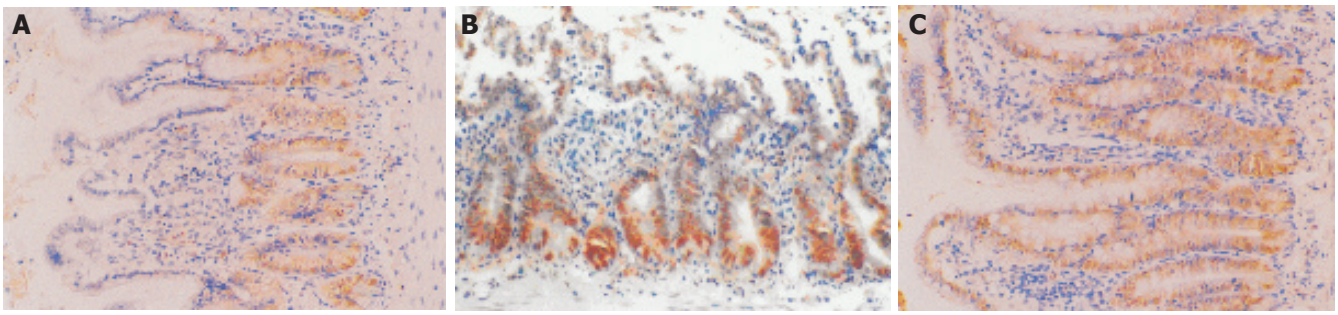

Figure 3 The expression of PCNA protein in sham-operated control group **(A)**, 6 h after ischemia-reperfusion in R group **(B)** and 6 h after ischemia-reperfusion in A group **(C)** (200×). PCNA was weakly expressed in sham-operated control group, with positive particles mostly distributing in the nuclei of the lower third of crypt cells. Protein contents of PCNA were significantly increased in villi and crypts at 6 h after reperfusion compared with control group. The contents of PCNA increased remarkably in villi and crypts at 6 h after reperfusion in A group *vs* R group.

Groups	Villus		Crypt	
	R group	A group	R group	A group
C group	8.5±5.0	8.5±5.0	31.5±5.2	31.5±5.2
I group	8.8±5.3	8.8±5.3	33.3±4.1	33.3±4.1
0.25 h after reperfusion	10.5±5.1	10.7±4.9	39.7±5.4	36.0±5.6
0.5 h after reperfusion	11.5±3.8	14.7±4.3	41.0±4.7[a]	43.8±5.2[a]
1 h after reperfusion	12.3±6.2	11.3±5.4	44.3±4.6[a]	51.5±6.0[a]
2 h after reperfusion	16.7±4.5[a]	23.3±5.1[ac]	48.2±5.3[a]	67.8±5.3[ac]
6 h after reperfusion	18.2±3.5[a]	25.0±6.4[ac]	47.3±5.5[a]	76.0±3.8[ac]
12 h after reperfusion	19.0±5.4[a]	25.3±4.5[ac]	52.1±5.1[a]	79.8±5.2[ac]
24 h after reperfusion	8.7±4.7	11.2±2.3	43.7±5.4	44.8±6.2
48 h after reperfusion	6.7±2.9	9.2±4.0	38.5±6.1	42.7±4.9

[a]P<0.05 *vs* C group; [c]P<0.05 *vs* R group at matched time points.

distributing in the nuclei of the lower third of crypt cells. However, the positive cellular rate elevated with the increment of duration after reperfusion injury. In the period after reperfusion, marked PCNA immunoreactivities were observed in the nuclei of crypt and villus cell. At 12 h after reperfusion, the positive cellular rates were maximal, the average increase was 2.2 times for villi [19.0±5.4 *vs* 8.5±5.0 (P<0.05)] and 1.7 times for crypts [52.1±5.1 *vs* 31.5±5.2 (P<0.05; Table 2)]. The positive cellular rates of PCNA were restored to the levels of sham-operated tissues at 24 and 48 h after reperfusion. During 2-12 h after reperfusion, treatment of aFGF could apparently induce protein expression of PCNA in intestinal mucosal epithelial cells from villi and crypts in comparison with R group at different matched times (P<0.05) (Table 2). There are approximately 1.3- and 1.5-time increments of PCNA expressive levels in both villus and crypts in rats of A group after reperfusion for 12 h compared with their littermates of R group, respectively. After reperfusion for 24 and 48 h, the positive signals of this protein had no substantial change in A group in comparison with R group (P>0.05).

The changes of plasma levels of D-lactate

As shown in Table 3, 45 min of ischemia followed by reperfusion in intestinal mucosa could result in plasma D-lactate level elevation. Plasma D-lactate level was significantly elevated from 30 min after reperfusion in R group, and reach its peak at 12 h, which was 1.5-folds of that in sham-operated group ((0.299±0.025) μg/mL *vs* (0.201±0.008) μg/mL, P<0.05), and then returned to the level of sham-operated group (P>0.05). Administration of aFGF produced decreases in the plasmas D-lactate level compared with R group during 0.25-12 h after reperfusion, except for 1 h after reperfusion, leading to statistically significant reduction of D-lactate contents (P<0.05). No significant decreases were observed at 24 and 48 h after reperfusion in A group compared with R group

Table 3 Effect of aFGF on plasma D-lactate levels after intestinal ischemia-reperfusion (n=6, mean±SD, μg/mL)

(P>0.05, Table 3).

DISCUSSION

The major clinical disorders involving gastrointestinal circulation are hemorrhage and ischemia. It is well recognized that the small intestine is very sensitive to the deleterious effects of I/R and it has been clearly demonstrated that I/R causes mucosal injury within the small intestine. Several recent studies have proposed that ischemia-reperfusion can induce an apoptotic response in the adult rat intestinal epithelium, although they did not quantitate this response along the crypt-villus axis[11,20]. In the current study, we found that I/R, following occlusion of the SMA, led to statistically significant increment of apoptosis in undifferentiated epithelial cells located in the proliferative compartment of the adult rat's small intestine, as well as in differentiated epithelial cells distributed in the villus at 2-12 h after reperfusion. The most apoptotic rates in the upper portion of the villus are the region, which is farthest from submucosal vessels that supply blood to the mesenchymal core of the villus. The asymmetric distribution of apoptosis may reflect the fact that hypoxia and deficient nutrient generated by SMA occlusion are greater in epithelial cells located in the upper villus compared with crypts. However, it is also possible that the signaling pathways that mediate the induction differ qualitatively or quantitatively between undifferentiated proliferating cells in the crypt and postmitotic differentiated cells in the upper villus. The actual mechanism needs to be deeply explored. Our studies displayed that administration of exogenous aFGF produced an approximately 1.5-fold reduction in the number of TUNEL positive cells that appear following transient SMA occlusion in proliferating undifferentiated crypt epithelial lineage as well as their postmitotic differentiated villus descendants. These results are compatible with the notion that exogenous aFGF might protect from intestinal injury caused by I/R insult through an identical mechanism in villus and crypt epithelial cells.

D(-)-lactate is the stereoisomer of mammalian L(+)-lactate. Mammalian tissue cannot produce D(-)-lactate and can only slowly metabolize it. It is a strict product of bacterial fermentation. Since intestinal I/R injury can cause mucosal injury and subsequent bacterial proliferation, D(-)-lactate releasing from the gut into the host blood circulation, the change of plasma D(-)-lactate level was used as a predictor of intestinal I/R injury[21,22]. In the present study, it was shown that plasma D(-)-lactate levels began to increase in rat's intestinal villus subjected to 45 min of ischemia followed by 30 min of reperfusion, maximal at 12 h after reperfusion. In the aFGF treated group, it was significantly decreased during 2-12 h after reperfusion compared with normal saline treated group, which was corroborated with the data obtained by the TUNEL method, indicating that aFGF exerts a positive protective effect on the mucosal barrier and decreases the intestinal permeability.

Our study also found that apoptosis occurred at 2 h post-reperfusion fδllowed by a return to baseline values by 24 h suggestsing that I/R induction of intestinal apoptosis and mucosal recovery were rapid processes. The reason for this interesting kinetics of induction of mucosal cell death and restoration was unclear. PCNA is a significant cell-cycle regulated nuclear protein for DNA-polymerase. PCNA-labeled nuclei identify cells in the late G1 and early S phases of the cell cycle, as well as cells undergoing DNA repair[23,24]. Our current study demonstrated that the expressing levels of PCNA at 2-12 h after reperfusion were significantly higher than the levels of C control in both crypt and villus epithelial cells. These findings indicated that the repair process of small intestinal mucosa was initiated by I/R and cellular regeneration continued for 12 h following reperfusion. At the same time, the PCNA protein was mainly located in the nuclei of proliferative cells in crypts. Administration of exogenous aFGF could induce protein expression of PCNA in mucosal cells, especially in crypt epithelial cells. At 2-12 h after reperfusion, PCNA was strongly expressed both in undifferentiated crypt epithelial cells as well as differentiated villus cells in comparison with normal saline treated group. These results suggest that aFGF treatment could inhibit cellular apoptosis of mucosal cells and induced cell proliferation, especially cells in crypt, to accelerate regeneration and repair of small intestinal mucosa after ischemia-reperfusion insult. Ischemia of the adult human small intestine could result in high mortality[25]. Because administration of exogenous aFGF can ameliorate the reperfusion injury that accompanies intestinal transplantation or the epithelial wound brought about by sepsis, interventions that elevate aFGF levels or enhance its activity may be useful for reducing the damage produced by ischemia-reperfusion insult.

In conclusion, the present study provided the primary evidence that the protective effects of aFGF against ischemia/reperfusion in rat's intestinal villus might be partially due to its abilities to inhibit ischemia/reperfusion-induced apoptosis and to promote crypt and villus epithelial cell proliferation. The precise mechanism for the attenuation of intestinal ischemia/reperfusion injury and acceleration of mucosal regeneration afforded by aFGF

requires further investigation.

Abstract

AIM: To study the role of hepatic sinusoidal capillarization and perisinusoidal fibrosis in rats with alcohol-induced portal hypertension and to discuss the pathological mechanisms of alcohol-induced hepatic portal hypertension.

METHODS: Fifty SD rats were divided into control group (n=20) and model group (n=30). Alcoholic liver fibrosis rat model was induced by intragastric infusion of a mixture containing alcohol, corn oil and pyrazole (1 000:250:3). Fifteen rats in each group were killed at wk 16. The diameter and pressure of portal vein were measured. Plasma hyaluronic acid (HA), type IV collagen (CoIV) and laminin (LN) were determined by radioimmunoassay. Liver tissue was fixed in formalin (10%) and 6-μm thick sections were routinely stained with Mallory and Sirius Red. Liver tissue was treated with rabbit polyclonal antibody against LN and ColIV. Hepatic non-parenchymal cells were isolated, total protein was extracted and separated by SDS-PAGE. MMP-2 and TIMP-1 protein expression was estimated by Western blotting.

RESULTS: The diameter (2.207 ± 0.096 *vs* 1.528 ± 0.054 mm, P<0.01) and pressure (11.014±0.395 *vs* 8.533±0.274 mmHg, P<0.01) of portal vein were significantly higher in model group than those in the control group. Plasma HA (129.97±16.10 *vs* 73.09±2.38 ng/mL, P<0.01), ColIV (210.49±4.36 *vs* 89.65±4.42 ng/mL, P<0.01) and LN (105.00±7.29 *vs* 55.70±4.32 ng/mL, P<0.01) were upregulated in model group. Abundant collagen deposited around the central vein of lobules, hepatic sinusoids and hepatocytes in model group. ColI and ColIII increased remarkably and perisinusoids were almost surrounded by ColIII. Immunohistochemical staining showed that ColIV protein level (0.130±0.007 *vs* 0.032±0.004, P<0.01) and LN protein level (0.152±0.005 *vs* 0.029±0.005, P<0.01) were up-regulated remarkably in model group. MMP-2 protein expression (2.306±1.089 *vs* 0.612±0.081, P<0.01) and TIMP-1 protein expression (3.015±1.364 *vs* 0.446±0.009, P<0.01) in freshly isolated hepatic non-parenchymal cells were up-regulated in model group and TIMP-1 protein expression was evidently higher than MMP-2 protein expression (2.669±0.170 *vs* 1.695±0.008, P<0.05).

CONCLUSION: Hepatic sinusoidal capillarization and peri-sinusoidal fibrosis are responsible for alcohol-induced portal hypertension in rats.

INTRODUCTION

In China, the number of patients with alcoholic liver fibrosis is increasing. It has been reported that about 20% of people with 10-20 years of alcohol drinking might develop alcoholic liver fibrosis[1]. Portal hypertension is a major complication of liver fibrosis and cirrhosis, which can lead to variceal bleeding, fluid retention and reduced renal blood flow, *etc.* being a major cause of death in patients with liver fibrosis. The pathological mechanisms of portal hypertension remain unclear. Recently, it has been found that pathological changes of hepatic microvasculature play a major role in the formation of portal hypertension[2]. Wang *et al*[3]. pointed out that alcohol might cause microvasculature obstruction and capillarization of hepatic sinusoids. Capillarization of the sinusoids is an early event in liver fibrogenesis, which is gradually formed by deposition of type IV collagen and LN in the perisinusoidal space and finally forms a complete and thick basement membrane[4]. When liver fibrosis occurs, it affects normal material exchange between blood and hepatocytes while the blood flow

resistance and portal hypertension ensue. Studies on the relation between alcoholic liver injury and portal hypertension are rarely available and the pathological mechanisms are still controversial. One of the popular hypotheses is that hepatic non-parenchymal cells might synthesize basement membrane proteins and take part in the formation of extra-cellular matrix (ECM)[5].

In order to understand the pathological mechanisms of alcohol-induced portal hypertension, we explored the possible changing rule by which ECM of perisinusoid basement membrane (types I, III and IV collagen and LN) abides. Moreover, the synthesis of MMP-2 and TIMP-1 protein in freshly isolated hepatic non-parenchymal cells and their correlation with portal hypertension were also investigated. Hopefully, this may provide new insights for the prevention of alcoholic liver fibrosis.

MATERIALS AND METHODS

Materials

Male SD rats weighing 160±10 g, were purchased from Vital River Experimental Animal Company (eligible certificate number: SCXK2002-2003). Pyrazole was purchased from Aldrich Chemical Company. Alcohol was purchased from Beijing Red Star Alcohol Ltd (concentration: 52%). Conventional corn oil was from the supermarket. Rabbit immunoglobulins directed against mouse ColIV, LN, MMP-2, and TIMP-1 were from Santa Cruz (USA). Secondary antibody (PV-6001) and DAB kit were purchased from Beijing Zhongshan Company. Unless specifically indicated, all other reagents were purchased from Beijing Chemical Agent Company.

Modeling alcoholic liver fibrosis

Fifty rats were divided into control group (n = 20) and model group (n = 30). Alcoholic liver fibrosis model was induced by intra-gastric infusion of a mixture containing alcohol, corn oil and pyrazole (1 000:250:3) as previously described[6,7]. The control rats received intra-gastric infusion of saline solution and had normal diet. Fifteen animals in each group were killed at wk 16.

Measurement of portal vein diameter and pressure

Rats were anesthetized with sodium pentobarbital (40 mg/kg, ip) and the abdomen was opened to expose the portal vein. Portal vein diameter and pressure were measured. The numerical value was recorded as previously described[8].

Radioimmunoassay of HA, ColIV and LN

Blood samples were obtained by abdominal aortic artery puncture for radioimmunoassay of HA, ColIV and LN using a standardized and optimized commercial radioimmunoassay kit.

Liver tissue collagen staining

Liver tissue was fixed in buffered formalin (10%) and embedded in paraffin. Sections (6-μm thick) were routinely stained with Mallory and Sirius Red, then observed under ordinary optical and polarization microscope.

Liver tissue immunohistochemical staining

Liver tissue sections were treated with 1% hydrogen peroxide, 0.1% proteinase K and 1% Triton X-100. The sections were reacted with 1:150 diluted rabbit polyclonal antibody against LN and ColIV overnight at 4 °C, then with PV-6001 kits for 2 h at room temperature (SP method).

Isolation of hepatic nonparenchymal cells

Hepatic non-parenchymal cells were isolated from male SD rats with proteinase E and collagenase digestion as described previously[9]. Following perfusion, hepatocytes were removed by low-speed centrifugation. Hepatic non-parenchymal cells were separated by density centrifugation in a Nycodenz (33%) gradient. Hepatic sinusoidal cells, Kupffer cells and hepatic stellate cells were harvested.

Western blotting

Hepatic non-parenchymal cells were treated with RIPA (50 mmol/L TrisHCl, 150mmol/L NaCl, 0.025% NaN_3, 0.1% SDS, 100 μg/mL PMSF, 1 mmol/L NaF, 1% NP-40, 2 mmol/L Na_3VO_4, 50mmol/L Hepes, 1% Triton X-100) to extract total protein. Total protein was detected with the BCA protein assay method. Total protein(12μg) was loaded into each lane. Cell extracts were separated by SDS-PAGE using a 12% gel and transferred onto a PVDF membrane. The membranes were blocked for 1 h at room temperature in 10 g/L BSA and incubated overnight at 4°C with surviving antibody(MMP-2 and TIMP-1), then with sheep anti-rabbit second antibody conjugated to horseradish peroxidase for 2 h. Finally the membranes were developed with DAB and incubated until color developed sufficiently. An equal amount of proteins was loaded onto the stocking gel, β-actin expression was simultaneously estimated in each sample as the internal marker by Western blotting using anti-actin monoclonal antibody.

Image analysis of immunohistochemical staining and Western blot results

Immunohistochemical staining results were analyzed by "5-point sampling" method using the Motic patho-image analysis system on 7 sections for each group. Under the same magnification (10×20), we collected 35 samples from each group, then measured the average facio-density (average facio-density = whole area of positive reaction grains/whole area of visual field). Western blotting results were analyzed by the Motic gel analysis system. We compared the gray scale value of target protein and internal marker to gain the relative optical density value.

Statistical analysis

SPSS version 10.0 was used. Data were analyzed using test and one-way ANOVA. All values were expressed as mean±SE. $P<0.05$ or <0.01 was considered statistically significant.

RESULTS

Changes of portal vein diameter and pressure

All data of portal vein diameter and pressure were collected and analyzed by a computer. The results are shown in Table 1. Portal vein diameter and pressure were significantly higher in model group than in control group ($^bP<0.01$)

Table 1 Comparison of portal vein diameter and pressure in control and model groups (mean±SE)

Group	*n*	Portal vein diameter (mm)	Portal vein pressure (mmHg)
Control	10	1.528 ± 0.054	8.533 ± 0.274 [b]
Model	10	2.207 ± 0.096	11.014 ± 0.395[b]

[b]*P*<0.01 *vs* control.

Plasma HA, ColIV and LN assay

Plasma HA, ColIV and LN levels were detectable by radioimmunoassay. The levels of plasma HA (129.97±16.10 *vs* 73.09±2.38 ng/mL), ColIV(210.49±4.36 *vs* 89.65±4.42 ng/mL) and LN(105.00 ±7.29 *vs* 55.70±4.32 ng/mL) were all up-regulated in model group compared to control group(*P*<0.01, Figure 1).

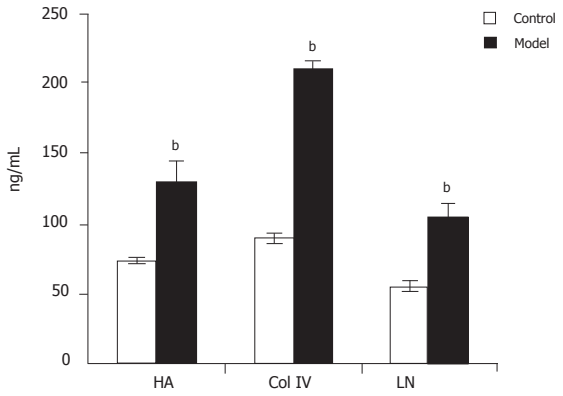

Figure1 Levels of plasma HA, ColIV and LN in model and control groups [b]*P*<0.01 *vs* control.

Results of Mallory and Sirius Red staining

More collagen was stained with Mallory in model group than in control group. Optical microscopy showed that there was only a little collagen around the central vein of lobules in control rats (Figure 2A). On the contrary, abundant collagen deposited around the central vein of lobules, hepatic sinusoids and hepatocytes in model group, which interweaved to form a net-shape pattern and connected with each other (Figure 2B). Polarization microscopy showed that ColIV was red or yellow while ColIV was green, suggesting that there was a small quantity of ColIV around the central vein of lobules in control rats (Figure 2C). But in model rats, ColIV and ColIV increased remarkably and perisinusoids were almost surrounded by increased ColIV (Figure 2D).

Immunohistochemical staining

The immune reaction for ColIV in normal liver was detected only at the level of portal tract and around the major central vein of lobules (Figure 2E). In alcoholic liver fibrosis tissue, positive ColIV was detected at the level of portal tract and in the central vein of lobules or in the Disse space between the sinusoid cells and hepatocytes (Figure 2F). Image analysis showed that the average facio-density of positive granules in ColIV of alcoholic liver fibrosis tissue was upregulated remarkably compared to the normal liver tissue (0.130±0.007 *vs* 0.032±0.004, *P*<0.01, Figure 3).

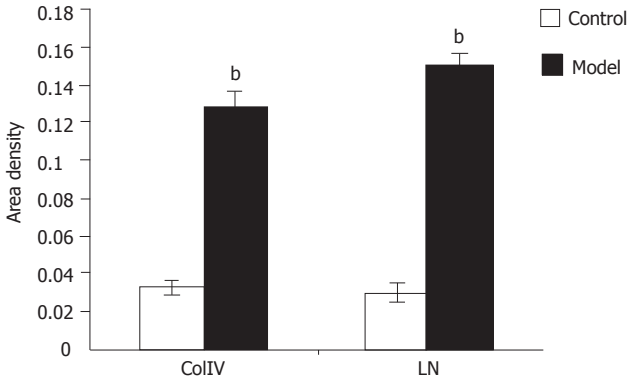

Figure 3 Density of ColIV and LN in positive granule area [b]*P*<0.01 *vs* control in model and co.

In normal liver tissue, a few LN positive cells were detected (Figure 2G). However, the LN positivity increased significantly in alcoholic liver fibrosis tissue. The LN positive granules deposited not only in the cytoplasm but also in the perisinusoidal area (Figure 2H). Image analysis showed that the average facio-density of positive granules in LN was upregulated remarkably compared to the normal liver tissue (0.1518±0.0058 *vs* 0.0299±0.0058, *P*<0.01, Figure 3).

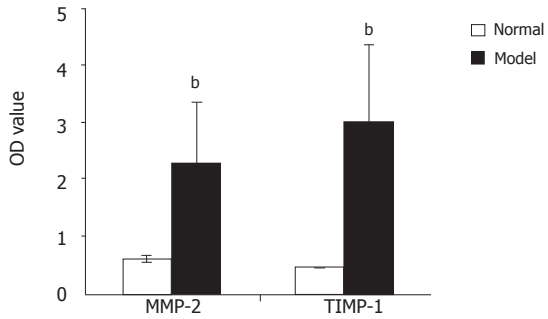

Figure 4 Comparison of MMP-2 and TIMP-1 protein expression in hepatic non-parenchymal cells between model and control groups[b]*P*<0.01, model group *vs* control group; [c]*P*<0.05, TIMP-1 *vs* MMP-2.

Western blotting analysis

Western blotting analysis showed that MMP-2 and

TIMP-1 proteins were significantly up-regulated in rat fibrosis liver tissue compared to control group (2.306±1.089 *vs* 0.612±0.081 and 3.015±1.364 *vs* 0.446±0.009, $P<0.01$). Image analysis of rat fibrosis liver tissue showed that protein expression was higher in TIMP-1 than in MMP-2 (2.669±0.170 *vs* 1.695±0.008, $P<0.05$, Figure 4).

DISCUSSION

In this study, portal vein pressure increased significantly in the early stage of alcoholic liver fibrosis. ColI, ColIII, ColIV and LN levels were increased in the ECM of basement membrane. Furthermore, TIMP-1 protein level was increased in hepatic non-parenchymal cells isolated from alcoholic liver fibrotic tissue, suggesting that the major pathological changes are capillarization of hepatic sinusoids and perisinusoidal fibrosis in early stage of alcoholic liver fibrosis.

Some studies demonstrated that kupffer cells, hepatic stellate cells (HSC) and sinusoidal endothelial cells (SEC) play a key role in the synthesis or decomposition of extra cellular matrix (ECM)[10,11]. Others believe that the levels of serum hyaluronate are strongly related to SEC injury and hepatic microcirculation disorders[12]. Serum hyaluronate is a better index of morphological and functional changes in SECs. Our results showed that the level of rat serum hyaluronate increased remarkably in the early stage of alcoholic liver fibrosis, indicating that SECs are severely injured. When SECs get injured, a large number of inflammatory leucocytes move to the injured sinusoids and trigger the self-recovery process. Therefore, the ECM of basement membrane increases and enwraps the injured sinusoids in order to defend against inflammatory leucocytes. After repeated injury, over-recovery emerges and the ECM of basement membrane including type I, III, IV collagen and LN is over-deposited in perisinusoid[13,14]. Deposition of type I, III, IV collagen and LN reduces hepatic sinusoidal penetration and causes sinusoidal capillarization[15].

Hepatic sinusoids are special capillaries that are limited by fenestrated endothelial cells without a genuine basement membrane and surrounded by perisinusoidal cells storing vitamin A and Kupffer cells as well as pit cells, resident macrophages and large granular lymphocytes[16]. Hepatic sinusoidal capillarization includes a series of pathological changes, in which SECs lose fenestrae, basement membrane develops and sinusoidal outlets collapse[17]. All these pathological changes disable the normal sinusoid intrinsic functions[18]. Capillarization of the sinusoid may cause a disturbance in the exchange of many bioactive substances between the sinusoidal blood and hepatocytes across the Disse space, contributing to the pathogenesis of alcoholic liver fibrosis. On the other hand, with the occurrence of sinusoidal capillarization, the sinusoidal space is significantly narrowed and the sinusoidal endothelial fenestrations are decreased in size and number or disappear in the end. All these pathological changes increase resistance of the hepatic vascular bed and pressure of hepatic portal vein.

Additionally, the breakdown of ECM is essential for tissue remodeling. The matrix metalloproteinases (MMPs), also called matrixins, are thought to play a central role in these processes[19]. The activities of MMPs are precisely controlled during the activation from their precursors and inhibited by tissue inhibitors of metalloproteinases (TIMPs)[20]. MMP-2 is secreted from Kupffer cells and HSCs as they become activated. Also, the activation of MMP-2 is in turn inhibited by TIMP-1. Generally, TIMP-1 and MMP-2 affect biological functions by non-covalent bond [20]. At the early stage of alcoholic liver fibrosis, with the activation of Kupffer cells and HSCs, the level of MMP-2 expression increases. MMP-2 can decompose type I, III, IV collagen and assist Kupffer cells, HSCs and SECs to activate and transfer. Emmanouil *et al*[21]. showed that increased MMP-2 could decompose the basal membrane of neighboring SECs. The signal of injured SECs triggers the mechanisms of TIMP synthesis to balance the levels of MMPs. However, while repeated injury occurs, the synthesis of ECM becomes stronger than decomposition[22,23]. We examined the expression of MMP-2 and TIMP-1 protein in freshly isolated hepatic non-parenchymal cells of normal and fibrotic rats by Western blotting. The results showed that the levels of MMP-2 and TIMP-1 protein expression were upregulated in the early stage of alcoholic liver fibrosis, the level of TIMP-1 was significantly higher than that of MMP-2, suggesting that the synthesis of basal membrane collagen is stronger than decomposition and more and more ECMs of the basement membrane are synthesized due to the inhibition deposit around SECs and hepatocytes of MMPS[24]. This in turn induces perisinusoidal fibrosis and causes aggravating portal hypertension[25,26]. The therapy of alcohol-induced liver disease varies according to the severity of histological liver damage and clinically overt portal hypertension and hepatic dysfunction[27,28]. Only a few studies have been conducted on alcohol-induced portal hypertension in the past decades[29,30]. Our experimental results showed that hepatic portal hypertension occurred earlier than alcohol-induced cirrhosis, suggesting that hepatic portal hypertension plays a potential role in cirrhosis.

In conclusion, hepatic sinusoidal capillarization and perisinusoidal fibrosis are the vital causes for alcohol-induced portal hypertension in rats. A thorough evaluation of hepatic microcirculation and anti-capillarization may provide the basis for new therapeutic avenues.

Abstract

AIM: To investigate the effects of AT_1 (Type 1 angiotensin II receptor) antagonist (Losartan) on the apoptosis, proliferation and migration of the human pancreatic stellate cells (hPSCs).

METHODS: hPSCs were isolated from pancreatic sample of patients with pancreatic carcinoma using radioimmunoassay (RIA) technique to detect the concentration of AngII in culture media and cell homogenate. Immunocytochemistry (ICC) and *in situ* hybridization (ISH) methods were utilized to test AT_1 expression in hPSCs. Effects of Losartan on hPSCs proliferation, apoptosis and migration were investigated using BrdU incorporation, TUNEL, flow cytometry (FCM), and phase-contrast microscope separately when cells treated with Losartan. Immunofluorescence and Western blot were applied to quantify the expression of type I collagen in hPSCs.

RESULTS: There exists AT_1 expression in hPSCs, while no AngII was detected in culture media and cell homogenate. Losartan induces cell apoptosis in a dose- and time-dependent manner (apparently at 10^{-5} mol/L), no pro-proliferative effect was observed in the same condition. Corresponding dosage of Losartan can also alleviate the motion capability and type I collagen content of hPSCs compared with AngII treatment and non-treatment control groups.

CONCLUSION: These findings suggest that paracrine not autocrine functions of AngII may have effects on hPSCs, which was mediated by AT_1 expressed on cells, while Losartan may exert anti-fibrotic effects by inhibiting hPSCs motion and partly by inducing apoptosis.

Key words: Pancreatic stellate cell; Angiotensin II receptor; Antagonist; Losartan

INTRODUCTION

Fibrosis is a dynamic process in which both altered matrix degradation and abnormal extracellular matrix (ECM) protein synthesis play key roles[1,2]. Chronic pancreatitis is accompanied by progressive fibrosis that is characterized by the loss of functional tissue and its replacement by ECM, while the molecular mechanisms of pancreatic fibrogenesis remain to be elucidated.

In 1998, star-shaped cells in the pancreas, namely PSCs, were identified and characterized[3,4]. These cells like their counterparts, hepatic stellate cells (HSCs) and pancreatic stellate cells (PSCs) are responsible for the development of pancreatic fibrosis. Meanwhile, many of the morphological and metabolic changes associated with the activation of PSCs in animal models of fibrosis also occur when these cells are grown in culture on plastics. Therefore, a culture of primary PSCs on plastics has been accepted as a model that mimics the *in vivo* process of PSC activation following pancreatic injury[5].

Numerous studies have emphasized the important role of the local Renin-angiotensin system (RAS) in the fibrogenesis that occurs in the setting of chronic kidney or cardiac diseases and the antifibrogenic effect of therapies with AT_1 blockers or angiotensin-converting enzyme (ACE) inhibitors in this condition. Recent study has shown that AngII may induce apoptosis in some type of cells triggered by the interaction with AT_1[6]. Also, AngII can promote cell migration even though the mechanism is still unclear. A local RAS has been described in the pancreas[7-9]. Though apoptosis, migration and proliferation of human pancreatic stellate cells (hPSCs) might affect the pancreatic fibrotic process, it has reason to hypothesize that AngII and AT_1 may participate in this process by different mechanisms.

The present study attempts to investigate the effects of Losartan, an antagonist of AT_1 on hPSCs, providing laboratory data for interfering pancreatic fibrosis.

MATERIALS AND METHODS

Cell isolation and culture

hPSCs were isolated from pancreatic sample of patients

with pancreatic carcinoma (kindly gifted by Prof. Bachem MG)[4], culturing in a 95% air and 50 mL/L CO_2 incubator at 37 ℃ with DMEM containing 10% FCS supplemented with 100 U/mL penicillin,100 μg/mL streptomycin and 2 mmol/L L-glutamine.

AngII level in culture media and cell homogenate

Cell homogenate and culture media were taken and kept at -30 ℃ for assays. The levels of AngII were determined by radioimmunoassay (RIA) method following the company directions (Northern Biot Co, China).

ICC Staining of AT_1

For analysis of AT_1 expression, cells were fixed with acetone for 5 min, exposed to a rabbit anti-human AT_1 antibody (4 ℃ overnight, 1∶200 in PBS, Boster, Wuhan, China), washing and incubating with an anti-rabbit secondary antibody (37 ℃, 2 h, 1∶200 in PBS, Dako, USA) and with the substrate solution (DAB in H_2O_2 in Tris buffer pH 7.4) for 15 min after repeating the above-mentioned steps. Pictures were visualized and taken with microscope (Olympus, Japan) and camera (Japan). For control staining, PBS was used instead of the primary antibody.

ISH for AT_1

In situ hybridization (ISH) kit (Boster, Wuhan, China) was used to detect AT_1 expression in hPSCs, Briefly, slides were incubated with the probe and a biotinylated secondary antibody subsequently. The bound antibody was visualized with an indirect biotin streptavidin system coupled to alkaline phosphatase and were detected by the DAB reagent. Human heart tissue was used as a positive control and the sense probes (included in kit) were used as a negative control.

Apoptosis evaluation of hPSCs

Immunocytochemistry (ICC) detection of apoptotic cells was carried out with the use of TUNEL, in which residues of digoxigenin-labeled dUTP are catalytically incorporated into the DNA by terminal deoxynucleotidyl transferase II. After treatment with Losartan (Merck & Co, New Jersey, USA) in different concentrations (10^{-9}, 10^{-7}, 10^{-5} and 10^{-3} mol/L), the slides were fixed and washed thrice in 0.01 mol/L PBS, the following procedures were performed according to the manufacturer's guidance (Boster, Wuhan, China). The positive particles of DAB staining were viewed with a microscope (Olympus Japan). The number of apoptotic cells was counted and expressed as a percentage of total hPSCs population. Next, after a certain concentration of Losartan treatment, harvested cells were washed twice with PBS (0.01 mmol/L, pH 7.4), and the cells were resuspended in bind buffer to a final concentration of 1×10^6 cells/mL. Annexin-V FITC/PI solution (Roche, Germany) was added, which can stain the damaged DNA in apoptotic cells, and then the cells were kept in a dark place at room temperature for 15 min. Quantitative analysis for apoptosis was performed with regular flow cytometry (FCM)[10].

Cell proliferation assessment

The effect of Losartan on hPSCs proliferation was determined by BrdU incorporation and cell counting. After being cultured for 3 d on glass slides, hPSCs were incubated with Losartan (a series of final concentrations 10^{-9}, 10^{-8}, 10^{-7} mol/L) for 48 h. Each concentration included six wells, cells being cultured for 48 h firstly, and then supplemented with BrdU (Boster, Wuhan, China) at 1×10^{-5} mmol/L. After 24 h, slides were stained according to the protocol. Positive signals were visualized by DAB reagent plus substrate intensifier. Five random areas of the slides were chosen for counting stained and unstained hPSCs nuclei [positive cells/(negative+positive cells)×100].

Migration study

Cell migration was assessed by an *in vitro* wound-healing assay. For the wound-healing assay, hPSCs were cultured until confluence on 35 mm-diameter culture dishes. Cells were serum-starved for 24 h, and a 2-mm wide linear wound was cleared. Cells were then incubated with AngII (10^{-8}mol/L, Sigma, USA), AngII (10^{-8} mol/L) plus Losartan (10^{-7} mol/L) for 24 h[11]. Cells migrating into the wound were detected using a phase-contrast microscope.

Western blotting

Western blotting was performed under standard conditions. Briefly, hPSCs (1×10^6) were cultured in 60 mm culture dishes, and were stimulated with AngII (10^{-7} mol/L) and AngII plus Losartan (10^{-6} mol/L) separately for 24 h, 4 mL of the cell media as precipitated with 0.76 g of sodium sulfite at 4 ℃ for 4 h and then centrifuged at 12 000 *g* for 30 min. Pellets were resuspended in buffer (containing 50 mmoL Tris-Cl, 50 mmol DTT, 2% SDS, 0.1% bromophenol blue, 10% glycerol), protein concentrations were determined by BCA protein assay (Pierce, IL). Protein samples were heated for 5 min at 100 ℃ and were subjected to electrophoresis on a 8% acrylamide gel, and transferred to PVDF membrane (Schleicher&Schuell, Germany). The membrane was blocked in 50 mL/L non-fat dried milk in TBS buffer for 2 h at 20 ℃, then membrane was incubated overnight at 4 ℃ with rabbit anti-human collagen type I antibody (diluted 1∶200 in TBS buffer; Boster, Wuhan China) and for 60 min with corresponding horseradish-conjugated secondary antibodies (Santa Cruz, USA) at room temperature. Membrane was washed thrice in Tris-buffered saline containing 1% Tween-20 for 10 min after each of the steps. The protein bands were visualized with ECL chemiluminescence system.

Immunofluorescent staining for collagen type I

hPSCs grew in chamber slides fixed with 2% paraformaldehyde, permeabilized by 0.1% Triton X-100. For non-specific binding site blocking, 1∶50 normal goat serum was applied for 10 min, and then incubated with primary antibody for type collagen I (Boster, Wuhan, China) at 4 ℃ overnight, biotinylated secondary antibody and streptavidin-conjugated FITC (Southern Biotechnology Association, Birmingham, USA) were used to intensify the images. Images were taken by fluorescent microscope (Olympus, Japan).

Statistical analysis

Data values we expressed as mean±SD, these experiments were performed in triplicate for each of the six samples.

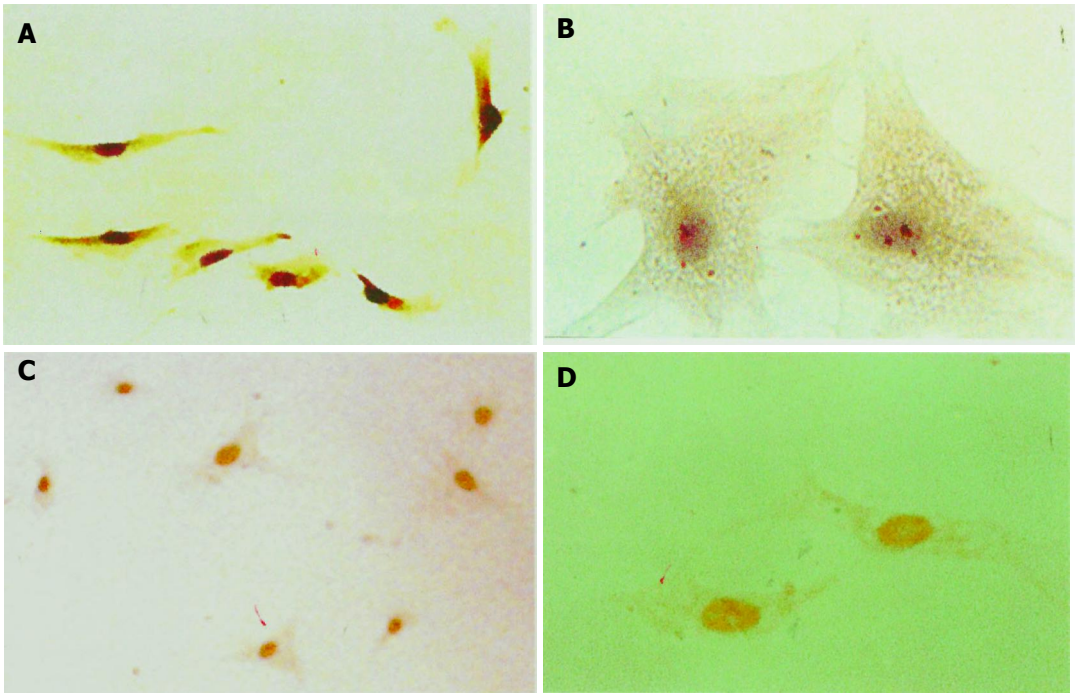

Figure 1 Immunocytochemistry and ISH detection of AT_1 in hPSCs at protein and mRNA levels. Immunostaining positive particles were located in plasm, **A** (magnification ×100); **B** (magnification ×400). ISH positive signals were located in nuclei **C** (magnification ×100); **D** (magnification ×400).

Statistical analysis was performed with a two-tailed Student's *t* test, and $P<0.05$ was considered statistically significant.

RESULTS

AT_1 expression and AngII concentration in hPSCs

hPSCs were cultured for 14 d (activated PSCs), immunostaining revealed that positive signals for AT_1 were located in cell plasm as shown (in Figures 1A and B). ISH assay shows positive nuclei in hPSCs at mRNA level, and representative examples of ISH staining are shown (in Figures 1C and D). AngII was not detected in the culture media or cell homogenate by RIA.

Effects of Losartan on hPSCs

TUNEL staining results suggest a marked increase in apoptotic cell death in Losartan treatment groups in a dosage-dependent manner compared to PBS treatment group (Figure 2).

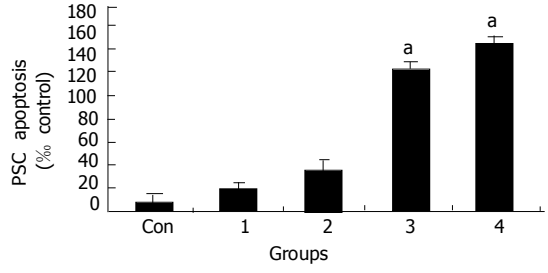

Figure 2 Dose-dependent induction of apoptosis by Losartan at different concentrations. (Con, 1 = 10^{-9}, 2 = 10^{-7}, 3 = 10^{-5}, 4 = 10^{-3} mol/L; $^aP < 0.05$ *vs* different from all groups).

The percentage of apoptotic cell induced by Losartan (Figure 3) was achieved using FCM (EpicsXL Coulter, USA). In the two-dimensional histogram the horizontal axis shows Annexin-V binding and the vertical axis shows PI uptake. The percentage of cells are indicated in the apoptotic quadrant (bottom right). Apoptosis began 24 h after certain dosage of Losartan (10^{-5} mol/L) treatment, and the percentage of apoptotic hPSCs rose from 3.7% (24 h) to 13.1% (72 h) during treatment.

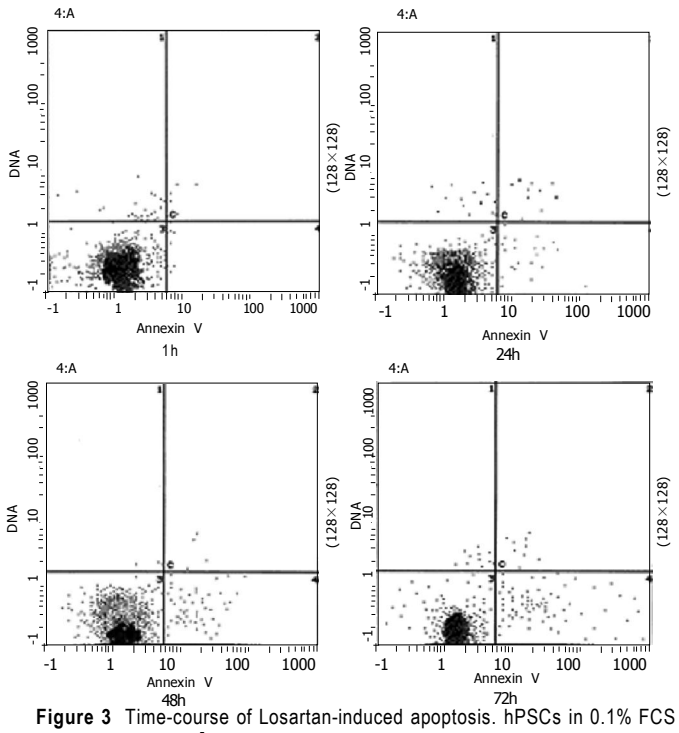

Figure 3 Time-course of Losartan-induced apoptosis. hPSCs in 0.1% FCS were exposed to 10^{-5} mol/L Losartan, and was assessd at 24, 48,72 h. Results indicate that Losartan induces apoptosis in a time-dependent manner.

The BrdU labeling index in control cells was 3.5±0.8%. Treatment with Losartan did not increase the labeling indices (4.7±1.1%, 3.6±0.7%, 4.3±0.5%, Figure 4).

Migration of hPSCs was assessed with an *in vitro* wound-healing assay. AngII (10^{-8} mol/L) and 10% FCS induced migration of hPSCs into the wound. This effect might be inhibited by Losartan (10^{-7} mol/L)[10], as demonstrated by the assay. Images are representative of this experiment (Figure 5).

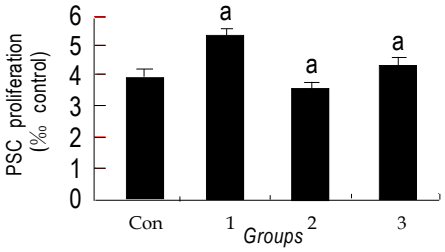

Figure 4 Effects of Losartan on hPSCs proliferation assessed with BrdU incorporation. Losartan itself did not affect cell proliferation compared to control group. (^aP>0.05 different from all the groups).

Western blotting and immunofluorescence assay for collagen type I

The collagen type I level was substantially down-regulated after 10^{-6} mol/L Losartan treatment in hPSCs. In contrast, levels of collagen were higher in control groups, and the same results were shown by immunofluorescence assay (Figure 6).

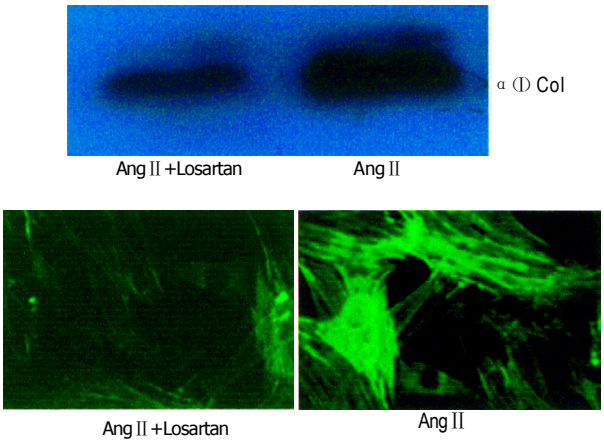

Figure 6 Losartan down-regulated collagen I protein expression by western blot and immunofluoresence. hPSCs were incubated with 10^{-6} mol/L Losartan. Samples were exposed to certain concentration of Losartan+AngII and AngII for 24 h.

DISCUSSION

Chronic pancreatitis is an irreversible progressive disease characterized by the destruction of acinar and ductule cells. Increased accumulation of ECM is a histologic characteristic of chronic pancreatitis that results in pancreatic fibrosis[12,13].

The molecular mechanisms resulting in the fibrosis in pancreas remain unknown. PSCs may participate in matrix remodeling through the regulation of ECM production and matrix degradation. Like his counterpart HSCs, it is now

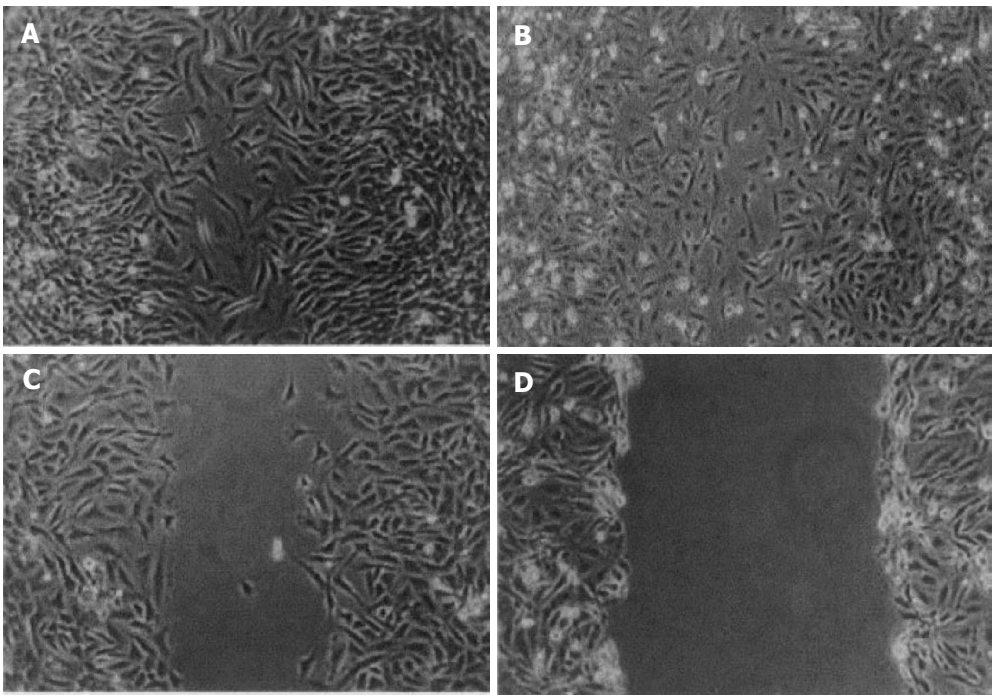

Figure 5 AngII accelerates *in vitro* wound healing confluent, culture-activated PSCs were serum deprived for 48 h. A wound was produced in the monolayer with a pipette tip, and the cells were exposed to (**A**) AngII (10^{-8} mol/L), (**B**) 10% fetal bovine serum, (**C**) AngII + Losartan, (**D**) serum-free medium along 24 h later, the cells were photographed.

generally accepted that PSCs are major ECM producing cells in the pancreas[14,15]. On activation by different stimuli, such as growth factor, cytokines, ethanol, oxidative stress, PSCs produce a large amount of ECM proteins. Increasing synthesis of ECM results from the number of PSCs, determined by the balance of cell proliferation and apoptosis, or cells migrating from non-injured areas to injured areas. Apoptosis, proliferation and migration of PSCs must play a crucial role in pancreatic fibrotic process.

Recent evidence indicates that AngII plays a role in liver fibrogenesis[16]. The AngII is locally expressed in injured livers, and AngII inhibition attenuates experimental liver fibrosis[17]. AngII is able to induce contraction and proliferation of HSCs[18], and also increase the expression of collagen I in lung fibroblasts[19]. Recently, it was shown that ACE inhibitor suppressed progression of hepatic fibrosis in rats[18]. In addition, AngII and AT_1 interaction results in hepatic fibrosis, which could be suppressed by AT_1 antagonist *in vivo* and *in vitro*[16]. Since the pathophysiologic process of pancreatic fibrosis is similar to hepatic fibrosis, and the hPSCs are a counterpart of HSCs, we hypothesize that AngII participates in pancreatic fibrogenesis, though the mechanisms underlying the fibrogenic action of AngII in the pancreas merit further investigation. We speculated that AngII and AT_1 also play an important role in the fibrogenesis of pancreas, so the expression of AT_1 in PSCs was assessed in our study.

It is reported that increased AngII may affect activation and proliferation of PSCs[20]. Therefore, we propose a link between AngII and PSCs during pancreatic fibrosis. While the effects of AngII on cells are mediated by interaction with its receptor (mainly AT_1), we here present evidence that hPSCs express AT_1 at protein and mRNA level, this finding suggests that AngII could exert biological actions in these cells. Moreover we found that no AngII was detected by RIA either in culture media or in hPSCs homogenate, indicating that it is paracrine but not autocrine function of AngII interacting with AT_1 in hPSCs, which plays a role in pancreatic fibrosis. In injured areas of pancreas, the level of AngII alleviate apparently. We observed that AngII derived from exogenous pathway could promote hPSCs migration, which is an important way for increasing hPSCs number in these areas, and this process can be blocked with certain concentration of Losartan. We know that AngII may modulate the re-organization of actin and vinculin through Paxillin and other downstream molecules such as small Rho family members after combining to a certain membrane receptor, leading to cell polarity and migration[21,22]. hPSCs migrating from uninjured areas accumulate in the injured area, and participate in ECM secretion and fibrotic formation[23,24]. The inhibitory effect of Losartan might be attributed to AngII receptor intervention. However, the precise modulating mechanisms still need to be elucidated.

It is well accepted that AngII can induce apoptosis through AT_1 in some cell types, and this apoptotic process could be alleviated with Losartan[25]. AT_1 and AT_2 are two subtypes receptor of AngII. The AT_1 regulates vasoconstriction and sodium and water re-absorption, as well as promote cell growth, proliferation, and collagen matrix deposition. The AT_2 appears to counterbalance the AT_1 by increasing the production of bradykinin, nitric oxide, and cyclic guanosine monophosphate-mediating vasodilation and by promoting cell differentiation, anti-proliferation, and apoptosis. It is meaningful that our results suggest that Losartan itself can induce hPSCs apoptosis in a dose- and time-dependent manner clarified by TUNEL and FCM assays, while there are no marked effects on hPSCs proliferation. We made a serial concentration of Losartan firstly in order to ascertain the adaptable pro-apoptotic dosage, and found that 10^{-5} mol/L had significant pro-apoptotic effect. Also we chose 0.1% FCS in time-course apoptotic test in order to decrease the serum's effect on anti-apoptosis. Based on this result, we used 10^{-6} mol/L in pro-proliferation study in order to avoid pro-apoptotic effect. Apoptosis is a physiological mechanism of deleting cells that regulates cell mass and architecture in many tissues. Inducing PSCs apoptosis or inhibiting PSCs proliferation are always hope-giving methods for complete treatment of pancreatic fibrosis. The regulatory mechanisms and signaling pathways in this process are poorly defined. However, how can we explain this paradox? Actually, AngII is also a potent anti-apoptotic factor, capable of reversing the effects of NO as well as the response to serum withdrawal-induced apoptosis was noted at concentrations as low as 10 nmol/L[26]. The observation that AngII inhibits cGMP analog-induced apoptosis suggests that the survival signal is downstream from the activation of cGMP protein kinase[26]. Given the pleiotropic effects of AngII on a variety of second messenger systems, such as calcium, protein kinase C, mitogen-activated protein kinase, and other tyrosine kinases, there are many potential mechanisms by which AngII may stimulate a cell survival signal[27,28]. It has been reported that AngII inhibits apoptosis mainly via the stimulation of the AT_1[26]. Other anti-apoptotic mechanism might be associated with down-regulation of iNOS expression and requires an intact phosphatidylinositol 3-kinase-Akt survival signal pathway[29]. Whether the interaction between Losartan and AT_1 could activate downstream molecular signals inducing apoptosis is worthy of further investigation. Losartan treatment also lowers the content of collagen I in culture media and hPSCs compared to control group determined by Western blot and immunofluorescence. This contention coincides with other reports that the specific blockade of AT_1 causes a reduction in collagen I.

It is demonstrated that PSCs possessing AT_1, have a possible impact on the pathogenesis of acute and chronic pancreatitis. In the injured pancreas, AngII production by the local RAS may contribute to an impaired microcirculation, resulting in increased intrapancreatic vascular resistance, reduced pancreatic juice efflux, and fibrotic reorganization[30]. Kuno *et al*.[12] recently demonstrated in an *in vivo* model of chronic pancreatitis that inhibition of the ACE attenuates pancreatic inflammation and fibrosis, further corroborating the view that AngII and AT_1 may play an important role in pancreatic pathophysiology. Taken together, our data provide evidence to support that Losartan has direct anti-migration, antifibrotic and pro-apoptotic effects on hPSCs *in vitro*, these processes might be mediated in part, by interaction with AT_1. These findings have important implications for

understanding the role of AT_1 and its antagonist in pancreatic fibrosis. If this is confirmed, the inhibition of AT_1 by Losartan could represent a novel approach to inhibit fibrogenesis in patients with chronic pancreatic disease.

Abstract

AIM: To investigate and compare the effects of spinal D-(-)-2-amino-7-phosphonoheptanoic acid (AP-7) and 6-cyano-7-nitroquinoxaline-2,3-dione disodium (CNQX), two glutamate receptor antagonists, on the responses of dorsal horn neurons to colorectal distension (CRD) in adult rats exposed to neonatal colon irritation (CI).

METHODS: Hypersensitive SD rats were generated by CI during postnatal days 8, 10 and 12. Experiments on adult rats were performed using extracellular single-unit recording. The effects of spinal application of AP-7 (0.001, 0.01, 0.1, 1 mmoL) were tested on the CRD-evoked neuronal responses in 16 controls and 17 CI rats. The effects of CNQX (0.2, 2, 5, 10 μmoL) were also tested on the CRD-evoked responses of 17 controls and 18 CI neurons.

RESULTS: (1) The average responses of lumbosacral neurons to all intensities of CRD in CI rats were significantly higher than those in control rats; (2) In control rats, AP-7（0.01 mmoL）had no significant effect on the neuronal response to all intensities of CRD (20, 40, 60, 80 mmHg); while AP-7 (0.1 mmoL) inhibited the neuronal response to 80-mmHg CRD. By contrast, in CI rats, AP-7 (0.01-1 mmoL) attenuated the CRD-evoked neuronal responses to all distention pressures in a dose-dependent manner; (3) In control rats, CNQX (2 μmoL) had no significantly effect on the neuronal response to all intensities of CRD; however, CNQX (5 μmoL) significantly attenuated the responses to CRD in the 40-80 mmHg range. By contrast, CNQX (2-10 μmoL) significantly decreased the neuronal responses in CI rats to non-noxious and noxious CRD in a dose-dependent manner.

CONCLUSION: Our results suggest that spinal *N*-methyl-D-aspartate (NMDA) and non-NMDA receptors may contribute to the processing of central sensitivity in a neonatal CI rat model, but they may play different roles in it.

Key words: Chronic visceral hypersensitivity; Dorsal horn neurons; Irritable bowel syndrome; NMDA receptors; Non-NMDA receptors

INTRODUCTION

Chronic pain is frequently associated with increased neuronal excitability in the spinal cord, a phenomenon often referred to as central sensitization. Central sensitization can be induced by a number of sensitizing stimuli, including repeated mechanical stimulation and peripheral tissue injury, triggering burst of activities in nociceptors that alter the strength of synaptic connections between the nociceptors and the neurons of the spinal cord. In functional pain disorders, the peripheral stimulus is mostly lacking, and the prevalent hypothesis is that hypersensitivity is caused by functional changes (plasticity) in the nervous system, including central sensitization[1]. A key step in the development of central sensitization is activation and modulation of the *N*-methyl-D-aspartate (NMDA) receptor in those dorsal horn neurons of the spinal cord that receive primary afferent input[2,3]. NMDA receptors have a voltage-dependent magnesium ion (Mg^{2+}) channel block at resting membrane potential[4] and, therefore, do not seem to contribute to transient pain transmission[5-7]. Transient pain transmission occurs through the release of glutamate from the nociceptor afferent neurons acting via the AMPA/kainate receptors at the dorsal horn, which do not have a Mg^{2+} block, resulting

in membrane depolarization. However, stimulation of nociceptive afferents following injury/inflammation causes an increased and sustained release of glutamate from the central terminals of nociceptor afferents in the dorsal horn; this results in depolarization beyond a critical threshold, with the removal of the Mg^{2+} block, activation of NMDA receptors and a consequent amplification of pain[8,9]. This phenomenon of NMDA receptor-mediated central sensitization is a well-established mechanism in both animal and human models of somatic pain hypersensitivity and is attenuated by NMDA receptor antagonists[10,11].

Persistent or inflammatory visceral stimuli also produce central sensitization via NMDA receptors. Spinal administration of NMDA aggravates behavioral and neural responses to both noxious and innocuous intensities of CRD; these responses can be blocked by NMDA receptor antagonists[12,13]. Visceral hyperalgesia produced by colonic inflammation is mediated by NMDA and non-NMDA spinal receptors[14,15]. However, to our knowledge, little is known about the role of NMDA or non-NMDA glutamate receptors in the central sensitization of chronic visceral pain.

Previous work done by our group has shown that colon irritation (CI) in neonates can engender chronic visceral hypersensitivity in adult rats with associated peripheral and central neuronal sensitization in the absence of identifiable peripheral pathology[1,16]. The present study investigated and compared the effects of spinal D-(-)-2-amino-7-phosphonoheptanoic acid (AP-7, TOCRIS), an NMDA receptor antagonist, and 6-cyano-7-nitroquinoxaline-2, 3-dione disodium (CNQX, TOCRIS), a non-NMDA receptor antagonist, on the responses of dorsal horn neurons responding to colorectal distension (CRD) in rats with neonatal CI and in controls. Part of these data have been reported in abstract[17].

MATERIALS AND METHODS

Experiments were performed on 68 adult male Sprague-Dawley rats (weight, 250-350 g) obtained as pre-weanling neonates (younger than 5 d) from Harlan Sprague-Dawley (Indianapolis, IN). Thirty five rats received colon irritation (CI) as neonates and 33 rats served as controls (see below). Rats were housed in plastic cages containing corn chip bedding (Sani-Chips; PJ Murphy Forest Products, Montville, NJ) and maintained on a 12:12 h light-dark cycle (lights on at 7 am). The irritation procedures and the experimental testing were conducted during the light component of the cycle. The neonates were housed 10 per cage with 1 mo until they were 28-d-old. The adult females were accessed to food and water *ad libitum*. After separation, the male young rats were housed 4 per cage with access to food and water *ad libitum*. The rats were observed daily, and their weights were measured at least once a week. Adequate measures were taken to minimize pain and discomfort. All studies were performed in accordance with the proposal of the Committee for Research and Ethical Issues of the International Association for the Study of Pain[18] and were approved by the Institutional Animal Care and Use Committee at the University of Texas Medical Branch in accordance with the guidelines provided by the USA National Institute of Health Guide for the Care and Use of Laboratory Animals (NIH Publications No. 80-23) revised in 1996.

Neonatal colon irritation

Neonatal colon irritation (CI) was applied using colorectal distension (CRD) during postnatal development. The CRD procedure was modified from a previous report by Al-Chaer *et al*[1]. Briefly, the rats (8-d-old) were divided into two groups for the purposes of two different treatments: Group 1 (CI rats) received CRD once on postnatal (PN) days 8, 10, and 12. The distention was applied using an angioplasty balloon (Advanced Polymers Inc., length: 20.0 mm; diameter: 3 mm), inserted rectally into the descending colon in awake neonates. The balloon was distended with 0.3 mL of water, exerting a pressure of 60 mmHg (as measured with a sphygmomanometer) for 1 min and then deflated and withdrawn. Group 2 (which served as controls) was handled in a way similar to group 1 except that no colonic insertion was made. Rats in this group were separated from the dams, gently held and touched on the perianal area on a schedule similar to that described for group 1. Above experiments were done by the same investigator. No treatment, procedures or further interventions were done by the investigator until the testing date.

Electrophysiological preparations

Animal preparation and surgical procedures Experiments were carried out on anesthetized and paralyzed adult rats (> 2 mo). Anesthesia for adult rats in both groups was induced by 5% halothane. The depth of anesthesia during surgery was maintained by ~2.5 % halothane, which was adjusted by monitoring withdrawal responses to pinch. During electrophysiological recording, anesthesia was maintained by ~1.0 % halothane. Once a stable level of anesthesia was reached, the rats were paralyzed with pancuronium bromide (0.3 mg/kg iv) and artificially ventilated. The adequacy of the depth of anesthesia during recordings was monitored by frequent examination of the pupillary reflexes and assessing stability of the level of end-tidal CO_2, which was kept between 3.5% and 4.5% by adjusting the respiratory parameters. Body temperature was monitored and maintained at 37 °C by a servo-controlled heating blanket. The L_6-S_1 segments of the spinal cord were exposed by laminectomy. The rat was placed in a head holder and suspended with thoracic vertebral and ishial clamps. The dura matter was carefully removed and the spinal cord was bathed in artificial cerebral spinal fluid (ACSF)[19].

Colon stimulation Colon stimulation in adult rats consisted of graded colorectal distension (CRD) produced by inflating a balloon inside the descending colon and rectum. The balloon was 4 cm in length and made of the

finger of a latex glove. It was attached to polyethylene tubing and inserted through the anus into the rectum and descending colon. The open end of the balloon was secured to the tubing with thread and wrapped with tape (1 cm wide). The balloon was inserted so that the thread was approximately 1 cm proximal to the anal sphincter, and was held in place by taping the tubing to the tail. The tubing was attached via a T-connector to a sphygmomanometer pump and a pressure gauge. Prior to use, the balloon was inflated and left overnight so that the latex stretched and the balloon became compliant. CRD was produced by rapidly inflating the balloon to the desired pressure (20, 40, 60 or 80 mmHg) for a duration of 10 s. Stimuli applied in an ascending graded manner (spaced by 4 min). To decrease the "human factor" bias to the minimum possible, the same stimulation paradigm was used in every rat. Colon stimulation was applied accurately according to the pressure gauge without observation of the oscilloscope or computerized record so that the experimenter was unaware of the response magnitude.

Electrophysiological recording Tungsten microelectrodes (2-6 MΩ Micro Probe Inc.) were used for extracellular single-unit recording in the L_6-S_2 spinal segments, 0-1.5 mm lateral to midline, 0.2-1.1 mm from the spinal cord dorsum. The search stimulus consisted of brushing the ipsilateral perianal/scrotal area with a small paint brush[20] and CRD (60 mmHg)[21]. When a neuron responsive to the cutaneous stimuli was identified, the colon was distended for several seconds to test whether the neuron was responsive to CRD. The electrophysiological recordings were conducted by an investigator blinded to the type of rats. Action potentials were fed into a window discriminator and monitored continuously by analog delay and displayed on a storage oscilloscope after initial amplification through a low-noise AC differential amplifier (DAM 80i). The output of the amplifier and window discriminator were fed into a data collection system (CED 1401 +) and Spike2 for Windows software (Cambridge Electronic design, UK) to compile rate histograms or wavemark files. Single units were differentiated on- and off-line. Only cells that had an excitatory response to CRD were chosen for the study. Care was taken to insure that noise was not captured by the window discriminator.

Experimental protocols

Each CRD-responsive neuron was tested with the same method (20, 40, 60, and 80 mmHg) before drug administration to establish a baseline response of the neuron. Drugs were dissolved in ACSF and 20 μL was applied spinally to the surface of the spinal cord[19]. The effects of spinal application of AP-7 (0.001, 0.01, 0.1, 1 mmoL) were tested on the CRD-evoked responses of 16 controls and 17 CI neurons. The effects of spinally administered CNQX (0.2, 2, 5, 10 μmoL) were tested on the CRD-evoked responses of 17 controls and 18 CI neurons. The drug was removed by tissue wick prior to application of the next dose. Only one neuron was studied in each animal. The reported doses were the applied dose, not a cumulative dose. A drug effect was described as a change by more than 20% in the response to CRD after the drug was applied, compared to baseline response recorded before drug application. Responses of LS neurons to CRD were recorded 15 min after each drug administration.

The responses to CRD were recorded and calculated as the difference between the rate of firing during the stimulus application and that during the baseline recording. The responses of CI rats were compared to those of controls for statistical significance. Drug effect was tested by recording responses of neurons to CRD before and after the drug application in controls and CI rats. For control purposes, the spinal cord was bathed in ACSF before the drug application. The effects of drugs on the baseline and the responses to CRD were analyzed within each group and were compared between the controls and CI groups for any statistical significance. At the end of the experiments, the rats were euthanized with an overdose of halothane.

Statistical analysis

The spontaneous activity of a neuron was measured for 20 s before CRD, and the response of a neuron to CRD was determined as the average increase in discharge during distention above the average spontaneous activity. The responses recorded in CI rats were compared to those recorded in control rats for statistical significance. Unless otherwise indicated, data were expressed as mean ± SE. The CRD data was analyzed using repeated measures analysis of variance (RM ANOVA). A model with the repeated factors of intensity, group, and the (intensity x group) interaction was used to examine significant intensity effects, group effects and (intensity x group) interactions. Significant group and interaction effects meant that responses in the corresponding groups increased in a significantly different manner (*i.e.,* responses of CI group were significantly different from responses of control group). For non-parametric data, the Mann Whitney rank sum test was used. $P<0.05$ was considered statistically significant in all cases.

RESULTS

Responses to CRD

The neuronal responses to CRD recorded in the controls or CI rats were stimulus-locked. In both controls and CI rats, responses of lumbosacral (LS) neurons to CRD were graded with stimulus intensity. A model with the repeated factors of intensity, group, and the (intensity x group) interaction showed that there was a significant intensity effect ($P<0.05$), group effect ($P<0.05$) and (intensity x group) interaction ($P<0.05$). The interpretation of these results is that there was a significant increase in the magnitude of neuronal responses with increasing levels of CRD in both groups (Figure 1). Also, the average responses of LS neurons to all intensities of CRD in CI rats were significantly higher than those in control rats (Figure 1).

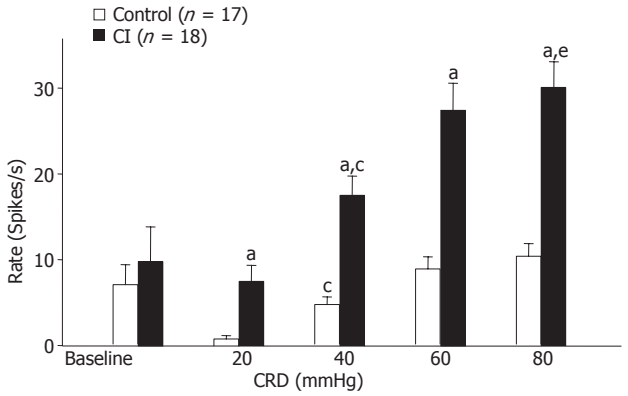

Figure 1 Average responses of LS neurons to CRD (20, 40, 60, 80 mmHg). Bar graph summarizes the average background activity (baseline; control, n = 17; CI, n = 18) and the responses of LS neurons to all intensities of CRD in control and CI rats. The responses to CRD are reported as the mean increase in firing rate above baseline. Responses recorded in CI rats were significantly higher than those recorded in control rats. [a]P<0.05 *vs* the values of normal rats with the same intensity; [c]P<0.05 *vs* 20 mmHg CRD in each group; [e]P<0.05 *vs* 40mmHg CRD in CI rats.

Effect of spinal AP-7 on LS neuronal response to CRD

Percentage of LS neurons inhibited by spinal AP-7 Generally, the effect of AP-7 occurred during 5-30 min after the drug administration.

In control rats, 4 of the 16 neurons (25%) were inhibited by AP-7 (0.001 mmoL); these responded to all graded CRD. Eight of the 16 neurons (50%) responded to CRD (20-60 mmHg); these were inhibited by AP-7 (1 mmoL). Thirteen of the 16 neurons (81.2%) that responded to CRD (80 mmHg) were inhibited by AP-7 (1 mmoL). The effect of AP-7 appeared to be incremental with dose and stimulus intensity with maximum effect seen on the response to 80 mmHg CRD in control rats (Table 1).

In CI rats, 6 of the 15 neurons (40%) that responded to all intensities of CRD were inhibited by AP-7 (0.001 mmoL). All nine neurons (100%) that responded to all intensities of CRD were inhibited by AP-7 (1 mmoL) (Table 1).

The effect of AP-7 on neuronal response to all intensities of CRD was more pronounced in CI rats compared to control rats. AP-7 dose-dependently attenuated the CRD-evoked responses at all distention pressures in all nine (100%) CI neurons.

Effect of spinal AP-7 on the average responses of LS neurons to CRD No significant changes were seen in the responses of 11 control neurons to intensities of CRD following spinal administration of AP-7 (0.01 mmoL) (Figure 2A). On the other hand, AP-7 (0.1 mmoL) significantly attenuated the average response to high intensity of CRD (80 mmHg) (n = 12) and AP-7 (1 mmoL) significantly attenuated the average responses to CRD (40-80 mmHg) in controls (n = 16) (Figure 3A).

AP-7 (0.01 mmoL) significantly attenuated the average responses to intensities of CRD in CI rats in a dose-dependant manner (Figures 2B and 3B).

Table 1 Percentage attenuation of responses to graded CRD of LS neurons by AP-7 in control and CI rats

Dose	20 (%)	40 (%)	60 (%)	80 (mmHg%)
Controls				
0.001 mmoL	25 (4/16)	25 (4/16)	25 (4/16)	25 (4/16)
0.01 mmoL	36.3 (4/11)	36.3 (4/11)	36.3 (4/11)	45.4 (5/11)
0.1 mmoL	41.6 (5/12)	50 (6/12)	58.3 (7/12)	75 (9/12)
1 mmoL	50 (8/16)	50 (8/16)	50 (8/16)	81.2 (13/16)
CI rats				
0.001 mmoL	40 (6/15)	40 (6/15)	40(6/15)	40 (6/15)
0.01 mmoL	60 (6/10)	60 (6/10)	60 (6/10)	60 (6/10)
0.1 mmoL	81.8 (9/11)	81.8 (9/11)	81.8 (9/11)	81.8 (9/11)
1 mmoL	100 (9/9)	100 (9/9)	100 (9/9)	100 (9/9)

Denominators in parentheses indicate the total number of LS neurons treated with AP-7 and numerators indicate the number of neurons affected by AP-7 at the same dose level in control and CI rats. A drug effect is described as a change by more than 20% in the response to CRD after the drug was applied, compared to baseline response recorded before the use of drug.

Table 2 Percentage attenuation of responses to graded CRD of LS neurons by CNQX in control and CI rats

Dose	20 (%)	40 (%)	60 (%)	80 (mmHg%)
Controls				
0.2 μmoL	23.5 (4/17)	23.5 (4/17)	23.5 (4/17)	23.5 (4/17)
2 μmoL	44.4 (4/9)	44.4 (4/9)	44.4 (4/9)	44.4 (4/9)
5 μmoL	50 (4/8)	62.5 (5/8)	62.5 (5/8)	62.5 (5/8)
10 μmoL	71.4 (5/7)	75 (6/8)	75 (6/8)	75 (6/8)
CI rats				
0.2 μmoL	45.4 (5/11)	45.4(5/11)	45.4 (5/11)	45.4 (5/11)
2 μmoL	77.8 (7/9)	77.8 (7/9)	77.8 (7/9)	77.8 (7/9)
5 μmoL	83.3 (5/6)	83.3 (5/6)	83.3 (5/6)	83.3 (5/6)
10 μmoL	100 (8/8)	100 (8/8)	100 (8/8)	100 (8/8)

Denominators in parentheses indicate the total number of LS neurons treated with CNQX and numerators indicate the number of neurons affected by CNQX at the same dose level in control and CI rats. The effect of CNQX on neuronal response to all intensities of CRD was more pronounced in CI rats than that in control rats. CNQX dose-dependently attenuated the CRD-evoked responses at all distention pressures in all 8 (100%) CI neurons.

Effect of spinal CNQX on LS neuronal response to CRD (20-80 mmHg)

Percentage of LS neurons inhibited by CNQX In general, the effect of CNQX occurred during about 10 min after the drug administration.

In control rats, spinal CNQX (0.2 μmoL) inhibited the responses of 4 of the 17 neurons (23.5%) that responded to intensities of CRD. At a higher dose, CNQX (10 μmoL) inhibited the responses of 6 of 8 neurons (75%) that responded to CRD (40-80 mmHg), (Table 2).

In CI rats, spinal CNQX (0.2 μmoL) inhibited the responses of 5 of the 11 neurons (45.4%) that responded to intensities of CRD. At a higher dose, CNQX (10 μmoL) inhibited the responses of all 8 neurons (100%) that responded to intensities of CRD (Table2). Thus, CNQX dose-dependently attenuated the CRD-evoked responses at all distention pressures in CI neurons. The effect of CNQX on neuronal response to all intensities of CRD was more pronounced in the CI rats compared to the control rats.

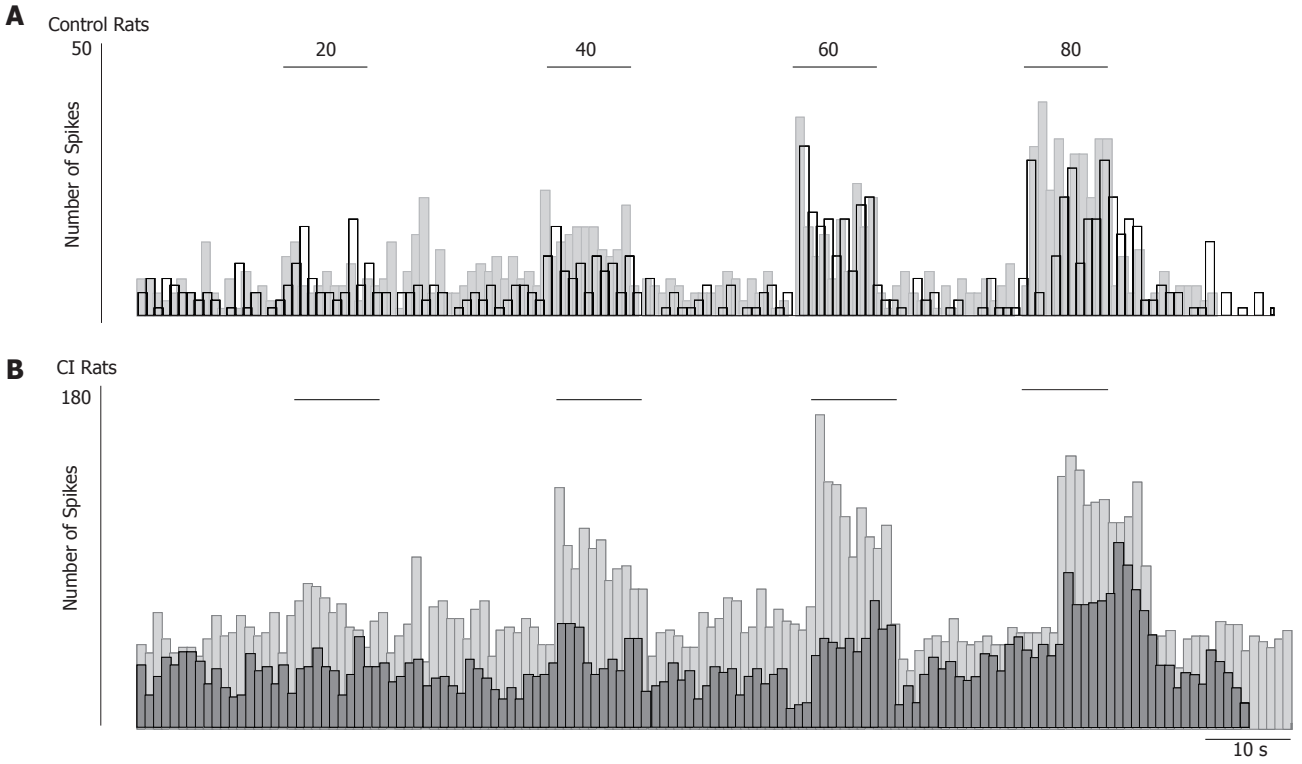

Figure 2 Effect of AP7 (0.01 mmoL) on dorsal horn neuronal responses to CRD in control or CI rats. Rate histograms illustrate the responses of a dorsal horn neuron isolated from a control rat (**A**) and of another neuron isolated from a CI rat (**B**) before (grey) and after (black) spinal administration of AP-7 (0.01 mmoL). Horizontal bars indicate the timing and duration (10 s) of CRD (20- 80 mmHg).

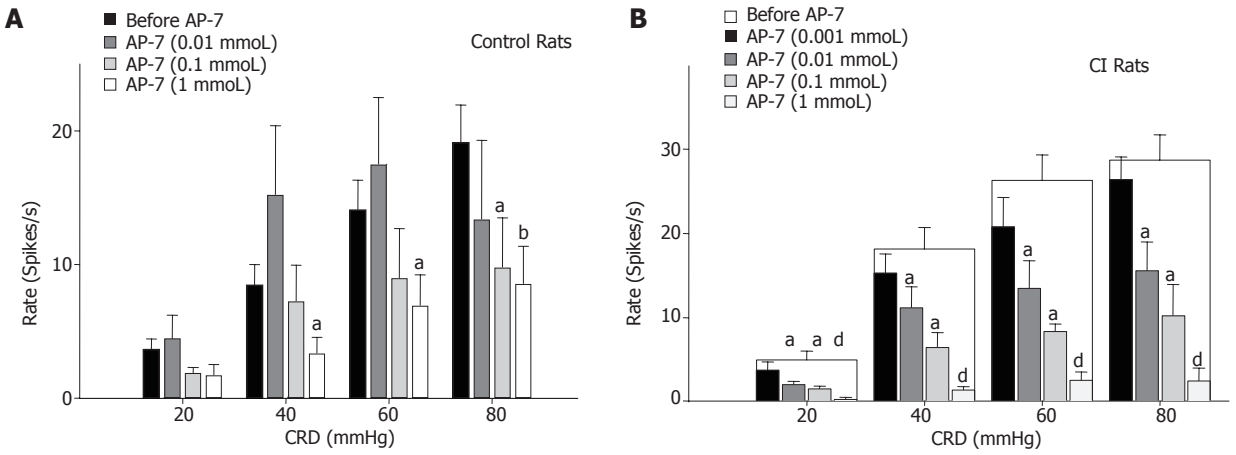

Figure 3 Effect of spinal AP7 on average responses of LS neurons to CRD. Bar graphs illustrate the responses of LS neurons to CRD (20-80 mmHg) recorded in control rats (A; left panel) or CI rats (B; right panel) before and after spinal administration of AP7. **A:** AP-7 (0.1 mmoL) significantly attenuated the average response to high intensity CRD (80 mmHg) and AP-7 (1 mmoL) significantly attenuated the responses to CRD (40-80 mmHg) in controls; **B:** AP-7 (0.01 mmoL) significantly attenuated the average responses to graded CRD in CI rats in a dose-dependant manner. [a]*P*<0.05, [b]*P*<0.01, [d]*P*<0.001 *vs* before AP-7 application at that distention pressure in each group.

Effect of spinal CNQX on the average responses of LS neurons to CRD CNQX (2 μmoL) had no significant effect on the responses of 9 control neurons to all intensities of CRD (Figure 4A). However, CNQX (5 μmoL) significantly attenuated the responses to CRD in the 40-80 mmHg range and CNQX (10 μmoL) significantly attenuated the response to all intensities of CRD in control rats (n = 8) (Figure 5A).

By contrast, CNQX (2 μmoL) significantly attenuated the average response of 9 CI neurons to all intensities of CRD (Figure 4B). In general CNQX (2-10 μmoL) decreased the neuronal responses in CI rats to non-noxious and noxious CRD in a dose-dependant manner (Figure 5B).

DISCUSSION

Injury and pain in neonates can have severe developmental

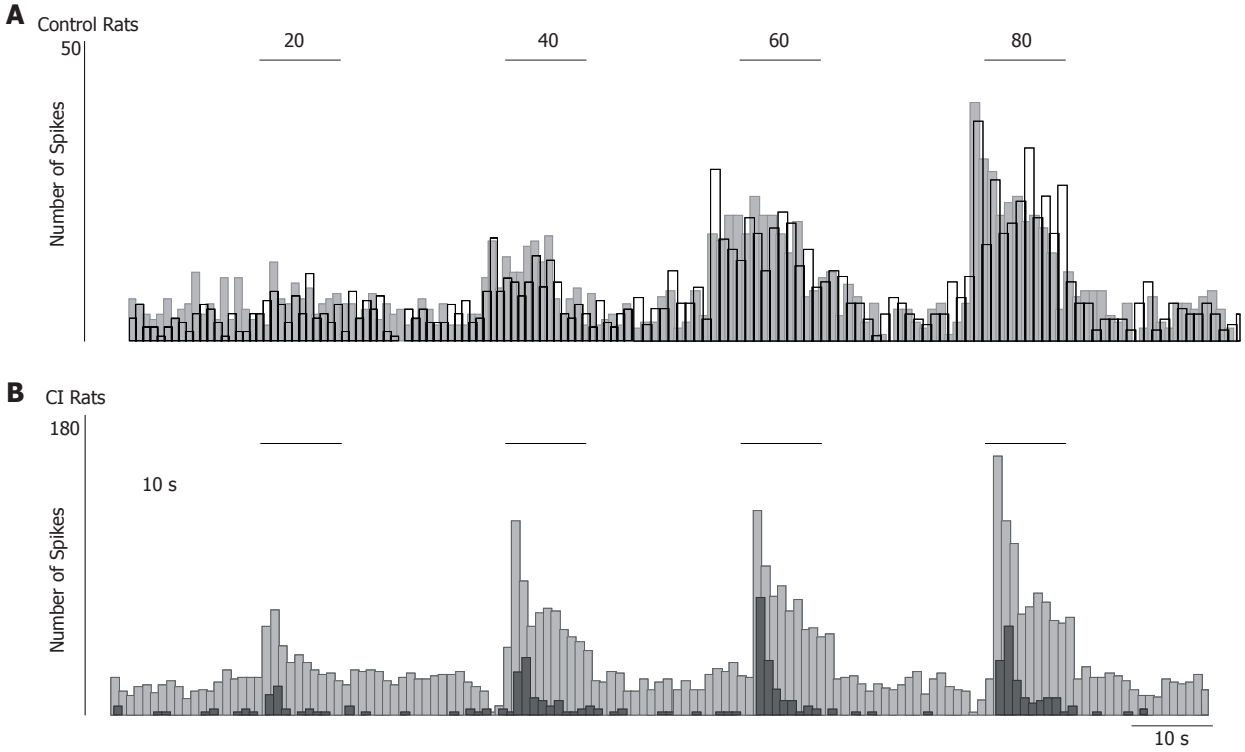

Figure 4 Effect of CNQX (2 μmoL) on dorsal horn neuronal responses to CRD in control or CI rats. Rate histograms illustrate the responses of a dorsal horn neuron isolated from a control rat (**A**) and of another neuron isolated from a CI rat (**B**) before (grey) and after (black) spinal administration of CNQX (2 μmoL).

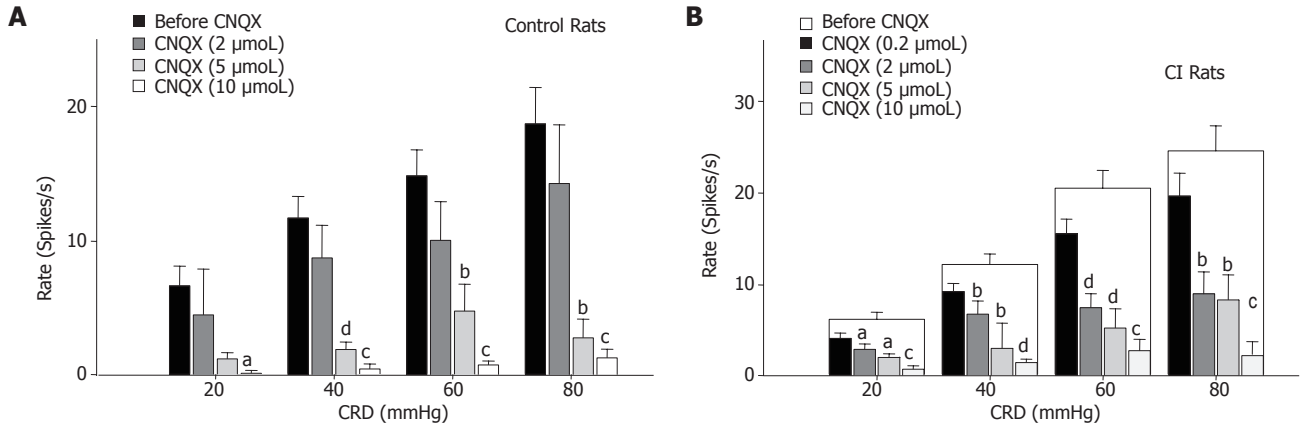

Figure 5 Effect of spinal CNQX on average responses of LS neurons to CRD. Bar graphs illustrate the responses of LS neurons to graded CRD (20-80 mmHg) recorded in control rats (A; left panel) or CI rats (B; right panel) before and after spinal administration of CNQX. **A:** In control rats, CNQX (5 μmoL) significantly attenuated the responses to CRD in the 40-80 mmHg range and CNQX (10 μmoL) significantly attenuated the response to all intensities of CRD; **B:** In CI rats, CNQX (2-10 μmoL) significantly decreased the response to all intensities of CRD in a dose-dependent manner. [a]*P*<0.05, [b]*P*<0.01, [d]*P*<0.001 *vs* before CNQX application at that distention pressure in each group; [c]*P* <0.05 *vs* 2 μmoL CNQX.

repercussions that may often alter the physiological and functional profile of the adult. In previous studies, our group has shown that colon pain in neonatal rats can cause long-term visceral hypersensitivity associated with central neuronal and peripheral sensitization, despite the lack of inflammation signs in the colon[1,16]. This chronic colorectal hyperalgesia can be blocked by a peripheral NMDA receptor antagonist (AP7)[22]. In this study, we showed that spinal application of AP-7 or CNQX attenuated the neuronal response to graded CRD in both control and CI rats with a more pronounced effect in CI rats. Thus, both spinal NMDA and non-NMDA receptors contribute to the central sensitization seen in adult rats with chronic visceral hypersensitivity.

Neonatal injury and central sensitization

Significant development of nociceptive neural circuits occurs during early postnatal life[9]. Painful or stressful stimuli, which are normally absent or limited during this critical developmental period, represent a unique sensory

experience that may result in permanent alterations in the afferent pathways of the newborn organism[23-28]. In human neonates, sensitization can be produced by repeated mechanical stimulation or heel lances and as a consequence of circumcision or surgery[29,30]. The neonatal nervous system appears particularly vulnerable and susceptible to plastic changes.

Our group has previously shown that neonatal colon pain or inflammation in rats can have a devastating effect on the physiology and function of the adult. Colon hypersensitivity, characterized by allodynia and hyperalgesia, could be observed two months after the initial injury despite the lack of an obvious pathology in the colon tissue. This hypersensitivity was shown to be associated with central neural and peripheral sensitization characterized by increased neuronal responses to CRD and a reduction in the thresholds of visceral nociceptors[1,16]. This was consistent with the work of others who have demonstrated the presence of central plastic changes in both somatic and visceral nociceptive systems[31-33], and also consistent with our earlier work on central processing of visceral nociception[34-36].

Generally, pelvic visceral input converges onto spinal neurons in the lumbosacral (LS) segments[37, 38] and hypogastric input onto thoracolumbar (TL) segments of the spinal cord. Many experiments have demonstrated that nociceptive afferent discharges in visceral afferents evoke profound central changes[31,32,39].

NMDA receptors and CRD

In somatic tissue, NMDA receptors contribute to the generation of central sensitization following tissue injury and inflammation[2,3]. Transient distension of the ureter evokes a pressor response that is inhibited by NMDA receptor antagonists[40]. Rice and McMahon[41] investigated the role of spinal NMDA receptors in central sensitization in an animal model of persistent visceral pain[12]. Likewise, NMDA receptor antagonists attenuated primary afferent[22,42] and spinal neuron responses to acute noxious and innocuous colorectal stimuli[13,43,44]. Our results indicated that, in control animals (without colon hypersensitivity), the lower doses of AP-7 had no effect on the neuronal response to noxious and innocuous CRD; while the higher dose of AP-7 lowered the neuronal response to noxious CRD. However, in chronic colon hypersensitivity rats in the absence of inflammation, lower doses of AP-7 significantly decreased the response to graded CRD as compared to the controls. These data support the proposition that spinal NMDA receptors contribute to chronic visceral hypersensitivity.

Non-NMDA receptors and CRD

Intrathecal administration of non-NMDA receptor antagonist, DNQX, was reported to attenuate enhanced reflex responses to mechanical stimulation of an inflamed colon, but was ineffective in non-inflamed rats[14]. On the other hand, systemically-administered DNQX attenuated spinal dorsal horn neuronal responses to noxious CRD in normal rats[45]. Our experiments showed that the response to noxious and innocuous CRD was dose-dependently attenuated by CNQX in 75% (6/8) and 71.4% (5/7) control neurons. But, the effect of CNQX on neuronal response to all intensities of CRD was more pronounced in CI rats than that in control rats. These results further support a role for spinal non-NMDA receptors in visceral sensory processing[19,35,46] .

In summary, a possible shift in the role of spinal NMDA and non-NMDA receptors residual to the neonatal injury may underlie the differential effects of AP-7 and CNQX between rats with neonatal CI and controls. These results further support the assertion that both spinal NMDA and non-NMDA receptors contribute to the central sensitization seen in adult rats with chronic visceral hypersensitivity and the conjecture that IBS pain may be associated with NMDA and non-NMDA receptors.

Abstract

AIM: To clarify the pathogenesis of biliary dilatation associated with anomalous union of the pancreatic and biliary ducts (AUPBD).

METHODS: Direct cholangiopancreatograms of 350 adult patients with or with suspicion of hepatobiliary or pancreatic disorders were reviewed. AUPBD was diagnosed cholangiopancreatographically, when the pancreaticobiliary ductal union was located above the narrow distal segment of the bile duct, which represents the action of the sphincter of Oddi. The narrow portion of the terminal choledochus was defined as symmetrical stricture of the common bile duct just above the pancreaticobiliary ductal union.

RESULTS: AUPBD was found in 36 patients. Among cholangiopancreatographic features, the narrow portion of the terminal choledochus was the most pathognomonic for AUPBD (accuracy, 98%); it was present in 29 (81%) patients with AUPBD, but was not found in any patients without AUPBD. Among patients with AUPBD, biliary dilatation (>10 mm) was more frequent in those with the narrow portion of the terminal choledochus (23/29) than in those without (2/7; P = 0.018) AUPBD. Among the patients with both AUPBD and the narrow portion of the terminal choledochus, there was a strong negative correlation between the minimum diameter of the narrow portion and the maximum diameter of the choledochus (r = -0.78, P<0.001), suggesting that the degree of biliary narrowing at the narrow portion correlates with that of upstream biliary dilatation.

CONCLUSION: The narrow portion of the terminal choledochus, a pathognomonic radiologic feature of AUPBD, may be a cause of biliary dilatation in patients with AUPBD.

INTRODUCTION

Anomalous union of the pancreatic and biliary ducts (AUPBD) is an uncommon congenital condition, which predisposes to various pancreaticobiliary disorders including congenital choledochal cyst[1-5], biliary cancer[6-8], and pancreatitis[9-12], and is more commonly seen in Asian than in Western countries[13]. This anomaly is defined as the pancreaticobiliary ductal union located above the action of the sphincter of Oddi as first described by Babbitt[1]. Although direct cholang-iopancreatography is the most reliable means of detecting this anomaly[14-16], the pathognomonic cholangiopancreatographic features of AUPBD have not been fully delineated.

AUPBD is frequently accompanied by biliary dilatation[1-5], but some patients with AUPBD show no biliary dilatation[8,17]. The causal relationship between AUPBD and biliary dilatation associated with this anomaly has not been fully established.

The aims of this study were to elucidate the cholang-iopancreatographic features specific to AUPBD and to clarify the pathogenesis of biliary dilatation associated with AUPBD, by analyzing direct cholangiopancreatograms of 350 Japanese adult patients with or without AUPBD.

MATERIALS AND METHODS

Patients

From January 1988 to July 1999, 535 consecutive adult patients with or with suspicion of hepatobiliary or pancreatic disorders underwent direct cholangiopancrea-

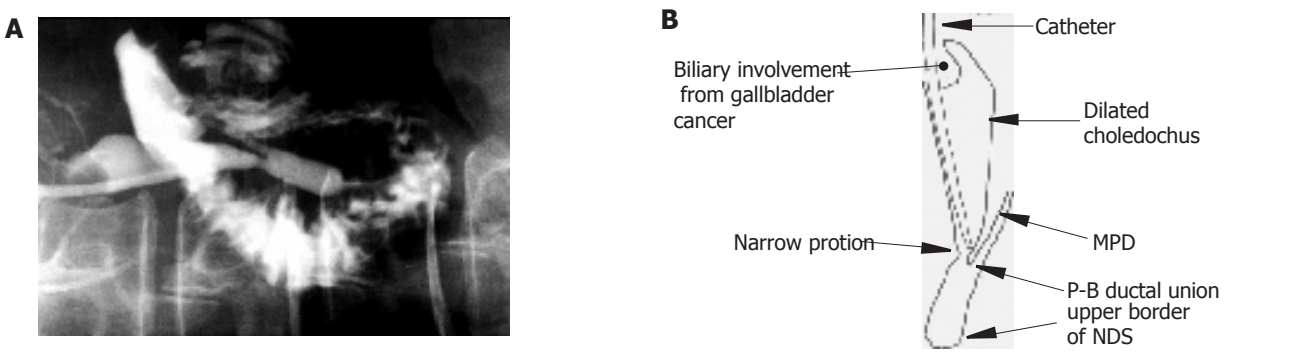

Figure 1 Endoscopic retrograde cholangiopancreatogram in a 55-year-old woman with gallbladder cancer associated with AUPBD and cylindrical biliary dilatation (**A**). Diagram of the cholangiopancreatogram (**B**). The minimum diameter of the narrow portion of the terminal choledochus is 4 mm, and the maximum diameter of the upstream choledochus is 15 mm. AUPBD: anomalous union of the pancreatic and biliary ducts; NDS: narrow distal segment; P-B ductal union: pancreaticobiliary ductal union; narrow portion: narrow portion of the terminal choledochus; MPD: main pancreatic duct.

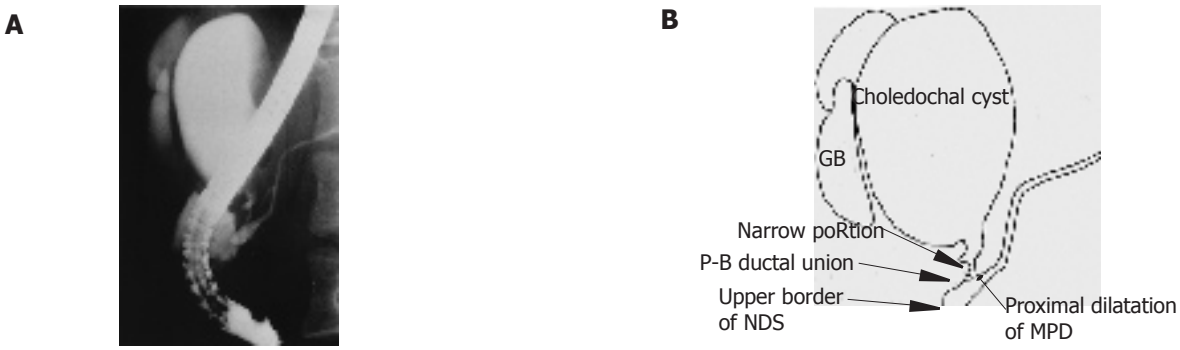

Figure 2 Endoscopic retrograde cholangiopancreatogram in a 21-year-old woman with AUPBD and cystic biliary dilatation (**A**). Diagram of the cholangiopancreatogram (**B**). The minimum diameter of the narrow portion of the terminal choledochus is 1.5 mm, and the maximum diameter of the upstream choledochus is 57 mm. Proximal dilatation of the MPD is also seen. AUPBD: anomalous union of the pancreatic and biliary ducts; NDS: narrow distal segment; P-B ductal union: pancreaticobiliary ductal union; narrow portion: narrow portion of the terminal choledochus; GB: gallbladder; MPD: main pancreatic duct.

tography before surgical intervention in our hospital. All were Japanese. Direct cholangiopancreatography included endoscopic retrograde cholangiopancreatography (ERCP) and percutaneous transhepatic cholangiography (PTC). One hundred and seventy-six patients were excluded due to biliary involvement from pancreaticobiliary malignancies which precluded opacification of the pancreaticobiliary ductal union, lack of opacification of one or both ducts, or failure to localize the pancreaticobiliary ductal union despite opacification of both ductal systems. Nine patients in whom the common bile and main pancreatic ducts entered separately into the duodenum were also excluded. The remaining 350 patients, in whom ERCP ($n = 324$) or PTC ($n = 26$) opacified the pancreaticobiliary ductal union, formed the basis of this retrospective study, including 174 women and 176 men with ages ranging from 18 to 86 years (median, 61 years). They included 118 patients with biliary malignancy, 118 with gallstone disease, 27 with liver tumor, 17 with pancreatic cancer, 16 with congenital choledochal cyst, 11 with chronic pancreatitis, and 43 with miscellaneous disorders.

Cholangiopancreatographic diagnosis of AUPBD

Although the criteria for AUPBD have not been standardized, the essential feature of this condition is the pancreaticobiliary ductal union located above the action of the sphincter of Oddi as first described by Babbitt[1]. Thus, in this study, AUPBD was diagnosed cholangiopancreatographically when the pancreaticobiliary ductal union was located above the narrow distal segment (NDS), which represents the functional region of the sphincter of Oddi (Figures 1 and 2)[8,16,17].

Terminology of cholangiopancreatographic features

Direct cholangiopancreatograms were reviewed in each of our patients to elucidate the presence or absence of the following major radiologic features: narrow portion of the terminal choledochus, biliary dilatation, and proximal dilatation of the main pancreatic duct.

The narrow portion of the terminal choledochus was defined as symmetrical stricture of the common bile duct just above the pancreaticobiliary ductal union and is a synonym for "stenosis of the distal choledochus"[3], "narrow segment distal to the common bile duct"[18], "narrow segment of the terminal bile duct"[19], "narrow portion of the choledochus"[20], "narrow segment of the common bile duct distal to choledochal cyst"[21], and "narrowed duct segment distal to the biliary cyst"[22]. The narrow portion of the terminal choledochus was always located just below choledochal cysts, when cysts were

Table 1 Diagnostic accuracy of cholangiopancreatographic features for the detection of AUPBD

Cholangiopancreatographic feature	Sensitivity(%)	Specificity(%)	Positive predictive value (%)	Negative predictive value (%)	Accuracy(%)
Narrow portion of the terminal choledochus (n = 29)	81	100	100	98	98
Biliary dilatation (>10 mm) (n = 25)	69	68	20	95	68
Proximal dilatation of the main pancreatic duct (>5 mm) (n = 7)	19	100	100	91	92

AUPBD: anomalous union of the pancreatic and biliary ducts.

present. The minimum diameter of the narrow portion of the terminal choledochus (if any) and the maximum diameter of the upstream choledochus were measured on cholangiopancreatograms in each patient (Figures 1 and 2).

Biliary dilatation was defined as a diameter exceeding 10 mm[17]. Biliary dilatation was classified as cystic, fusiform, or cylindrical based on its contours on cholangiopancreatogram[23].

Proximal dilatation of the main pancreatic duct was defined as the proximal portion of the main pancreatic duct with a diameter exceeding 5 mm[24,25].

Kune first demonstrated that the NDS of the bile duct as visualized on cholagiopancreatography represents the functional region of the sphincter of Oddi[26-28]. The NDS was defined as the region lying between the upper border of the "notch" of the bile duct, sudden narrowing of the choledochal lumen just above the ampulla of Vater[29], and the orifice of the ampulla of Vater (Figures 1 and 2).

Statistical analysis

Statistics were calculated with the SPSS 9.0 J software package for Windows (SPSS Japan Inc., Tokyo, Japan). Fisher's exact test and the Spearman's rank correlation were used for data analysis. P values of <0.05 were accepted as statistically significant.

RESULTS

AUPBD was diagnosed in 36 patients (10%) on direct cholangiopancreatograms, including 27 women and 9 men. They had concomitant pancreaticobiliary disorders, including congenital choledochal cyst (n = 16), gallbladder cancer (n = 13), benign gallbladder polyps (n = 3), chronic pancreatitis (n = 2), carcinoma of the common bile duct (n = 1), and adenomyomatosis of the gallbladder (n = 1).

Cholangiopancreatographic features specific to AUPBD

The accuracy of cholangiopancreatographic features for the detection of AUPBD is summarized in Table 1. The narrow portion of the terminal choledochus was present in 29 (81%) patients with AUPBD, but was not found in any patients without AUPBD.

Relationship between the narrow portion of the terminal choledochus and upstream biliary dilatation

In 36 patients with AUPBD, biliary dilatation was more frequent in patients with the narrow portion of the terminal choledochus (23/29, 79%) than in those without (2/7, 28%; P = 0.018) AUPBD. Thus, the presence of the narrow portion of the terminal choledochus was associated with upstream biliary dilatation.

Among the 29 patients with both AUPBD and the narrow portion of the terminal choledochus, there was a strong negative correlation between the minimum diameter of the narrow portion of the terminal choledochus and the maximum diameter of the upstream choledochus (r = -0.78, P < 0.001) (Figure 3). Thus, the degree of biliary narrowing at the narrow portion of the terminal choledochus correlated with that of upstream biliary dilatation.

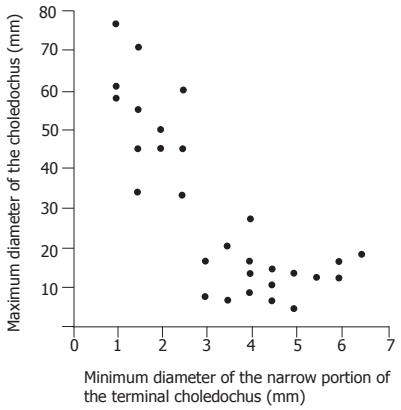

Figure 3 There was a strong negative correlation between the minimum diameter of the narrow portion of the terminal choledochus and the maximum diameter of the upstream choledochus (r = -0.78, P < 0.001).

Also, among the 29 patients with both AUPBD and the narrow portion of the terminal choledochus, a strong positive correlation was noted between patient's age and the minimum diameter of the narrow portion of the terminal

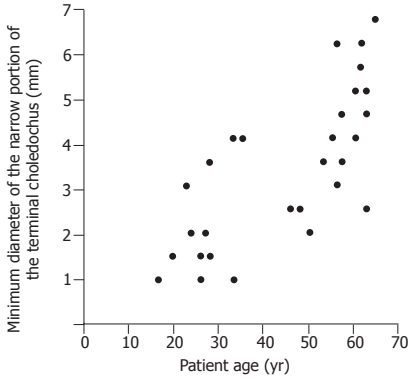

Figure 4 Patient's age was strongly correlated with the minimum diameter of the narrow portion of the terminal choledochus (r = 0.78, P<0.001).

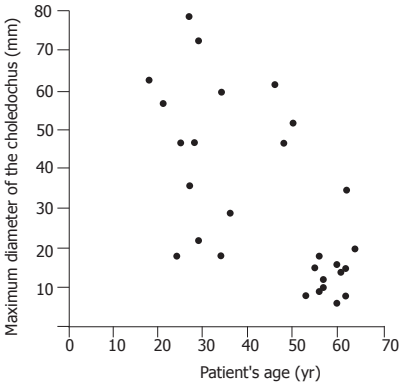

Figure 5 Patient's age was negatively correlated with the maximum diameter of the choledochus (r = –0.53, P = 0.001).

choledochus (r = 0.78, P < 0.001) (Figure 4), whereas there was a negative correlation between patient's age and the maximum diameter of the choledochus(r = -0.53, P = 0.001) (Figure 5). Thus, younger the patient, the more marked were the biliary narrowing at the narrow portion of the terminal choledochus and upstream biliary dilatation.

DISCUSSION

The narrow portion of the terminal choledochus is a characteristic feature of congenital biliary dilatation[18-22]. The current study demonstrated that it is also a pathognomonic feature of AUPBD. AUPBD is often associated with congenital biliary dilatation[2-5]. Thus, we hypothesized that the narrow portion of the terminal choledochus contributes to the development of upstream biliary dilatation frequently seen in AUPBD patients.

Previous studies from Japan reported a prevalence of AUPBD on ERCP ranging from 1.5% to 3.2%[6,10,30]. The extremely high prevalence of AUPBD in our series (10%) may be explained by the fact that our hospital is a tertiary referral center and that only surgical patients were included in this study.

While pancreaticobiliary ductal union located above the sphincteric action[16,17,31], long common channel[10,30], and concomitant cystic biliary dilatation[2-5] have been advocated as characteristic radiologic findings, the diagnostic significance of the narrow portion of the terminal choledochus has not been emphasized. The current study revealed that the narrow portion is present in most adult patients with AUPBD and is a pathognomonic radiologic feature of AUPBD. The narrow portion of the terminal choledochus is an important finding when diagnosing AUPBD by direct cholangiopancreatography.

Previous studies suggested that the narrow portion of the terminal choledochus may lead to the development of congenital biliary dilatation in pediatric patients[18,32,33]. Ito *et al*[18] reported that the length rather than the width of the narrow portion of the terminal choledochus is positively correlated with the degree of upstream choledochal dilatation in children with congenital biliary dilatation. Experimental studies revealed that bile duct obstruction causes cystic biliary dilatation in young animals, while it leads to cylindrical, not cystic, biliary dilatation in adult animals[32,34,35], suggesting that increased intraluminal pressure leads to cystic dilatation of the bile duct, only if the ductal wall is immature. This may explain the fact that cystic biliary dilatation is more common in pediatric patients[6,36] and that the degree of biliary dilatation was more marked in younger patients in our series. The current study is the first demonstration that biliary narrowing at the narrow portion correlates with upstream biliary dilatation even in adult patients with AUPBD. In summary, increased intraluminal pressure due to the narrow portion of the terminal choledochus may cause upstream biliary dilatation in both pediatric and adult patients with AUPBD, although the form of upstream biliary dilatation appears to differ between pediatric and adult patients.

Another possible cause of biliary dilatation in patients with AUPBD is the reflux of pancreatic juice into the bile duct. It has been reported that the refluxed pancreatic juice into the bile duct may lead to increased intraluminal pressure and dilatation of the bile duct[1,37,38]. However, the strong negative correlation between the minimum diameter of the narrow portion of the terminal choledochus and the maximum diameter of the upstream choledochus in the current study suggests that increased intraluminal pressure due to biliary narrowing, rather than refluxed pancreatic juice, may cause upstream biliary dilatation in patients with AUPBD.

Kusunoki *et al*[20,39] reported the presence of "oligoganglio-nosis" in the choledochal wall just below the cystic dilatation in patients with congenital choledochal cyst, suggesting that autonomic dysfunction at the "oligoganglionic" segment of the bile duct may play a role in the development of upstream biliary dilatation. This "oligoganglionic" segment appears to correspond to the narrow portion of the terminal choledochus, as defined in the current study, and may functionally obstruct biliary passage through the segment. It is unknown, however, whether the "oligoganglionosis" was present in our patients because histologic specimens of the narrow portion of the terminal choledochus were not available in any of our patients.

The limitations of the current study include the fact that it was retrospective, and that 176 patients were excluded due to inadequate opacification of the pancreaticobiliary ductal system. However, we feel that these limitations did not significantly influence the outcome of the study because the correlations between variables were too marked to have resulted from chance. The current results are the clearest demonstration to date of the causal relationship between the narrow portion of the terminal choledochus and upstream biliary dilatation in patients with AUPBD.

In conclusion, the narrow portion of the terminal choledochus is a pathognomonic radiologic feature of AUPBD and may be a cause of biliary dilatation in patients with AUPBD.

Abstract

AIM: To evaluate the influence of familiality on the prevalence of gallstone disease (GD) in Italy.

METHODS: Families of 79 subjects with gallstones (cases) and of 79 subjects without gallstones (controls) were investigated for the presence of gallstones by ultrasonography. Index cases and index controls were matched for age, sex, and operative unit. Sixty-three and sixty-two husbands and wives of index cases and index controls, respectively, were also studied.

RESULTS: Overall,the prevalence of GD was significantly higher (χ^2=14.52, P<0.001) in the 202 first-degree relatives of subjects with gallstones than that in the 201 first-degree relatives of subjects without gallstones (28.6% *vs* 12.4%, relative risk (RR) 1.80, 95% confidence interval (CI) 1.29-2.63). In particular, prevalence of GD was significantly higher in mothers, fathers, and sisters of index cases than that in the respective family members of index controls. The highest RR was observed in mothers (RR=2.35, 95%CI 1.38-4.3). Prevalence of GD was not obviously different in brothers and also in husbands and wives of index cases and index controls. Family members of index cases did not differ from family members of control cases with respect to the most important risk factors for gallstones (age, diabetes, BMI, and number of pregnancies) with an exception of a higher prevalence of diabetes in fathers of index controls than in fathers of index cases.

CONCLUSION: This study confirms that familiality plays a very important role in the pathogenesis of gallstones.

Key words: Gallstones; Familiality

INTRODUCTION

Gallstone disease (GD) is very common among the Western civilized countries. Nonetheless the literature concerning family inheritance is scarce, although consistent. Körner[1] collected 74 family pedigrees of probands with gallbladder disease and showed that gallstones were five times more common in families of affected individuals than in families of his control group. Van der Linden and Lindelöf[2] investigated the presence of gallstones in wives and husbands of subjects with gallstones and also in siblings of the same sex of the wife or husband, demonstrating the data of a clear 2:1 ratio in favor of familial occurrence. Because familial occurrence does not necessarily reflect genetic factors, Van der Linden and Westlin[3] studied the occurrence of GD in spouses who had lived together continuously and presumably shared the same environment, especially diet, during adult life. They found that women married to subjects with gallstones do not suffer more often from the disease than do other women.

The importance of familiality has been well identified also in epidemiological studies. Jorgensen[4] in Denmark demonstrated a relative risk (RR) of 2:1 in first degree relatives of gallstone patients. The Sirmione study[5] found a RR of 3.3:1 in sons of subjects with gallstones with respect to sons of subjects without gallstones. Similarly, in Israel[6] and in India[7] too, an elevated prevalence of gallstones has been demonstrated in family members of subjects with gallstones with respect to family members of subjects without gallstones. The MICOL study[8] demonstrated that subjects with a family history of GD are at an increased risk for the presence of gallstones in their gallbladder. To our knowledge, a formal family study for gallstones is lacking in Italy. We, therefore, aimed to evaluate the influence of familiality on the prevalence of GD in Italy.

MATERIALS AND METHODS

This study was performed in 16 operative units (5 in the north, 5 in the center and 6 in the south of Italy). Each operative unit was equipped with an ultrasonographic apparatus of similar characteristics (i.e., equipped with a 3.5-MHz linear transducer) and was instructed to follow an identical protocol (all the subjects were examined in the supine and left decubitus position).

Seventy-nine families of cases and 79 families of controls were enrolled in the study. All subjects with gallstones consecutively observed by the medical staff of the operative units were included as cases (case subjects), if at least one parent and a sibling were living and gave their consent to participate in the study. For each case subject, a control subject matching the sex and age (±3 years) was selected among those who attended the outpatient echographic services of the single operative unit and did not show any presence of gallstones or were previously submitted to cholecystectomy. Cases and controls were matched not only for age and sex, but they did not differ also for the other most important risk factors for gallstones: BMI, number of pregnancies (for females) and prevalence of diabetes (Table 1). Families without a matching family within the same operative unit were excluded from the calculations.

Table 1 Levels of the most important risk factors for gallstones in cases with or without gallstones

	Cases $n=79$	Controls $n=79$	*P*
Male/female (*n*)	30/49	30/49	NS
Age (yr); mean (CI)	48.6 (45.8–51.4)	48.5 (45.7–51.4)	NS
BMI; mean (CI)	25.5 (24,9–26.4)	25.7 (24.7–26.7)	NS
Number of pregnancies (females); mean (CI)	1.71 (1.29–2.13)	1.47 (1.04–1.89)	NS

All the available first degree relatives of cases were invited to participate in the study. Husbands and spouses were also studied, when available. Participations among living first degree relatives of cases and controls were 82% and 80%, respectively; among living spouses and husbands of cases and controls were 88% and 89%, respectively. A precoded questionnaire regarding personal, physiological and pathological history, dietary habits and number of pregnancies (females) was administered by a member of the medical staff to all the family members. Each family subject was also submitted to anthropometric measurements (weight and height) and ultrasonographic examination of the biliary tract. BMI was calculated by dividing the weight (kg) by the square of height (m).

Subjects were considered as having GD, if they showed presence of gallstones in their gallbladder or had already been submitted to cholecystectomy.

Statistical analysis

All statistical analyses were carried out with the NCSS statistical software program, 329 North 1000 East Kaysville, UT 84037, USA. The Student's *t*-test and the χ^2 test were used when appropriate. A *P* value less than 0.05 was considered statistically significant. We computed Mantel-Haenszel estimates of RR with 95% confidence intervals (CI).

RESULTS

Overall, prevalence of GD was significantly higher (χ^2=14.52, *P*<0.001) in the 202 first-degree relatives of subjects with gallstones than that in the 201 first-degree relatives of subjects without gallstones (28.6% *vs* 12.4%, RR 1.80, 95%CI 1.29-2.63)(Table 1).

In particular, 13 of the 31 (41.9%) fathers of the index cases and 6 of the 34 fathers of the index controls had GD. The difference was significant according the χ^2 test although the lower limit of the 95%CI of the RR was below 1 (Table 2). Fathers of cases and controls did not differ for age and BMI, but fathers of controls had a significantly higher prevalence of diabetes (Table 2).

Prevalence of GD was significantly higher among the 51 mothers of index cases as compared to the 51 mothers of index controls (56.9% *vs* 21.6%, RR 2.35 95%CI 1.38-4.3, Table 2). Mothers of cases did not differ from mothers of controls as far as the most important risk factors for gallstones were concerned, i.e. age, BMI, prevalence of diabetes, and number of pregnancies.

Brothers of cases and brothers of controls (Table 3) showed similar prevalences of GD and similar levels of risk factors for gallstones, i.e. age, BMI, and prevalence of diabetes. Among the sisters, prevalence of GD

GD (%)	10.0	8.5	25.6[a]	9.1

[a]$P<0.05$ *vs* controls ($\chi^2=4.04$; RR = 2.03 [0.94-6.22 95%CI])

was significantly higher among the sisters of index cases as compared to the sisters of controls (25.6% *vs* 9.1%; $\chi^2=4.04$, $P<0.05$), but the lower limit of the RR confidence interval was below 1 [RR = 2.03 (0.94-6.22 95%CI)]. The sisters of cases and sisters of controls did not differ in age, BMI, prevalence of diabetes, and number of pregnancies.

None of the sons of the cases and controls had GD.

No significant difference was observed in prevalence of GD among husbands and spouses of the index cases and controls (Table 4). Husbands and wives of index cases or controls also did not differ for the most important risk factors for gallstones (Table 4).

GD (%)	9.5	11.2	NS

DISCUSSION

This study confirms that genetic factors play a very important role in the pathogenesis of GD. Overall, the prevalence of GD was significantly higher in the first-degree relatives of subjects with gallstones than in those of subjects without gallstones. The highest relative risks were found in female family members (mothers and sisters). This finding might be explained by the fact that GD is inherited as a sex-linked dominant trait. One might argue that an increased familial prevalence of gallstones might not necessarily involve a genetic defect, but rather reflects a common environmental risk factor. However, our results regarding the prevalence of GD in husbands and wives of index cases and index controls were in agreement with previous data by Van Der Linden and Westlin[3] and Leoci *et al*[9]. On the other hand, family members of index cases and control cases had similar levels of the most important risk factors for GD. These results support the hypothesis that the differences in GD prevalences were due to genetic rather than to environmental factors.

The results of our study further confirmed that a positive family history of GD might be included among the variables that can be used in order to select populations with a higher prevalence of gallstones than that predicted simply on the basis of age and sex. Using a similar approach[10], we were able to demonstrate that selection of subjects with multiple factors associated with gallstones increases the a priori probability of gallstone diagnosis by a factor 2 in females and 3 in males.

Some studies have identified genes (Lith1 on Chr 2, Lith 2 on Chr 19, Lith 3 on Chr 17) that are resporsible for increased gallstone formation in mice[11-18]. Although there is no evidence yet, that any of the Lith genes in the mouse is important in human gallstone susceptibility, some are likely to be and an era of "pre-gallstone disease" identification and possibly prevention seems open.

Abstract

AIM: To study the *in vitro* and *in vivo* inhibitory effects of genistein on invasive potential of Bel 7402 hepatocellular carcinoma (HCC) cells and to explore the underlying mechanism.

METHODS: Bel 7402 HCC cells were exposed to genistein. The invasive activity of tumor cells was assayed in transwell cell culture chamber. $p125^{FAK}$ expression and cell cycle were evaluated by a functional assay. Cell apoptosis analysis was performed with TUNEL method. In addition, bilateral subrenal capsule xenograft transplantation of HCC was performed in 10 nude mice. Genistein was injected and the invasion of HCC into the renal parenchyma was observed. Microvessels with immunohistochemical staining were detected.

RESULTS: Genistein significantly inhibited the growth of Bel 7402 cells, the inhibitory rate of tumor cells was 26–42%. The invasive potential of Bel 7402 cells *in vitro* was significantly inhibited, the inhibitory rate was 11–28%. Genistein caused G2/M cell cycle arrest, S phase decreased significantly. The occurrence of apoptosis in genistein group increased significantly. The expression of $p125^{FAK}$ in 5 μg/mL genistein group (15.26±0.16%) and 10 μg/mL genistein group (12.89±0.36%) was significantly lower than that in the control group (19.75±1.12%, $P<0.05$). Tumor growth in genistein-treated nude mice was significantly retarded in comparison to control mice, the inhibitory rate of tumor growth was about 20%. Genistein also significantly inhibited the invasion of Bel 7402 cells into the renal parenchyma of nude mice with xenograft transplant. The positive unit value of microvessels in genistein-treated group (10.422 ± 0.807) was significantly lower than that in control group (22.330 ± 5.696, $P < 0.01$).

CONCLUSION: Genistein can effectively inhibit the invasive potential of Bel 7402 HCC cells by altering cell cycle, apoptosis and angiogenesis, inhibition of focal adhesion kinase may play a significant role in this process.

INTRODUCTION

Genistein (5,7,4'-trihydroxyisoflavone), an isoflavinoid in soy beans, has been identified as a potential cause for the low incidence of certain types of tumor such as breast cancer, gastric cancer, colon cancer, prostate cancer, *etc.*[1-4]. As a natural tyrosine kinase inhibitor[5-7], genistein can suppress the formation and development of these tumors[8-11]. However, only limited data are available to demonstrate the effects of genistein on human HCC. The purpose of this study was to investigate the invasive potential and apoptotic effects of genistein *in vitro* and *in vivo* on HCC cells and to gain insights regarding the underlying mechanism mediating the effects of genistein.

MATERIALS AND METHODS

Cell culture and genistein

The human HCC cell line, Bel 7402, was obtained from Cancer Institute of Sun Yat-Sen University in Guangzhou. The cells were maintained in RPMI 1640 medium supplemented with 10% fetal bovine serum (FBS), penicillin (100 U/mL), and streptomycin (100 μg/mL) and cultured at 37 °C in a humidified atmosphere containing 50 mL/L CO_2 in air. Genistein purchased from Sigma

Chemical Co. was suspended in dimethylsulfoxide (DMSO) for the experiments.

In vitro assays of Bel 7402 cell growth and viability

The cells were seeded at the density of 1×10^4 cells with 1mL of medium/well onto 24 plates and incubated with or without genistein for 6 d. On the indicated day thereafter, cells were trypsinized and the number of cells was scored. An equivalent volume of DMSO was added to control cultures.

Cell viability was assayed using methyl thiazol tetrazolium (MTT) method. A 96-well plate was incubated with exponentially growing cells at the density of 1×10^4/well, following incubation of Bel 7402 cells with or without genistein in different columns of 96-well microtiter plates on d 1, 3, 5, and 7, MTT was added to each well and incubated at 37 °C for further 4 h before 595 nm absorbance (A_{595nm}) was detected. Each assay was performed in quadruplicate.

Inhibitory rate of tumor cell growth = (average $A_{595\ nm}$ value of control group-average $A_{595\ nm}$ value of genistein group)/average $A_{595\ nm}$ value of control group[12].

In vitro assays of Bel 7402 cell adhesion and invasion

Ninety-six-well microtiter plates were precoated with 20 mg/L fibronectin and incubated at 4 °C overnight. Wells were blocked with 2% BSA for 45 min at 37 °C. The cells were cultured in 2% serum-containing medium for 24 h, harvested at about 70% confluency, resuspended in serum-free RPMI 1640 medium supplemented with 0.1% BSA and distributed to wells (8×10^4/well). The cells were incubated at 37 °C in a 50 mL/L CO_2 atmosphere for 20, 40, 60, and 90 min with or without genistein. The wells were washed thrice with PBS to remove unattached cells, then the attached cells were incubated with MTT and the absorbance was measured at 595 nm. Each assay was performed in triplicate.

Adhesion rate = average $A_{595\ nm}$ value of genistein group/average $A_{595\ nm}$ value of control group×100%.

Inhibitory rate of adhesion = (average $A_{595\ nm}$ value of control group-average A595 nm value of genistein group)/average A595 nm value of control group×100%.

The invasive activity of Bel 7402 cells was assayed in transwell cell chambers (Corning Inc., USA), according to the method reported by Kido *et al*[13]. The basement membrane Matrigel was obtained from the Department of Cell Biology, Peking University Health Science Center. Polyvinylpyrrolidone-free polycarbonate filters with an 8.0-μm pore size were precoated with 5 μg of fibronectin in a volume of 50 μL on the lower surface. The Matrigel was diluted to 100 μg/mL with cold PBS and applied to the upper surface of the filters (5 μg/filter), and dried overnight under a hood at room temperature. The coated filters were washed extensively in PBS, and then dried immediately before use. Log-phase cell cultures of Bel 7402 cells were harvested and washed thrice with serum-free RPMI 1640, and resuspended to a final concentration of 2×10^6/mL in RPMI 1640 with 0.1% BSA. Cell suspensions (100 μL) with or without genistein were added to the upper compartment and incubated for 10-20 h at 37°C in a 50 mL/L CO_2 atmosphere. The filters were fixed with methanol and stained with Giemsa. The cells on the upper surface of the filters were removed by wiping with cotton swabs. The cells invading the lower surface of the filter through Matrigel and filter were manually counted under a microscope at a magnification of ×400, and each assay was performed in triplicate.

Invasion rate = average cell numbers invading the lower surface of the filter in genistein group/average cell numbers invading the lower surface of the filter in control group×100%.

Inhibitory rate of invasion=(average cell numbers invading the lower surface of the filter in control group-average cell numbers invading the lower surface of the filter in genistein group)/average cell numbers invading the lower surface of the filter in control group×100%.

Cell cycle analysis

Bel 7402 cells were seeded at the density of 5×10^5/well in six-dishes. After 24 h, the cells were treated with or without genistein for 72 h and harvested by trypsinization. The cells were then centrifuged at 300 r/min for 10 min, washed in PBS, and resuspended in cold 70% ethanol. The cells were then subjected to flow cytometric analysis on a FACScan cytofluorimeter (Becton Dickinson) after propidium iodide labeling.

Detection of focal adhesion kinase expression by flow cytometry assay

On d 3 of cell culture, control and genistein-treated Bel 7402 cells were centrifuged at 300 r/min for 10 min, washed and fixed in 1 mL 70% ethanol at 4 °C, treated with 0.1% Triton X-100 and 1% FBS, and anti-focal adhesion kinase (FAK C-20 sc-558, Santa Cruz Biotechnology, Inc., USA) and IgG1 (1 ∶ 100) were added. Cells were then treated with RNAse (1 mg/mL, Sigma, USA) and propidium iodide (10 μg/mL) for 30 min at room temperature. FAK expression was measured using a FACScan cytofluorimeter (Becton Dickinson).

Terminal deoxynucleotidyl transferase-mediated dUTP nick end-labeling (TUNEL) assay

Control cells and genistein-treated cells were harvested at 72 h by trypsinization and collected by centrifugation. Cells were washed twice in PBS-0.1% bovine serum albumin and prepared for TUNEL assay. Cells were fixed for 30 min in 4% paraformaldehyde, washed twice in PBS, and then permeabilized in 0.1% Triton-X 100 and 0.1% sodium citrate. Cells were labeled with terminal deoxynucleotidyl transferase for 60 min at 37 °C in a dark humidified incubator. The samples were washed twice, resuspended in 500 μL of PBS, and then analyzed on a FACScan cytofluorimeter (Becton Dickinson).

In vivo experiments

Six-week-old male BALB/C nu/nu mice were obtained from the Medical Laboratory Animal Center, Sun Yat-Sen University, China. They were kept under sterile conditions

in autoclaved cages with filter bonnets in laminar flow units and fed with sterilized MF pellets and distilled water. The mice were maintained in accordance with institutional accredited guidelines.

Bel 7402 cells were grown to 80-90% of confluence and detached with 0.25% trypsin. The cells were washed twice, counted, and resuspended in PBS at 1×10^7/mL (viability over 95%). Cells (0.3 mL) were injected into the male nude mice. Each animal received two injections, one on each side of the neck. Animals were killed 3 wk after tumor inoculation, when the largest tumors reached about 10 mm in diameter. Surgical excision of primary tumor was carried out, and tumor tissues were cut into 1-mm^3 pieces for bilateral subrenal capsule xenograft transplantation in next 10 nude mice anesthetized with chloral hydrate. The xenograft volume was assessed and calculated by the formula: length×width×depth×0.5236.

Mice bearing subrenal capsule xenograft transplant were randomly selected for the treatment with genistein ($n = 5$) and those without genistein treatment served as control ($n = 5$). Genistein (50 mg/kg) was administered ip daily to each mouse in genistein group for 15 d, while control animals were given the same vehicle. The animals were killed by cervical dislocation 16 d after transplantation of the tissues. Autopsies were performed and the kidney was excised, fixed, and embedded in paraffin, and examined histologically. The inhibitory rate of transplant growth was calculated by comparing the changes in xenograft transplant volume[15,16]. The criteria for invasive capacity of tumor cells in subrenal capsule xenograft transplant were as previously described[14,16,17].

Immunohistochemical determination of angiogenesis

After deparaffinization, dehydration, and washing, sections from xenograft transplant were incubated with trypsin at 37 °C for 30 min, quenched with 0.3% H_2O_2-methanol for 30 min, and blocked with 10% normal goat serum in a buffer containing 100 mL of PBS, 1.0 g of BSA, and 0.1 mL of Tween-20. The sections were treated with a rabbit polyclonal antibody against human factor VIII-related antigen at a 1∶100 dilution with the PBS-BSA-Tween-20 buffer, followed by a biotinylated universal antibody at a 1∶100 dilution. The sections were then treated with avidin-biotin complex followed by 3,3-diaminobenzidine as a substrate for staining. Positive unit (PU) of the microvessels with staining was tested and calculated according to the method described by Shen[17].

Statistical analysis

The statistical significance of difference between the groups was determined by applying the one-way ANOVA and χ^2 using the Stata 6.0 program.

RESULTS

In vitro effects of genistein on Bel 7402 cell growth

Genistein significantly inhibited Bel 7402 cell growth over the 7 d of experiment. The inhibitory rate of tumor cell growth in 5 and 10 μg/mL genistein groups was 26.71%±10.2% and 42.64±16.1%, respectively. The inhibitory rate of tumor cell growth in 10 μg/mL genistein group was significantly higher than that in 5 μg/mL genistein group ($P<0.01$). The dose-dependent effects of genistein on Bel 7402 cell growth are presented in Figure 1.

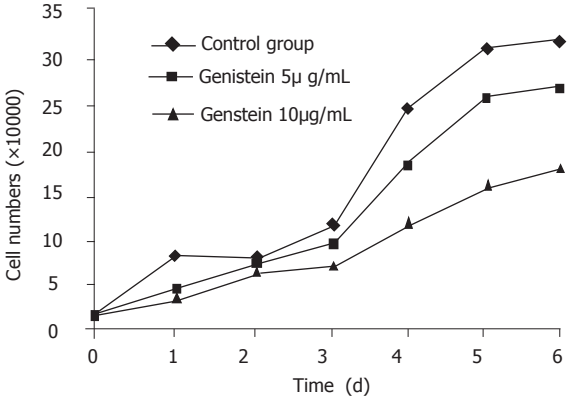

Figure 1 Effects of genistein on Bel 7402 cell proliferation *In vitro* effects of genistein on adhesion and invasion of Bel 7402 cells.

The adhesion rate of Bel 7402 cells for 20, 40, 60, and 90 min was 30.61%, 56.48%, 61.89% and 81.55% in 5 μg/mL genistein group, and 17.78%, 15.82%, 42.98% and 64.48% in 10 μg/mL genistein group. The inhibitory rate of Bel 7402 cells for 20, 40, 60, and 90 min was 69.39%, 43.52%, 38.11%, and 18.45% in 5 μg/mL genistein group, and 82.22%, 84.18%, 57.02%, and 35.52% in 10 μg/mL genistein group. Our results showed that genistein could inhibit tumor cell adhesion to fibronectin-coated substrates in a concentration-dependent fashion, and more potent inhibitory effect of genistein on adhesion occurred within 40 min.

We also investigated the capability of metastatic tumor cells through reconstituted basement membrane Matrigel. The cells invading the lower surface of the filter through Matrigel in control group, 5 μg/mL genistein group, and 10 μg/mL genistein group were 243.7±12.6/filed, 216.7±21.3/filed, and 174.5±9.6/filed, respectively. The invasion rate in 5 and 10 μg/mL genistein group was 88% and 71%, respectively, the inhibitory rate of invasion was 11% and 28%, respectively. Our results showed that genistein could inhibit the in vitro invasion of Bel 7402 cells, the inhibitory effect on invasion of Bel 7402 cells in 10 μg/mL genistein group was more significant than that in 5 μg/mL genistein group ($P<0.05$).

In vitro effects of genistein on cell cycle progression

Bel 7402 cells treated with genistein in the G0/G1 and G2/M phases increased significantly than cells in control group, the increase of cells in G0/G1 and G2/M phases was more remarkable in 10 μg/mL genistein group than in 5 μg/mL genistein group ($P<0.05$). S fractions decreased significantly in cells treated with genistein ($P<0.05$). Percentage of apoptotic cells in genistein-treated

group increased significantly compared to that in control group (P<0.05). The results of cell cycle analysis by flow cytometry in Bel 7402 cells are presented in Table 1.

Table 1 Effects of genistein on cell cycle progression in Bel 7402 cell line (mean±SD)

Treatment	Cell cycle phase			Apoptosis (%)
	G0/G1 (%)	G2/M (%)	S (%)	
Control	64.58±8.46	0.78±0.02	34.64±1.36	0.47±0.01
Genistein 5 μg/mL	71.74±4.46	2.75±0.03[b]	25.50±2.28[b]	1.02±0.06[a]
Genistein 10 μg/mL	75.27±6.12[ac]	6.37±0.08[d]	18.36±1.53[b]	2.12±0.12[b]

[a]P<0.05 *vs* control; [b]P<0.01 *vs* control; [c]P<0.05 *vs* 5 μg/mL genistein; [d]P<0.01 *vs* control and 5 μg/mL genistein.

Effects of genistein on induction of apoptosis of Bel 7402 cells

TUNEL assay in our studies showed that the percentage of cells undergoing apoptosis was significantly higher in 10 μg/mL genistein group (1.05±0.09%) and 5 μg/mL genistein group (0.80±0.12%) than in control group (0.43±0.08%, P<0.01 and P<0.05, respectively) being consistent with genistein's ability to induce apoptosis observed in cell cycle analysis.

Evaluation of expression of p125^{FAK} protein

We investigated whether genistein could modulate protein expression of the signal transduction molecule-p125FAK. After 72-h treatment with genistein, p125FAK expression in 10 μg/mL genistein group (12.89±0.36)% was significantly lower than that in control group (19.75%±1.12%, P<0.05). p125FAK expression in 5 μg/mL genistein group (15.26±0.16)% also decreased, but there was no statistically significant difference between 5 μg/mL genistein group and control group (P>0.05).

Effects of genistein on growth of subrenal capsule xenograft transplant

The anti-tumor activity of genistein was evaluated in nude mice bearing subrenal capsule xenograft transplant. Treatment with genistein inhibited the local tumor growth significantly compared to the control group. At the end of the treatment (15 d post implantation), the increase of tumor volume in genistein group (63.32±8.96 mm^3) was significantly less than that in control group (79.25±6.85 mm^3, P<0.05). Tumors in mice treated with genistein reduced in volume by 20% compared to the control group.

Effects of genistein on in vivo tumor invasion

The criteria for invasive capacity of tumor cells in subrenal capsule xenograft transplant were as previously described[17]. The 0-IV invasion rank to renal parenchyma was recorded[14,16]. In the control group, invasion rank 0 was observed in 1 of 10 mice (1/10), invasion rank I in 8 of 10 mice (8/10), and invasion rank II in 1 of 10 mice (1/10). In genistein-treated group, invasion rank 0 was observed in 8/10, rank I in 2/10 and rank II in 0/10 mice. No rank III or rank IV invasion was observed in both groups. Our results showed that treatment with genistein could significantly inhibit the invasion of Bel 7402 cells to the renal parenchyma (P<0.05). Hematoxylin-eosin stained specimens are shown in Figure 2.

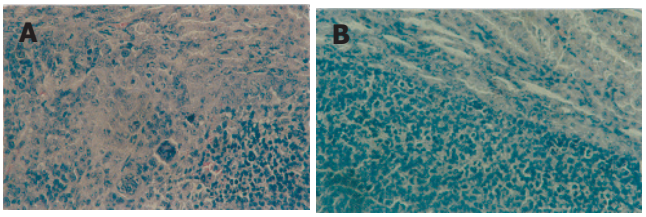

Figure 2 Tumor invasion of renal parenchyma in control (**A**) and genistein-treated nude mice (**B**). HE, magnification ×200.

Effects of genistein on tumor angiogenesis

In untreated tumor tissues, tumor cells were arranged in large nests with plenty of blood sinusoids. Whereas, in genistein-treated tumor tissue, tumor cells were characterized by small cancerous nests with scanty blood vessels. PU value of microvessels in the subrenal capsule xenograft transplant, as a marker of tumor angiogenesis, significantly decreased in genistein group (10.422±0.807) compared to that in control group (22.330±5.696, P<0.01). Immunohistochemical staining for the determination of angiogenesis in subrenal capsule xenograft transplant of the nude mice is shown in Figure 3.

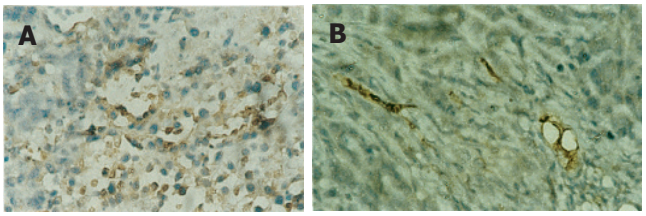

Figure 3 Tumor tissue with plenty of blood vessels (**A**) and scanty blood vessels (**B**) in control and genistein-treated nude mice. HE, magnification ×200.

DISCUSSION

Invasion and metastasis are the most devastating aspects of cancer. Advances in surgical techniques and adjuvant therapies have been proved to be useful in the treatment of primary tumors[18]. However, invasion and metastasis remain a major cause of poor prognosis and death in cancer patients. Reports from epidemiological and experimental studies indicate that genistein plays an important role in the prevention and inhibition of tumors such as breast cancer, prostate cancer, colon cancer, leukemia, melanoma, *etc*.[19]. However, there are still a few reports of studies on the correlation between genistein and the invasion and metastasis of human HCC. Our data provide evidence that genistein can also inhibit HCC cell proliferation and invasion.

In this report, we haveshould for the first time that genistein could significantly inhibit the growth and

viability of Bel 7402 cells. The inhibitory rate of tumor cell growth was about 26%-42%. We also found that genistein induced cell cycle arrest in the G0/G1 and G2/M phases. These findings are in agreement with other reports[19-24]. Although the exact mechanisms of genistein await further elucidation, induction of apoptosis may be partly responsible[25-27]. In our studies with TUNEL assay, the percentage of Bel 7402 cells undergoing apoptosis was significantly higher in genistein group than in control group, which is consistent with those found in other studies[28,29].

The adhesion and invasiveness of tumor cells represent some important properties necessary for the formation of metastases. We investigated the effect of genistein on the adhesive properties of Bel 7402 cells, and found that genistein could inhibit tumor cell adhesion to fibronectin-coated substrates, the most potent inhibitory effect of genistein on adhesion occurred within 40 min, demonstrating that reduction in cell adhesion after the treatment with genistein may account for the ability of Bel 7402 cells to transgress normal tissue boundaries and disperse to the adjacent sites. The invasion assay both *in vitro* and *in vivo* was further performed in our experiments. Bel 7402 cells invading the lower surface of the filter through Matrigel was significantly inhibited in genistein-treated groups compared to control group. Our experiments with the subrenal capsule xenograft transplant of nude mice showed that the treatment with genistein could significantly inhibit the invasion of Bel 7402 cells to the renal parenchyma, which was correlated with the biological behavior *in vitro*.

Inhibition of angiogenesis was observed in our studies. Angiogenesis is virtually absent in the healthy adult organism and is restricted to a few conditions including wound healing, placenta, endometrium, etc., representing the ordered and self-limited processes[30,31]. In certain pathological conditions, angiogenesis is dramatically enhanced and is no longer self-limited[30]. The most important manifestation of pathological angiogenesis is induced by solid tumors[32]. In our immunohistochemical studies, tumor cells were characterized by small cancerous nests with scanty blood vessels in genistein-treated mice. The PU value of microvessels was significantly decreased in genistein group compared to the control group. As angiogenesis is an important step in the invasion and metastasis process of tumors[33,34], the changes in angiogenesis caused by genistein may play a crucial role in inhibition of the invasiveness of Bel 7402 cells.

FAK is a cytoplasmic tyrosine kinase that plays an important role in integrin-mediated signal transduction pathways closely related to cell adhesion, motility, and growth[35-39]. Upregulation of FAK expression is associated with oncogenesis[40-43] and decrease in FAK is associated with the loss of ability to attach, decreased migration and induction of apoptosis[44-48]. We have reported that FAK is overexpressed in HCC, the expression of FAK in invasive or metastatic HCC is significantly higher than that in non-invasive or non-metastatic HCC[16]. Therefore, FAK seems to be an important pharmacologic target site[49]. In the present study, a significant downregulation of p125FAK after genistein treatment was observed, suggesting that genistein may serve as a potential important anticancer agent for HCC progression by blocking the FAK signaling process, which play a crucial role in angiogenesis and apoptosis.

In summary, our results provide the preliminary evidence that genistein is an effective chemopreventive agent for HCC. Further in-depth studies coupled with clinical trials are needed to establish the scientific basis for the use of genistein in the prevention and treatment of HCC.

Abstract

AIM: To investigate the effect of *H pylori* eradication on atrophic gastritis and intestinal metaplasia (IM).

METHODS: Two hundred and fifty-nine patients with atrophic gastritis in the antrum were included in the study, 154 patients were selected for *H pylori* eradication therapy and the remaining 105 patients served as untreated group. Gastroscopy and biopsies were performed both at the beginning and at the end of a 3-year follow-up study. Gastritis was graded according to the updated Sydney system.

RESULTS: One hundred and seventy-nine patients completed the follow-up, 92 of them received *H pylori* eradication therapy and the remaining 87 *H pylori*-infected patients were in the untreated group. Chronic gastritis, active gastritis and the grade of atrophy significantly decreased in *H pylori* eradication group ($P<0.01$). However, the grade of IM increased in *H pylori* -infected group ($P<0.05$).

CONCLUSION: *H pylori* eradication may improve gastric mucosal inflammation, atrophy and prevent the progression of IM.

Key words: *H pylori*; Atrophic gastritis; Intestinal metaplasia

INTRODUCTION

H pylori-infected gastric mucosa evolves through stages of chronic gastritis, glandular atrophy (GA) and intestinal metaplasia (IM) which is a main cause of intestinal type of gastric adenocarcinoma. *H pylori* infection induces gastric epicyte apoptosis. The index of apoptosis and proliferation decrease after *H pylori* eradication[1,2]. *H pylori* eradication can prevent gastric cancer. Whether the precancerous lesions are reversed or terminated after *H pylori* eradication is crucial to evaluate this therapy for a preventive purpose. To investigate the histological changes in the gastric mucosa, we followed up chronic atrophic gastritis patients who received *H pylori* eradication therapy for 3 years.

MATERIALS AND METHODS

A total of 259 *H pylori*-infected patients, who were diagnosed as having antral atrophic gastritis (without organic gastropathy, e.g., ulcer, tumor, etc.) by gastroscopy and biopsy in our hospital during 1997 to 1999, were followed up in our study; 154 of them received *H pylori* eradication therapy and the remaining 105 did not receive *H pylori* eradication therapy. Patients who failed to respond to *H pylori* eradication therapy and had uncertain *H pylori* infection were excluded. Patients who did not return for re-evaluation or became *H pylori* negative without receiving *H pylori* eradication therapy were also excluded. A total of 179 patients including 82 men and 97 women aged 30-74 years (92 in the *H pylori* eradicated group and 87 in the control group) completed the 3-year follow-up study.

All the subjects underwent gastroscopy when they entered the study and fulfilled the 3-year follow-up; some patients underwent gastroscopy every year. During gastroscopy, 3 antral biopsy specimens (from the greater and lesser curvatures 2-3 cm from the pylorus) were taken. One antral biopsy specimen was submitted to rapid urease test (RUT) and the other two were cut into sections for histological examination.

The patients were confirmed to have *H pylori* infection only when both RUT and histological stain (modified Giemsa stain) produced positive results. Otherwise they were considered as non-*H pylori*-infected healthy volunteers. Uncertain cases that were positive in one test and negative in the other test should be excluded. After they were treated for more than 4 wk, *H pylori* status was determined by ^{14}C-urea breath test.

Biopsy specimens were stained with H&E. A single pathologist, who was unaware of the conditions of the patients and assigned treatment of biopsies, performed

the histological assessment. The gastritis was graded using the visual analog scales of the updated Sydney system[3] as none (0), mild (1), moderate (2), or marked (3). Histological grading of the same subject before and 3 years after the therapy was compared and classified as improvement, no improvement, or exacerbation.

To eradicate *H pylori* infection, the patients received omeprazole (20 mg) or lansoprazole (30 mg), clarithromycin (500 mg), amoxicillin (1 g) or furazolidone (0.1 g), twice daily for 1 wk. During the whole follow-up period, two group patients received expectant treatment.

Statistical analysis

The results of histology score were expressed as mean. The differences between the two groups before treatment with respect to histological grades were calculated using Mann-Whitney *U* test. Changes in histological grading in *H pylori* eradication and control groups before and 3 years after the treatment were compared by Stuart-Maxwell test. Differences in the proportions of histological grading with improvement, no improvement and exacerbation between two groups were made using the χ^2 test. $P<0.05$ was considered statistically significant (two-sided).

RESULTS

The *H pylori* eradicated group and control group were comparable in age and sex ratio ($P>0.05$). At entry into the study, the percentage of mild and moderate GA was 75% in *H pylori*-eradiated group and 25% in control group. The percentage of mild, moderate and marked GA was 77%, 21.8% and 1.2%, respectively. IM was 51% in *H pylori*-eradicated group and 58.6% in control group.

Active (AI) and chronic inflammation (CI) were found in both groups. Overall, the pretreatment histological scores were comparable in two treatment groups (Table 1).

Histological scores in paired samples before and after 3-year treatment in two groups are shown in Table 2.

After cure of infection, scoring of CI, AI and GA decreased significantly ($P<0.01$) and that of IM increased slightly with no significant difference ($P>0.05$). In control group, scoring of IM increased significantly ($P<0.05$), but that of other pathologic changes had no statistical significance ($P>0.05$).

The histological changes in paired samples before and after 3-year treatment in *H pylori*-eradicated group and control group are shown in Figure 1. CI and AI were improved by 38.04% and 63.04% in *H pylori*-eradicated group, but only by 17.24% and 21.84% in the control group ($P<0.01$). The GA was improved by 28.26% in the treatment group and 14.94% in the control group. GA was exacerbated by 4.35% in treatment group and 4.6% in control group ($P>0.05$). IM was improved by 23.91% and exacerbated by 31.52% in *H pylori*-eradicated group, and by 20.69% and 33.33% in the control group ($P>0.05$).

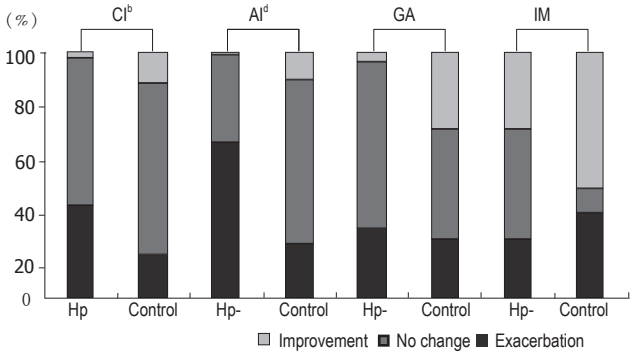

Figure 1 Percentage changes in gastric histology 3 years after treatment in *H pylori*-eradicated group and control group. [b]$P<0.01$, [d]$P<0.001$ *vs* baseline. CI: chronic inflammation; AI: active inflammation; GA: glandular atrophy; IM: intestinal metaplasia; *Hp-*: *H pylori*-eradicated group; Control: the control group.

DISCUSSION

H pylori is one of the causative factors for gastric cancer. Its eradication may play an important role in the prevention of gastric cancer. GA and IM are pre-cancerous lesions, but data on the effects of anti-*H pylori* therapy on GA and IM are conflicting. Vander Hulst *et al*[4] reported that the severity of GA and IM does not change after treatment. Forbes *et al*[5]showed that no changes in GA and IM are to be found after *H pylori* eradication treatment.

Sung *et al*[6] showed that IM in the gastric antrum is slightly improved in *H pylori*-eradicated patients and GA in the corpus is significantly improved in *H pylori*- infected patients. Ohkusa *et al*[7]demonstrated that 89% of GA and 61% of IM are improved. Ito *et al*[8] have reported a marked decrease in the average grade of IM and GA after treatment. Correa *et al*[9]reported the proportions of GA and IM are increased significantly in *H pylori*-eradicated

Table 1 Histological scores at entry of study in *H pylori*-eradicated group and control group (mean±SD)

	H pylori-eradicated group ($n=92$)	Control group ($n=87$)
Chronic inflammation	1.95±0.40	1.97±0.32
Active inflammation	1.84±0.41	1.90±0.40
Glandular atrophy	1.25±0.44	1.24±0.46
Intestinal metaplasia	0.64±0.76	0.63±0.57

Table 2 Histological scores at baseline and 3 yr after treatment (mean±SD)

	H pylori-eradicated group ($n=92$)		Control group ($n=87$)	
	Baseline	3-yr	Baseline	3-yr
Chronic inflammation	1.95±0.40	1.56±0.53[b]	1.97±0.32	1.91±0.47
Active inflammation	1.84±0.41	0.39±0.19[d]	1.90±0.40	1.78±0.44
Glandular atrophy	1.25±0.44	0.97±0.83[b]	1.24±0.46	1.19±0.82
Intestinal metaplasia	0.64±0.76	0.73±0.77	0.63±0.57	0.83±0.87[a]

[a]$P<0.05$, [b]$P<0.01$, [d]$P<0.001$ *vs* baseline

patients. Ruiz *et al*[10] showed that GA in the antrum improves significantly after *H pylori* eradication, but no significant change is observed by standard visual scoring method.

In our study, after a 3-year follow-up the scoring of GA decreased significantly in *H pylori*-eradicated group, while no significant change was found in control group ($P<0.01$). The proportion of change in GA was higher in *H pylori*-eradicated group than in control group (28.26% *vs* 14.94%), but it was not statistically significant ($P>0.05$). Though the GA grade in our study was mild and moderate, the results showed that eradication of *H pylori* was beneficial to some patients with GA in the antrum. Compared with GA, IM had no significant change after *H pylori* eradication. But the scoring of IM in the control group demonstrated that eradication of *H pylori* could prevent the further development of IM.

The reasons for these discrepancies may be due to the difference in sample size, follow-up time, histological standard, quantity and location of biopsy specimens and other gastric diseases. But the normal subjects or atrophic gastritis patients may cause deviation in statistics leading to different conclusions. Therefore, patients with different lesions (e.g., GA and IM) should be observed at different grades and at different times to demonstrate the possibility of reversal.

Whether GA and IM could be reversed is controversial, since bile reflux and other bacterial infections can also cause GA and IM. Moreover, age and dietary structure influence gastric mucosa lesions. Therefore, eradication of *H pylori* cannot cure all GA and IM.

Kokkola *et al*[11] reported that inflammation, GA and IM decrease significantly in patients with severe atrophic gastritis, including that GA and IM can be reversed by *H pylori* eradication. Dixon[12] considered that it is impossible to reverse GA and IM by *H pylori* eradication.

Our follow-up study demonstrated that gastritis activity and CI severity decreased significantly in *H pylori*-eradicated group but not in control group, suggesting that *H pylori* eradication can effectively treat gastritis. If we eradicate *H pylori* at the stage of gastric mucosa inflammation, the lesions can be reserved and will not develop into GA and IM. Therefore, in order to prevent gastric carcinoma, eradication of *H pylori* infection will be more beneficial, if the therapy is given at the early stage of lesions, i.e. before the formation of pre-cancerous lesions.

Abstract

AIM: To investigate the relationship between infiltrating inflammatory cell and tumor angiogenesis in hepatocellular carcinoma (HCC) tissues and their clinicopathological features.

METHODS: The paraffin-embedded specimens from 70 cases with HCC were stained using EliVision immunohistochemistry with mAbs against CD68, tryptase, and CD34. The counts of tumor-associated macrophage (TAM), mast cell (MC) and tumor microvessel (MV) were performed in the tissue sections.

RESULTS: The mean counts of TAM, MC, and MV in HCC tissues were significantly higher than those in pericarcinomatous liver tissues (TAM: 69.31 ± 11.58 *vs* 40.23 ± 10.36; MC: 16.74 ± 5.67 *vs* 7.59 ± 4.18; MV: 70.11 ± 12.45 *vs* 38.52 ± 11.16, $P<0.01$). The MV count in the patients with metastasis was markedly higher than that with non-metastasis ($P<0.01$). In addition, the MC count in the patients with poorly differentiated HCC was obviously higher than that with well differentiated HCC ($P<0.01$). The correlation analysis showed that the TAM count was significantly correlated with the count of MV ($r=0.712$, $P<0.01$), and the MC count was obviously correlated with the MV count ($r=0.336$, $P<0.05$).

CONCLUSION: TAM and MC might be closely related to the enhancement of tumor angiogenesis. The MV count might be associated with tumor invasion and metastasis. Moreover, the MC count might be associated with tumor differentiation and prognosis of HCC.

INTRODUCTION

Tumor angiogenesis is one of the fundamental requirements for tumor growth and proliferation, and the regulatory mechanisms of tumor angiogenesis are very complicated. The tumor neovascularization and its controlling factors have become investigative hot points in current tumor studies[1-5]. Tumor infiltrating inflammatory cells in the microenvironment plays very important functions in tumor angiogenesis[6-8]. Hepatocellular carcinoma (HCC) is a kind of a familiar malignant tumor in our country, though the treatment of HCC has obtained the substantial advance, the total treatment results are still unsatisfactory[9-12]. Until recently, there is some lack of knowledge in literature regarding the relationship among the count of tumor-associated macrophage (TAM), mast cell (MC), and microvessel (MV)_ in HCC tissues and their relation to the clinicopathological characteristics of HCC. In this study, we applied immunohistochemical method to detect the count of TAM, MC, and MV in HCC, and to investigate their relation to the clinicopathological characteristics of HCC, so that we could understand the regulating function of microenvironment in tumor angiogenesis. We believed that this study would offer some new clues for tumor angiogenesis research and biological therapeutic approach, such as suppressing tumor angiogenesis.

MATERIALS AND METHODS

Materials

Fresh surgical specimens were obtained from 70 HCC

patients (all specimens contained pericarcinomatous liver tissues) who had undergone partial hepatectomy during the period from January 1996 to February 2003 in Xiangya Hospital. All specimens were fixed in 40 g/L formaldehyde, embedded in paraffin, sliced into consecutive sections, and pathologically diagnosed explicitly. Of 70 HCC patients, 53 were males and 17 were females with average age of 53.4 years (range, 27-68 years). The size of tumors was less than 5 cm in 25 cases, 5.1-10 cm in 29 cases and larger than 10 cm in 16 cases. Among all cases, 19 cases contained several tumor tubercles in liver tissues. None of the patients received any preoperative treatment, such as radiotherapy and chemotherapy. The HCC tissues were graded according to the Edmondson standard. Of them, 11 cases had grade I, 31 cases grade II, 23 cases grade III, and 5 cases grade IV tumors. All the pericarcinomatous liver tissues had liver fibrosis with cirrhosis of different degrees and 22 pericarcinomatous liver tissues had dysplasia. The antibodies against CD68, trypsin of MC and CD34, and "two step" EliVisions reagent box were all obtained from Maixin Biochemical Development Company of Fuzhou.

Immunohistochemical staining

Briefly, after the sections were deparaffinized, the endogenous peroxidase was blocked by incubation with 30mL/L hydrogen peroxide for 30 min, followed by carrying out the two-step method of immunohistochemistry according to the manufacturer's instructions. The sections were incubated with the primary antibodies at room temperature overnight. For negative control, the primary antibodies were replaced with PBS.

Brown-yellow staining was observed in the cytoplasm of TAM, whereas brown-yellow grains were observed both in the cytoplasm and nucleus of MC. According to the count method of Molin *et al*[13], we chose five random microscopic fields in each section under high power, counting the number of TAM and MC in each visual field, respectively. In addition, in the same visual field, we counted the number of MC that had the phenomenon of taking-off grains. MV and its endothelial cells showed brown-yellow staining. Similarly, according to the count method of Weidner *et al*[14], we chose five random microscopic fields in each section under high power, counting the number of MV in each visual field.

Statistical analysis

The data were analyzed using *t* test and relativity analyses in the statistical computer software SPSS10.0. A *P* value less than 0.05 was considered statistically significant.

RESULTS

Expressional characteristics of CD68, MC, CD34

The cytoplasm of CD68-positive cells was stained with brown-yellow color. We could observe in all the sections, that most of the CD68-positive cells had the characteristic of microphage in appearance and the TAM was primarily distributed in the perimeter of tumor cells. Moreover, brown-yellow grains were observed in the cytoplasm and nucleus of MC. In the relatively normal areas, MC was circular or oval with complete cell membrane, clear outline, abnormally dyed grains in cytoplasm and some of the MCs appearing to have the phenomenon of taking-off grains. But in the HCC tissue and its adjacent areas, the number of MC was obviously increased, the physical volume enlarged with a different appearance, and the majority of MC appeared to have the phenomenon of taking-off grains. The CD34 staining was located in the cytoplasm of vascular endothelial cells. We could observe a single endothelial cell or a cluster of cells in some areas containing partly irregular tube cavity and irregular MV distribution, which could mostly be seen in the perimeter areas of the tumor.

Counts of TAM, MC, and MV

The counts of TAM, MC, and MV were all obviously higher in HCC tissues compared with the pericarcinomatous liver tissues ($P<0.01$, Table 1).

Table 1 Counts of TAM, MC, and MV in HCC tissues and pericarcinomatous liver tissues (mean±SD)

	TAM	MC	MV
HCC tissues	69.31± 11.58	16.74±5.67	70.11±12.45
Pericarcinomatous liver tissues	40.23±10.36[b]	7.59±4.18[b]	38.52±11.16[b]

[b]$P<0.01$ *vs* HCC tissues

Relationship between the counts of TAM, MC, and MV and the clinicopathological characteristics of HCC

The counts of TAM, MC, and MV were significantly higher in metastatic HCC than that in non-metastatic HCC, and the count of MC in low grade HCC tissues was markedly higher compared to high grade HCC tissues ($P<0.05$). In addition, we also discovered that MC having the phenomenon of taking-off grains was more and more

familiar in low grade HCC tissues. However, no obvious relationship was found between the counts of TAM, MC, and MV and the clinicopathological characteristics of HCC (Table 2).

Relationship of the counts of TAM and MC with the count of MV in HCC tissues

Using the relativity analyses of the counts of TAM and MC with the count of MV in HCC tissues, we found that the TAM count and MV count in HCC tissues had a close and positive relationship of high degree ($r=0.712$, $P<0.01$), and the MC count and MV count in HCC tissues had a close and positive relationship ($r=0.336$, $P<0.05$).

DISCUSSION

Tumor growth and proliferation are highly dependent on tumor neovascularization. Tumor angiogenesis is mediated by tumor-secreted angiogenic factors that interact with their surface receptors expressed on endothelial cells[15-19]. In fact, the mechanisms of regulation of tumor angiogenesis have become one of the investigative hot points in current tumor studies[1-5]. Our study showed that the MV count was significantly higher in HCC tissues as compared with the pericarcinomatous liver tissues, and also higher in the metastatic HCC compared with the metastatic HCC, suggesting that tumor angiogenesis has a crucial role in the development and metastasis of HCC.

Tumor angiogenesis is a complicated process, including many regulating factors[20-24]. The angiogenic response in the microvasculature is associated with the changes in cellular adhesive interactions between adjacent endothelial cells, pericytes and surrounding extracellular matrix. In addition, the infiltrating inflammatory cells in tumor are closely related with tumor angiogenesis. The infiltrating inflammatory cells in tumor, such as neutrophil, microphage, lymphocyte, eosinophil, MC, *etc*., can produce various cell factors and enzymes which participate in the growth and spread of tumor. Microphage is a main composition of the infiltrating inflammatory cells in the tumor and usually belongs to TAM in tumor tissues[23-28]. On one hand, it can produce several growth-stimulating and repressing factors, and albumen hydrolyze enzymes, such as fibroblast growth factor, vascular endothelial growth factor, etc. and thereby plays an important role in chain responding of tumor angiogenesis. On the other hand, tumor cells also can produce various chemoattractant factors, such as monocyte chemoattractant proteins, macrophage colony-stimulating factor etc, which have an important effect on the activation and migration of macrophage. These TAMs, being closely related to microvessel density, also have something to do with tumor angiogenesis, metastasis, and prognosis. In this study, we found that the count of TAM was obviously higher in HCC tissues as compared with the pericarcinomatous liver tissues, suggesting that TAM plays an important role in the development of HCC. In addition, the TAM count and the MV count in HCC tissues had a close and positive relationship, which suggested that TAM might promote tumor angiogenesis.

Several studies have shown that MCs in the local milieu may have something to do with the growth, invasion, metastasis, and neovascularization of malignant tumor[29-30]. Our results showed that the MC count was obviously higher in HCC tissues as compared with the pericarcinomatous liver tissues, suggesting an important role of MC in the development of HCC. We also found that the MC count in the lower grade HCC tissues was higher than that in the higher grade HCC, which suggested that the high MC count might be related to the low grade and poor prognosis of HCC. In addition, we observed that MC showing the phenomenon of taking-off grains was more and more familiar in low grade HCC tissues; however, its concrete relationship still needs further research. The counts of MC and MV in HCC tissues had a close and positive relationship, which revealed that MC might promote HCC angiogenesis.

Abstract

AIM: To investigate the distribution of HBV genotypes and their YMDD mutations in Guangxi Zhuang population, China, and to study the relationship between HBV genotypes and clinical types of HB, ALT, HBV DNA, HBe system as well as the curative effect of Lamivudine (LAM) on hepatitis B.

METHODS: A total of 156 cases were randomly chosen as study subjects from 317 patients with chronic hepatitis B (CHB). HBV genotypes were determined by PCR-microcosmic nucleic acid cross-ELISA. YMDD mutations were detected by microcosmic nucleic acid cross-nucleic acid quantitative determination. HBV DNA was detected by fluorescence ratio PCR analysis. LAM was given to 81 cases and its curative effect was observed by measuring ALT, HBV DNA load, HBeAg, and HBeAg/HBeAb conversion rate.

RESULTS: HBV genotypes B, C, D, and non-classified genotypes were found in Guangxi Zhuang population. accounting for 25.6%, 47.4%, 58.3%, and 16.0%, respectively. Seventy-four cases were CD-, CB-, BD-mixed genotypes (47.7%). Forty-six (29.5%) cases had YMDD mutations. Genotype B was mostly found in mild and moderate CHB patients. Genotypes C, D and mixed genotype mostly occurred in severe CHB cases. Genotypes D and CD HBV-infected patients had higher ALT and HBV DNA than patients with other types of HBV infection. There was no significant difference among the genotypes in YMDD mutations, clinical types, ALT and HBV DNA level. Non-classified types geno had a significantly lower positive rate of HBeAg than other genotypes (χ^2=12.841, P<0.05). There was no significant difference in ALT recovery rate, HBV DNA load, HBeAg, and HBeAg/HBeAb conversion rate, 48 wk after LAM treatment between groups of genotypes D, CD, and non-classified type.

CONCLUSION: Genotypes B, C, and D, non-classified and mixed genotype of HBV are identified in the Guangxi Zhuang population. Variations in genotypes are associated with clinical severity and serum ALT levels, but not with YMDD mutation or HBV DNA load. Therapeutic effects of LAM on clinical parameters are not influenced by differences in genotypes. Further studies are needed to gain an in-depth understanding of the relationship between HBV genotypes and serum HBeAb and HBeAg.

INTRODUCTION

Guangxi Zhuang Autonomous Region is an endemic area of HBV infection. To examine the distribution of HBV genotypes and their associations with clinical characteristics of hepatitis B (HB) in Zhuang population, a total of 156 cases selected randomly from chronic hepatitis B (CHB) 317 patients without any previous antiviral treatment were studied, and some cases were given Lamivudine (LAM) treatment. The results reported are as follows.

MATERIALS AND METHODS

General data of patients

A total of 156 patients, 89 males and 67 females, aged 15-70 years, were selected randomly from CHB 317 patients from out-patient and in-patient departments of our hospital during January 2001 to June 2003. These patients received no previous LAM treatment or any antiviral treatment within a year. Their serum HBsAg, HBeAg or HBcAb and HBV DNA were positive. Those

infected with HCV, HDV, and HIV were excluded. All cases fulfilled the diagnostic criteria modified at the Tenth Viral Hepatitis Conference of Chinese Medical Association[1].

Detection of HBV genotypes

HBV DNA genotypes were detected by PCR-microcosmic nucleic acid cross-ELISA. One hundred microliters of serum samples was mixed with a reaction solution in a 0.5 mL centrifuge tube, heated to 100 °C for 15 min, and centrifuged at 12 000 *g* for 5 min. Twelve-microliter supernatant from the previous step was centrifuged at 10 000 *g* for 10 s before being placed in a PCR reactor, pre-denatured at 94 °C for 2 min, amplified for 35 cycles (at 94 °C for 50 s, at 53 °C for 50 s, and at 72 °C for 65 s), followed by extension at 72 °C for min and a final extension at 98 °C for 10 min. The samples were chilled immediately in an ice-bath for 10 min. Package was pinked at the microcosmic openings at 37 °C for 14 min in $NaHCO_3$ solution (pH 9.6). Nonspecific conjugate at the microcosmic openings was sealed by seal reagent. Ninety microliters of (three drops) hybridization liquid, 20 μL denatured output, 23 μL each nucleic pink (one kind was added to one opening) were added to different reaction openings, mixed up lightly and put into 50 °C water bath for 60 min, and poured completely. Then, 200 μL (eight drops) lotion was added at 37 °C for 3-5 min, poured completely and baptized once again. One hundred microliters of enzyme-antibody liquid (two drops) was added and kept at 37 °C for 30 min, poured and dried by water absorber, 200 μL (eight drops) lotion was added and kept at room temperature for 3-5 min, baptized twice, then color reagents A and B (one drop) were added, respectively, kept at room temperature in the dark for 10 min. Then, 2 mol/L H_2SO_4 solution (one drop) was added and the photoabsorption degree value (A) was detected at 450 nm. HBV DNA was considered positive, if P/N≥2.1 and negative if P/N<2.1. Positive result in hybridization indicated the virus gene

Detection of YMDD mutation

Reagent kits were provided by Biomedicine Diagnosis and Research Center of Basic Medicine Department of the First Military Medical University. YMDD mutations were detected by PCR. Twenty-five specimens were tested in Biomedicine Diagnosis and Research Center of Basic Medicine Department of the First Military Medical University, and the other 131 specimens were tested according to the manual of the kits and results were evaluated by experts at the Central Laboratory of our hospital.

Quantitative determination of HBV DNA

FX990 micro-fluorometer and HBV-PCR fluoroscopy reagent kits (detection limit is 103 copies/mL) were used to detect HBV DNA according to the instructions of the kits and results were evaluated by experienced experts.

Detection of HBVM

HBVM was detected by ELISA. Reagent kits were provided by Zhongshan Bioengineering Co., Ltd, Guangdong, China. The function of the liver was examined by the method of Laishi, and the normal level of ALT was lower than 40 U/L

Treatment

According to the common clinical practice[2], LAM (10 mg/d.p.o.) was given to 30 patients with single genotypes B, C, or D, and 35 patients with mixed genotypes CD, CB, or DB, and 16 non-classified types. HBV DNA and ALT were high, and HBeAg was positive in all cases selected. Twenty-eight cases had YMDD mutation. Liver function, HBVM and HBV DNA load were detected every 4 wk, for 48 wk.

Statistical analysis

The incidence rate of YMDD mutations, the rate of various clinical types of HB, the abnormal rate of ALT, the high loading rate of HBV DNA, and the positive rate of HBeAg in different genotypes of HBV were compared before and after LAM treatment by χ^2 using SAS statistical software. $P<0.05$ was considered statistically significant.

RESULTS

HBV genotypes in 156 CHB patients

Genotypes in 156 selected cases included B, C, D, mixed, and non-classified types. Genotypes A, E, and F were tested but not discovered. Genotype D accounted for 58.3% (91/156), type C 47.4% (74/156), type B 25.6% (40/156), and non-classified type 16.0% (25/156), mixed types (CD, CB, and BD) 47.4% (74/156). Single genotypes (B, C, or D) accounted for 36.5% (57/156, Table 1)

Table 1 Distribution of HBV genotypes in 156 cases

Patterns of genotype	A	B	C	D	E	F	CD	CB	BD	Non-A–F
n	–	9	15	33	–	–	43	16	15	25
Incidence rate (%)	–	5.8	9.6	21.2	–	–	27.6	10.3	9.6	16.0

Relationship between different HBV genotypes and YMDD mutations, clinical types of CHB, ALT, and HBV DNA, and HBe system

Natural YMDD mutations occurred in 46 cases (29.5%). Genotype B had no YMDD mutation. Genotypes had a different incidence rate of YMDD mutations, but there was no significant difference among them. Genotype B was seen mostly in mild and moderate CHB patients, while genotypes C, D and mixed types of CD, BD occurred mostly in severe CHB patients. The abnormal rate of ALT and the high loading rate of HBV DNA in genotypes D, and CD were higher than those in other genotypes, but there was no significant difference. The positive rate of HBeAg in non-classified genotype was low, and there was a significant difference between non-classified and other genotypes ($\chi^2 = 12.841$, $P<0.05$, Table 2).

Table 2 Relationship between different HBV genotypes and YMDD mutations, clinical types of CHB, ALT, and HBV DNA level, HBe system

Genotypes	*n*	Rate of YMDD mutation (%)	Clinical type of CHB		Clinical test

χ^2		0.168	0.411	0.561	0.065
P		>0.05	>0.05	>0.05	>0.05

Observation of curative effects of LAM

ALT and HBV DNA level in all genotypes decreased in different degrees, 4 wk after LAM treatment. There was no significant difference in ALT recovery rate, HBV DNA level, HBeAg, and HBeAg/HBeAb conversion rate 48 weeks after treatment between the groups (Table 3). Twenty-eight cases showed natural mutations of single mixed and non-classified genotypes. After 48 weeks, HBV DNA level decreased in 22 cases to a level <103 copies/mL and ALT became normal. Rebound of HBV DNA level and base line of ALT were not found. HBeAg became negative in 15 cases and 10 cases had HBeAg/HBeAb conversion 48 weeks after the treatment.

DISCUSSION

Research data indicate that HBV can be divided into eight genotypes[3], ranging from A to H. Genotype A is frequently found in northwest Europe and Africa. Genotypes B and C are common in Asia, while genotype D is prevalent in the Mediterranean and Near East. Genotype E is restricted to Sub-Saharan Africa, and F is localized in American aboriginal population. Genotype G has been found in France and USA, and genotypes A –H[4] have been found in patients with HBV infection in San Francisco. The distribution of HBV genotypes is related to immigration[5–7] and race background of the carriers. In China, genotypes B and C are predominant, while genotypes A and D are rare. But type D has a high percentage in minority nationalities. In our study, HBV genotypes were determined in 156 Zhuang CHB patients by PCR-microcosmic nucleic acid cross-ELISA. Genotypes B–D and non-classified type were identified. HBV genotype D was mostly found (58.3%), followed by genotypes C (47.4%), and B (25.6%). Non-classified type (16.0%) was significantly higher than that reported in Taiwan[8]. The distribution of genotypes B and C is consistent with most reports[9–11] in China. Type D is the predominant genotype in Zhuang population, which is different from other reports[11]. It may be related to the geographical and ethnic characteristics of Zhuang population. There was a high rate (47.4%) of mixed

genotypes. The mixed infection occurred between genotypes B and C or B and D, but mostly between genotypes D and C, which is also different from other reports[9] in China. The reasons may be as follows: (1) super infection and mixed infection, patients are easily treated, (2) gene mutation, detection methods, recombination of different genotypes[12]. Our study did not rule out the possibility of recombination of different genotypes. Further studies are needed to explore whether it is related to the special genobackground of Zhuang population or random mechanism.

YMDD motif, located in the C-domain of the catalytic site of the polymerase gene, is also the binding site of the antiviral drug LAM. Long-term treatment with LAM induces mutation of the YMDD motif; however, it was reported recently that YMDD mutations are occurring naturally[13-16]. Original research considered that the natural occurrence of YMDD mutant strains is associated with a great amount of HBV existing in patients[13]. Further research revealed that YMDD mutations occur spontaneously as they gain fitness without any particular cause[17]. The detection rate (29.5%) of mutant strains in our study is in accordance with that reported by Zhang *et al*[15]. showing that wild YMDD mutant strains exist in HBV DNA. There were differences of incidence rate of HBV YMDD wild mutant strains in HBV genotypes D, C, non-classified, and mixed genotypes of CD, BC, and CB. Although no significant difference was found among these genotypes, we cannot exclude the relation between YMDD mutations and HBV genotypes because of the limited samples in our study.

The virus gene controls antigen expression, leading to different genotypes and disease spectrum after infection. However, the conclusions are controversial. It was reported that genotype A is related to chronic active hepatitis, genotype D is related to acute self-limited hepatitis[18], and HBV-D is related to chronic symptomatic carriers[19]. All chronic HBV infections found in Jeju Island are genotype C[20]. But most scholars[21–23] found that genotype C is related to severe hepatitis or the aggravation of illness. Yuen *et al*[24] reported that genotype B has a higher mortality than genotype C because of decompensation of liver function. Our study showed that genotype A was not found in 156 CHB patients, while genotype D was predominant. This may be associated with uneven distribution of genotypes and simple clinical type, or the ethnic background. Genotype B was mainly found in chronic mild and moderate HBV patients, while genotypes C and D were mainly in chronic severe HBV patients. They seemed to increase with the progression of the illness. But there was no statistical significance. Studies on whether mixed genotype infection can worsen liver diseases are available[25–27], but the conclusion is controversial. In our study, mixed genotype CD and BD infections were mainly found in patients with chronic severe HBV infection, indicating that mixed genotype infection can lead to liver disease.

More attention has been paid to the relationship between HBV genotype and HBe, ALT, and HBV DNA. In our study, genotypes of CD and D had higher levels of ALT and HBV DNA than other genotypes, indicating that different genotypes are related with the level of ALT and HBV DNA. Compared to HBeAg-positive rate, there was a significant difference between non-classified and other genotypes ($P<0.05$), indicating that HBV genotype is related with HBe. Further studies are needed.

LAM is one of the first-line medicines for CHB patients[28,29]. Whether the effect of LAM treatment is influenced by HBV genotype is a topic of the researchers. Some studies showed that the effect of LAM treatment is not influenced by HBV genotype[30–32]. In our study, the effect of LAM treatment was not influenced by HBV genotype, suggesting that determination of HBV genotype cannot predict antiviral effect before LAM treatment[30]. Among the 28 cases with YMDD mutations, after 48 weeks of LAM treatment, HBV DNA levels in 22 cases decreased to below 103 copies/mL, and ALT became normal, and HBeAg became negative in 15 cases and 10 cases had HBeAg/HBeAb conversion, showing that LAM has a short-term effect in patients with YMDD wild mutation. This may be associated with the fact that wild viral strains are in the dominant side, while YMDD mutational strains are in the weak side and have a lower duplication activity and weaker pathogenicity.

In short, there are some unique characteristics in the distribution of HBV genotypes of Guangxi Zhuang population. This may be related to the geographic location and ethnics. HBV genotypes are not correlated with YMDD mutation, ALT, and HBV DNA level. The effect of LAM is not influenced by these factors. Further studies are needed to examine the relationship between the characteristics of HBV genotype, the mutation of pre-C-zone and different genotypes, as well as the conversion and prognosis of the disease.

Abstract

AIM: To explore the biological behavior of gastric carcinoma micrometastasis (MM) with a marker of cytokeratin 18 (CK18) and to evaluate the clinical stage of gastric carcinoma and its prognosis.

METHODS: Reverse transcription-polymerase chain reaction (RT-PCR) was used to examine the expression of CK18 mRNA in 298 lymph nodes from 35 patients with gastric carcinoma and 20 lymph nodes from 10 patients with chronic peptic ulcer and gastric perforation diagnosed by pathological examination and surgery. CK18 mRNA expression of peripheral blood from 54 patients with gastric carcinoma and 10 healthy people were also examined.

RESULTS: Expression of CK18 mRNA was not found in 10 patients with benign pathological changes. CK18 mRNA expression in gastric carcinoma tissues was strongly positive. In gastric carcinoma patients, pathological examination revealed that 99 of 298 (33.2%) lymph nodes were positive, while RT-PCR showed that 133 of 298 (44.6%) lymph nodes had expression of CK18 mRNA. The difference was significant ($P < 0.05$). Among the 199 negative lymph nodes identified by pathological examinations, 34 (17.1%) displayed positive expression of CK18 mRNA by RT-PCR. The positive expression of CK18 mRNA was associated with lymph node micrometastasis (LMM) of gastric carcinoma. CK18 mRNA was negatively expressed in all 10 healthy cases and positively expressed in 38.9% of 54 blood specimens from gastric carcinoma patients. The positive rate was not correlated with tumor invasion of gastric carcinoma, but was significantly associated with TNM stage, lymph node metastasis ($P = 0.0290$, $P < 0.05$) and tumor differentiation ($P = 0.2956$, $P<0.05$).

CONCLUSION: RT-PCR with CK18 mRNA as a molecular marker is highly sensitive and specific in detecting LMM of gastric carcinoma. It can benefit the diagnosis of MM and guide studies on biological behavior, clinical phase, and therapy as well as relapse monitoring.

INTRODUCTION

Gastric carcinoma ranks second in alimentary canal diseases and third in all tumors in China. Metastasis and relapse are two major reasons for the death of patients. The two important metastatic pathways of gastric carcinoma are lymph nodes and peripheral blood, which are important factors for the prognosis of patients after curative surgery. This study used reverse transcription-polymerase chain reaction (RT-PCR) to detect the expression of cytokeratin 18 (ck18) mRNA and to explore its correlation with gastric carcinoma micrometastasis (MM).

MATERIALS AND METHODS

Patients and tissue samples

Enrolled in this study were 54 patients (24 females, 30 males) undergone curative gastrectomy for gastric carcinoma at the First and Second Hospitals of Jilin University between October 2001 and August 2002. The patients' age ranged from 34 to 74 years (mean age of 51.2 years). Control group I included 10 patients with peptic ulcer, control group II consisted of 10 healthy people.

A total of 298 lymph nodes were obtained from 54 patients with gastric carcinoma. Lymph nodes were divided into two parts: one for pathological examination and the other stored at -80 °C for use.

Five milliliters of peripheral blood was collected from 54 patients with gastric carcinoma. Blood specimens were anti-coagulated with heparin. Peripheral blood

mononuclear cells (PBMC) were separated from the whole blood by Ficoll-Hypaque density-gradient centrifugation and stored at -70 °C for use. Five milliliters of peripheral blood was collected from negative controls.

Preparation of RNA samples and RT-PCR

RNA was isolated from PBMC and lymph nodes with TRIzol reagent. Lymph nodes were collected from normal controls and gastric carcinoma patients in 1 mL of TRIzol reagent per 100 mg of tissue using power homogenizer. RNA pellet was dried and RNA dissolved in RNase-free water was stored at -70 °C for use. RNA was used as a template for amplification. Oligonucleotides as specific primers and probes for CK18 were synthesized by a company (Biotechnology, Dalian, China). As a PCR control reaction, β-actin was also detected in each run. The sequences of primers are as follows: CK18: 5' -PCR primer AAGAAAACCCGAAGAGG, 3'-PCR primer CTGACTCAAGGTGCAGC; β-actin: 5'-PCR primer GTGGGGCGCCCCAGGCACCA, 3'-PCR primer CTTCCTTAATGTCACGCACGATTTC. The expected sizes of PCR products were 402 bp for CK18 and 540 bp for β-actin. Complementary (c) DNA was synthesized using Rous-associated virus reverse transcriptase (TAKARA Biomedicals).

PCR was performed following the procedure: briefly 130 ng of RNA was used for RT-PCR. For cDNA synthesis, 130 ng in 4 μL of sample RNA solution and 2 μL of oligo dT were heated at 70 °C for 5 min and cooled rapidly. After adding 1 μL of a ribonuclease inhibitor (Takara, Dalian, China), 4 μL of 2.5 mmol/L dNTP (dATP, dCTP, dGTP, dTTP, Takara, Dalian, China) and 4 μL of Rous-associated virus reverse transcriptase (Takara, Dalian, China), 10 μL of 5×PCR buffer, 25 μL of DEPC-water, the mixture was incubated at 65 °C for 60 min, and then at 95 °C for 5 min. The PCR mixture contained 25 μL of cDNA , 7.5 μL of 10×PCR buffer, 6μL of 25 mmol/L $MgCl_2$,8 μL of 2.5 mmol/L dNTP, 50 μL of DEPC-water , 2 μL of 5'- and 3'-PCR primer , 0.5 μL of μ-actin and 1.0 μL of thermostable Taq polymerase (Takara, Dalian, China). The amplification was done with a DNA thermal cycler (Geneam PCR System 2400). After denaturation at 94 °C for 4 min, the amplification was conducted for 35 cycles at 94 °C for 45 s, at 55 °C for 45 s, and at 72 °C for 60 s. This was followed by a final extension for 1 min at 72 °C. Ten microliter aliquots of the product was analyzed by electrophoresis on a 2% agarose gel and visualized by UV fluorescence after being stained with ethidium bromide.

Standard of result assessment

The expected sizes of PCR products were 402 bp for CK18 and 540 bp for β-actin. CK18 mRNA expression of two DNA bands in the corresponding location was positive. CK18 mRNA expression of one 540 bp band was negative (Figure 1).

Statistical analysis

Data were analyzed by χ^2 test using Instat software. $P<0.05$ was considered statistically significant.

Classification standard for lymph node metastasis

According to the 1997 International Union Contrele Cancer (UICC)/American Joint Committee on Cancer (AJCC) pN classification, PN0: without lymph node metastasis, PN1: 1-6 lymph node metastases, PN2: 7-15 lymph node metastases, PN3: >15 lymph node metastases.

RESULTS

Expressions of CK18 mRNA in lymph nodes and peripheral blood are shown in Figure 1.

Lymph node MM, correlation between CK18 mRNA expression in lymph nodes, peripheral blood and tissue differentiation, tumor stage and invasion are summarized in Tables 1-3.

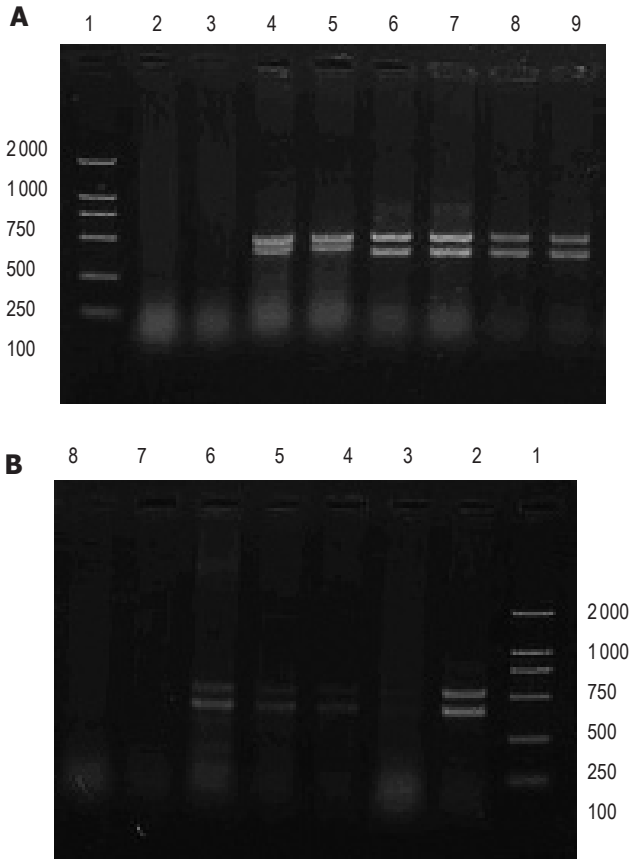

Figure 1 Expression of CK18 mRNA gene in lymph nodes **(A)** and peripheral blood **(B)**. Lane 1: 2-kb DNA ladder marker; lane 2: positive gastric carcinoma tissue; lanes 3-6: positive peripheral blood specimens; lanes 7 and 8: negative lymph nodes.

DISCUSSION

Micrometastasis

MM spreads from primary tumor to distant secondary tumors in lymph system, blood circulation, bone marrow, liver, kidney, lung, and other organs during the development of malignant neoplasm in non-hematopoietic system. It often has no clinical symptoms[1,2]. Gastric carcinoma is one of the most common malignant neoplasms in China. Many patients showing lymph node metastasis of gastric carcinoma experience relapse and eventually die after curative surgery. Even those with no metastasis of gastric carcinoma ultimately die in the relapse of metastasis. The essential reason is MM, that cannot be detected. MM has become the focus in recent studies on malignant neoplasm. The growth and metastasis of gastric carcinoma are a complicated process with a variety of gene mutations. Although most carcinoma cells entering into circulation are destroyed through mechanisms such as immunization, the residual carcinoma cells can disseminate through a number of mechanisms, such as changes of cell modulation, excretion of protease, growth of blood vessels, and increase of cell dynamics[3]. MM of malignant tumor is controlled by the positive and negative functions of a number of genes at molecule level. Successful clones of "correlating genes of tumor metastasis" and "restraining genes of tumor metastasis" are related with tumor metastasis. Genes at molecule level such as c-met, ras, myc and HER-2/neu, and restraining genes of tumor metastasis such as nm23, p53 and CD44 are related to tumor metastasis[4]. Loss, mutation and abnormal expression of the genes are correlated with invasive metastasis of tumor. Lymph node MM is the main pathway of gastric carcinoma MM. Lymph node MM has been considered as cancer metastasis that cannot be detected by traditional pathological methods[4]. MM foci of lymph node could be easily ignored or missed. Amplifying tumor- or tissue-specific mRNA by RT-PCR can detect tumor cells from 106 to 107 normal cells, and further detect the MM foci of lymph nodes. Patients with MM identified by RT-PCR are often in the developing stage of the disease, and symptoms are likely to turn out to be negative after the therapy. Therefore, lymph node metastasis is not only a prognosis indicator but also an indicator for assessing the effectiveness of therapy and monitoring early relapse[5]. Lymph node metastasis was not only an index of dys-outcome, but also has curative effect and monitoring earlier period relapse[3]. The hematogenous dissemination is another pathway of gastric carcinoma MM. Although the presence of carcinoma cells in blood does not necessarily lead to metastasis, entry of carcinoma cells into blood is the first step for the occurrence of tumor transfer in remote areas. Tumor cells shedding from pro-foci in perioperative or postoperative periods have spread to blood, lymph nodes, marrow or other organs even before pro-foci formation. However, it is difficult to detect metastasis in patients without clinical symptoms by traditional methods such as imaging and clinical pathology. Therefore, many researchers are dedicated in searching sensitive and specific methods to detect MM.

CK18 as a marker for micrometastasis

Cytokeratins (CKs) constitute the cytoskeleton of intermediate filament type in most epithelial cells. They consist of at least 20 members, designated as CK1–CK20 according to their molecular weights and isoelectric points[6,7]. Each type of epithelial cells has a rather stable CK composition, termed as CK pattern, which has been used in the identification of different epithelial tissues and their neoplasms[7]. CKs are expressed in the epithelial tissues, but not in the intermediate filament tissues (blood vessel, nerve, lymph tissues). They are continuously expressed in epithelial cells during malignant transformation and tumor formation, but not in normal lymph nodes, which provides the basis for applying CKs in diagnosing gastric carcinoma MM[8]. Molecular markers of malignant tumor MM from epithelial tissues have been explored recently[9–11]. For example, Liu *et al*[9] from abroad used CK20 mRNA as a marker to examine large intestine carcinoma with RT-PCR. With CK19 mRNA as a marker Ueda *et al*[10] examined lung carcinoma with RT-

PCR. Noguchi *et al*[11] examined CK19 mRNA in lymph nodes from 10 cases of gastric carcinoma with RT-PCR. Domestic researchers have detected lymph node MM of gastric carcinoma by targeting CK19, CK20 with RT-PCR technique[12,13]. Lymph node MM of gastric carcinoma by choosing CK7, CK8 with immunofluorescence stain and immunocyte chemical technique[1]. Different from other CKs, CK18 has a stricter specific distribution in epithelial cells and a specific expression in cells from glandular epithelium[14]. Therefore, if CK18 mRNA is expressed in lymph nodes from gastric carcinoma patients, it indicates the existence of tumor metastasis in lymph nodes; If CK18 mRNA is expressed in peripheral blood from gastric carcinoma patients, it indicates the possibility that metastasis has been transferred to other distant organs.

Correlation between gastric carcinoma micrometastasis and CK18 expression

RT-PCR was used in this study to detect CK18 mRNA. Results from analyzing 298 lymph nodes of gastric carcinoma and 20 lymph nodes from control group I indicate that: (1) In contrast to the findings of negative expression in all the benign pathological changes of lymph nodes, CK18 mRNA showed positive expression in gastric carcinoma tissues, indicating that RT-PCR technique has a high specificity for detecting CK18 mRNA. Expression of CK18 mRNA was detected in lymph nodes from patients with gastric carcinoma, indicating that the cancer is transferred. CK18 mRNA was positively expressed in 34 of 199 lymph nodes (17.1%), showing that RT-PCR has a high sensitivity for detecting lymph node metastasis of gastric carcinoma. As lymph node metastasis of gastric carcinoma directly affects the prognosis of gastric carcinoma patients, lymph nodes around gastric carcinoma tissues should be removed. According to UICC/AJCC new classification of lymph node metastasis of gastric carcinoma in 1997[15], 199 lymph nodes with PN0 from 35 patients with gastric carcinoma demonstrated by pathological examination in postoperative, contained 17.1% lymph node micrometastases by RT-PCR that should be classified into PN1. The main risk factors for lymph node metastasis include the size of primitive tumor, the degree of differentiation and depth of invasion[16]. Fukagawa *et al*[17] have found that metastasis occurs more often from tumescent growth tumors than from invasive growth tumors. The current study has revealed that lymph node MM is highly correlated with the depth of invasion (T)[18]. It was reported that patients (PT3N0) without lymph node metastasis detected by routine pathological examination have lymph node metastasis (PT3N1) detected by RT-PCR[19]. Suggesting that MM examination should be conducted for PN0 to improve the accuracy of clinical stage of gastric carcinoma, MM in peripheral blood does not necessarily develop clinical symptoms, but it correlates with biological behavior of gastric carcinoma. Zhang *et al*[20] demonstrated that CK20 mRNA is a marker of gastric carcinoma MM. Chausovsky *et al*[21] used CK20 mRNA as a target gene to examine MM of gastric carcinoma in peripheral blood from 116 patients with malignant neoplasm, and found that CK20 mRNA is a target gene for MM of epithelial tumor. Majima *et al*[22] took CK19 and CK20 mRNA as target genes to examine MM in peripheral blood from 52 patients with gastric carcinoma and found that CK19 mRNA is better than CK20 mRNA as a marker. The current study detected the expression of CK18 mRNA in peripheral blood from 54 patients with gastric carcinoma and found that the positive expression was 38.9% (21/54) compared to control group II, suggesting that patients with gastric carcinoma develop MM in peripheral blood. Suppressed by the organic defense mechanism, carcinoma cells in peripheral blood are in dormant status after they disseminate into the organs. However, carcinoma cells can grow and reproduce again due to multiple factors such as aggravation of the disease which eventually lead to clinical metastasis and relapse, thus influencing prognosis. Therefore, examination of MM in peripheral blood among patients with gastric carcinoma is recommended. It helps to determine relevant assistant therapy and to evaluate prognosis.

In conclusion, RT-PCR has a high specificity and sensitivity in detecting CK18 mRNA in gastric carcinoma patients and can be used to evaluate metastasis of gastric carcinoma at the molecule level.

Abstract

AIM: To explore the quantitative analysis of diffusion-weighted magnetic resonance imaging (DWMRI) in differential diagnosis of focal hepatic lesions.

METHODS: DWMRI was performed in 149 hepatic lesions, including hepatocellular carcinoma (34 cases), hepatic metastases (37 cases), cavernous hemangioma (42 cases), hepatic cyst (36 cases). Apparent diffusion coefficient (ADC) values were evaluated using four different *b* values in different sequences. The ratio of ADC values of lesion/liver in hepatocellular carcinoma and hepatic metastases was also calculated.

RESULTS: The mean ADC values of hepatic lesions were as follows: hepatocellular carcinoma $(0.95 \pm 0.11) \times 10^{-3}$ mm^2/s, hepatic metastasis $(1.13 \pm 0.21) \times 10^{-3}$ mm^2/s, cavernous hemangioma $(1.86 \pm 0.36) \times 10^{-3}$ mm^2/s, hepatic cyst $(3.14 \pm 0.31) \times 10^{-3}$ mm^2/s. The ratio of ADC values in lesion/liver in hepatocellular carcinoma was 0.91 ± 0.11, being significantly different from that in hepatic metastasis (1.21 ± 0.18, $P < 0.05$).

CONCLUSION: ADC values and quantitative analysis of focal hepatic lesions are of significant values in differential diagnosis of focal hepatic lesions.

Key words: Diffusion-weighed magnetic resonance imaging; Hepatic lesion; Quantitative analysis

INTRODUCTION

Diffusion-weighted magnetic resonance imaging (DWMRI) is a new technique of magnetic resonance imaging (MRI) at the level of molecular movements and can reflect the functions and structures of the body without trauma. It has been used to diagnose diseases in the central nervous system[1-3]. Radiologists have paid more attention to its values in differential diagnosis of focal hepatic lesions[4-6]. This study was to evaluate the value of DWMRI in differential diagnosis of focal hepatic lesions by quantifying apparent diffusion coefficient (ADC) values.

MATERIALS AND METHODS

In this study, DWMRI was performed in 149 patients with focal hepatic lesions (31 women and 109 men, aged 24-89 years, mean 52.37 years), including 34 hepatocellular carcinomas, 37 hepatic metastases, 42 cavernous hemangiomas, 36 hepatic cysts. The diameter of the above lesions was 1.1-20.5, 0.8-25.8, 0.9-8.6, and 0.8-2.7 cm, respectively.

The criteria for selecting the patients were as follows: (1) The diagnosis of all cases of hepatocellular carcinoma was confirmed by α-fetal protein, clinical data, ultrasound, CT or/and MR imaging, and pathology. (2) All cases of hepatic metastasis of primary malignant tumors were surgically confirmed. (3) The diagnosis of all the cases of cavernous hemangioma and hepatic cyst was confirmed by clinical data, ultrasound, CT or/and MR imaging, and follow-up observation.

DWMRI was performed by 1.5 T MR scanner with a body coil (Signa, Horizon LX, GE, USA). All data were measured in control console. All lesions were scanned with spin-echo (SE) T1WI and fast SE T2WI in the axial plane. The imaging parameters of DWMRI with SE-echo planar imaging (EPI) sequence were set as follows: repetition time ms/echo time ms: 10 000/90; matrix: 128×128; field of view: 36 cm×36 cm; section thickness: 8 mm; gap: 2 mm; slice number: 10-15; one signal. Four different *b* values (b=0 mm^2/s, 100, 500, 1 000 mm^2/s) and three directions were used, total acquisition time was 40 s.

The standards of measurement of signal intensities in hepatic lesions on DWMRI were as follows: the largest diameter of lesions was measured, three regions of interest in each lesion were marked off and measured, the regions of blood vessels and artifacts were rejected, the edges of parenchyma in the lesion were measured, when apparent necrosis was present, and regions of interest should involve parenchyma and the diameter of it should be longer than 1 cm, the same area of the section should be chosen for the measurement of different sequences, the signal intensity of each ROI was measured thrice and a mean value of SI was acquired for ADC calculation.

ADC values were evaluated with the following formula: $ADC=(\ln[S_l+S_h])/(b_h-b_l)$, where ln is the natural logarithm, S_l and S_h are the signal intensities of low b value and high b value, respectively.

All data were expressed as mean±SD. Statistical analysis was performed by t-test using SPSS software 10.0. $P<0.05$ was considered statistically significant.

RESULTS

In this study, 149 focal hepatic lesions were detected by DWMRI, the DWMRI sensitivity was 100%. We used four different b values ($b=0$, 100, 500, and 1 000 mm^2/s). The higher the b values on the DWMRI ($b=1\ 000$ mm^2/s). The lower the b values on DWMRI ($b=100$ mm^2/s), the higher the ADC values. Thus, we measured the highest b value ($b=1\ 000$ mm^2/s) on DWMRI. Table 1 shows the ADC values in focal hepatic lesions.

Table 1 ADC values in focal hepatic lesions (×10^{-3} mm^2/s)

Hepatic lesion	$b=100$	$b=500$	$b=1\ 000$
Hepatocellular carcinoma	0.56-1.33	0.60-1.31	0.57-1.23
Hepatic metastases	0.75-1.62	0.71-1.59	0.72-1.35
Cavernous hemangioma	1.26-2.54	1.32-2.36	1.37-2.21
Hepatic cyst	2.70-3.85	2.73-3.71	2.78-3.51

The ADC values in hepatic cyst were significantly higher than those in hepatic hemangioma, metastasis, and hepatocellular carcinoma, respectively; the t-test value was 2.329-3.237 ($P<0.01$). There was a significant difference in ADC values of hepatic hemangioma, hepatic metastasis, and hepatocellular carcinoma, respectively, with the t-test value being 1.139-3.467 ($P<0.05$). No significant difference was demonstrated between hepatic metastasis and hepatocellular carcinoma with the t-test value being 1.432 (Table 2).

Table 2 ADC value in focal hepatic lesions ($b=1\ 000$ mm^2/s, mean±SD)

Hepatic lesion	ADC value (×10-3 mm^2/s)
Hepatocellular carcinoma	0.95±0.11
Hepatic metastases	1.13±0.21
Cavernous hemangioma	1.86±0.36
Hepatic cyst	3.14±0.31

The ratio of ADC values of lesion/liver between hepatocellular carcinoma and hepatic metastasis was significantly different with the t-test value being 2.328 (Table 3).

Table 3 Ratio of ADC values of lesion/liver between hepatocellular carcinoma and hepatic metastasis (mean±SD)

Hepatic lesion	Coverage	Ratio of ADC values of lesion/liver
Hepatocellular carcinoma	0.73-1.05	0.91±0.11
Hepatic metastases	1.07-1.43	1.21±0.18

DISCUSSION

Diffusion is known as the Brownian motion caused by thermal movement of molecules, and is arbitrary and irregular. The effect of molecular diffusion movement is weak, but it can result in MR signal missing converge, the attenuation degree lies on MR gradient intensity and amplitude of molecular movement[7,8]. DWMRI is an imaging method to observe microcosmic molecular movement using macroscopical flowing phase displacement theory. Body diffusion coefficient is affected by microcirculation factors[9], such as humoral flowing, cellular osmosis and temperature, perfusion of capillary vessels, glutinous degree and proportion of intra- and extra-cellular water, direction of cellular membrane transition. It is also affected simultaneously by macro factors and circadian function, such as breath, pulsate, and peristalsis. In fact, apparent diffusion coefficient (ADC) regularly replaces the diffusion coefficient, and is always greater than the latter[10,11].

In theory, ADC value can be obtained by one pulsate sequence using two different b values. In experimental researches and clinical applications, ADC values are constantly related to the kinds and quantities of b value in sequences and perfusion of tissue[12-14]. The bigger the b value, the more accurately the ADC value. We measured the four different b values in different sequences (b=0, 100, 500, and 1 000 mm^2/s), and found that ADC values had higher stabilization with higher b values. The technique of EPI, which has a more rapid imaging speed and higher section efficiency, could complete signal collection of single images in several milliseconds and freeze-up artifact of physiological functions. Therefore, it is the commonly used diffusion imaging sequence[15-17]. We adopted images of 1 000 mm^2/s as a reference to give enough attention to attenuation degrees of four different lesions.

Animal experiments and clinical researches indicate that ADC value depends on imaging materials and molecular spatial distribution[18,19]. Cavernous hemangioma and hepatic cyst are mainly composed of liquid component, which has more movement freedom in the two lesions; ADC values are greater than those in hepatic parenchymatous mass. Cavernous hemangioma often presents fiber septation, scar, and hemorrhage, and the blood glutinous degree is higher than that of hydatid fluid in hepatic cyst. This is why the ADC value in hepatic cyst is lower than that in cavernous hemangioma[20-22]. Thus,

entity mass, cavernous hemangioma and hepatic cyst have significantly different ADC values. These findings are consistent with the results in our study.

Our results indicate that the different ADC values in DWMRI could differentiate hepatic cyst and cavernous hemangioma from other hepatic entity masses[23]. We also analyzed the ratio of ADC values of the lesion/liver. Statistical analysis demonstrated that ADC ratio was different between hepatocellular carcinoma and hepatic metastasis.

We believe that the ratio of ADC value of lesion/liver could differentiate hepatocellular carcinoma from hepatic metastasis, and provide some information for the diagnosis of focal hepatic lesions that are less than 3 cm in diameter. This theory is based on the situation in our country that hepatocellular carcinoma generally results from cirrhosis, but hepatic metastasis is not the case[24-26]. Although the ADC values in hepatic metastasis foci are slightly greater than those in hepatocellular carcinoma foci, the ADC values in liver parenchyma with hepatic metastasis are lower than those in hepatocellular carcinoma. Patients with hepatic metastasis have a higher ratio of ADC values of lesion/liver than those with hepatocellular carcinoma.

In conclusion, DWMRI is a new functional MRI technique, and is of great value in the differential diagnosis of focal hepatic lesions.

Abstract

AIM: To investigate the effects of 8-Br-cAMP on differentiation and apoptosis of human esophageal cancer cell line Eca-109, and the related gene expression.

METHODS: The cultured Eca-109 cells were divided into four groups: E1 group (co-cultured with 8-Br-cAMP for 24 h); E2 group (co-cultured with 8-Br-cAMP for 48 h); C1 group (treated without 8-Br-cAMP for 24 h); and C2 group (treated without 8-Br-cAMP for 48 h). The same concentration of cell suspension of each group was dropped separately onto the slides and nitrocellulose membranes (NCM). The biotin-labeled cDNA probes for c-myc, wild-type (wt) p53, bcl-2 and iNOS were prepared for *in situ* hybridization. The expressions of epidermal growth factor receptor (EGFR), p38 kinase, FAS, FasL and caspase-3 were detected using immunocytochemistry, and the NOS activity and the ratio of differentiated cells/proliferating cells were examined by cytochemistry. Immunocytochemistry, cytochemistry, and *in situ* hybridization were separately carried out on both slides and NCM specimens for each group. In addition, TUNEL was used to detect the cell apoptosis rate in each group.

RESULTS: The apoptotic rate of E2 group was significantly higher compared to E1 group, while there was no difference in the ratio of differentiated cells/proliferating cells between E1 and E2 groups. The signals of wt p53 and iNOS were markedly stronger, while the signals of c-myc and EGFR were obviously weaker in E1 group than those in C1 group ($P<0.05$). Moreover, the signals of wt p53, iNOS, p38 kinase, caspase-3 and NOS activity were significantly stronger, whereas, the signals of bcl-2, c-myc and Fas/FasL were markedly weaker in E2 group than those in C2 group ($P<0.05$).

CONCLUSION: The differentiation and apoptosis of human esophageal cancer cell Eca-109 can be induced after 24- and 48-h treatment with 8-Br-cAMP, respectively. Upregulation of wt p53, iNOS and downregulation of c-myc may be associated with differentiation and apoptosis of Eca-109 cells. Furthermore, upregulation of FasL, p38 kinase and caspase-3 as well as downregulation of bcl-2, and Fas may be involved in the apoptosis of Eca-109 cells.

INTRODUCTION

There are two isoforms of cAMP receptor proteins, type I (PKAI) and type II (PKAII). PKAI can stimulate cell growth, while PKAII can inhibit it. Cho-Chung[1] have reported that the nontoxic 8-Br-cAMP is one of the site-selective cAMP analogs to combine with the PKAII attractively and 8-Br-cAMP could induce cancer cell differentiation via regulatory balance of the intracellular signal transducers of cAMP. It was reported that cAMP analogs or upregulation of cAMP/PKA pathway could suppress tumor malignancy through growth inhibition and differentiation induction[2,3]. In our previous studies, we found that 8-Br-cAMP could inhibit growth-related gene expressions in Eca-109 cells mainly through regulation of c-myc, epidermal growth factor receptor (EGFR), c-fos and wild-type (wt) p53 expressions; and facilitate retinoblastoma Rb44 cell differentiation mainly through iNOS gene expression[4,5]. Some studies demonstrated that the acid-denatured and methyl green-pyronin stain could be used for the identification of differentiated non-proliferating cells[6-8]. It is known that the oncogene/proto-oncogene, EGFR and c-myc can enforce cell proliferation, while the anti-oncogene, wt p53, can inhibit it; iNOS,

p38 kinase, Fas/FasL and caspase-3 are mainly associated with apoptosis, while bcl-2 is of anti-apoptotic; besides, different expression levels of the same gene may result in different effects. In this study, we aimed to investigate the effects of 8-Br-cAMP on differentiation and apoptosis of human Eca-109 cells, and to examine the alteration of related gene expressions by using *in situ* hybridization, immunocytochemistry and cytochemistry.

MATERIALS AND METHODS

Cell culture

The human esophageal cancer cell line Eca-109 was cultured in DMEM (Gibco BRL, USA) supplemented with 100 mL/L fetal bovine serum. The Eca-109 cells were cultured with 2×10^{-5} mol/L of 8-Bromo-cAMP (Sigma, USA) for 24 h as the experimental 1 (E1) group and for 48 h as the experimental 2 (E2) group. The Eca-109 cells were cultured with the same medium without any drug for 24 h as the control 1 (C1) group and for 48 h as the control 2 (C2) group.

Preparation of specimen

The cultured cell suspension (1×10^6 cells) of each group was dropped onto the pretreated slides and then the slides were dried, followed by fixation with 20-40 g/L paraformaldehyde and stored at -20 °C.

Furthermore, the cultured cell suspension (1×10^6 cells) of each group was dropped onto the nitrocellulose membrane (NCM, Protran™, USA) pretreated with 20 × SSC for dot blot hybridization or with RNase-free water for immunodot blotting, and then NCM specimens were dried and stored at -20 °C.

Labeling and sensitivity detection of cDNA probes

The denatured cDNAs of wt p53, c-myc, bcl-2, and iNOS were labeled with biotin-11-dUTP (Sigma, USA) by random primer system (Promega, USA), and the sensitivity of each probe was detected using DNA dot blotting.

In situ hybridization

After being pretreated with 5 mg/mL final concentration of proteinase K (Promega, USA) for 10 min, post-fixation with paraformaldehyde and pre-hybridization without the cDNA probes for 3 h, the slide specimens of each group were hybridized with each kind of cDNA probes in final concentration of 0.5 μg/mL at 42 °C overnight. Then the slides were stringently washed four times with 0.1× SSC at 42 °C for 15 min. The streptavidin-alkaline phosphatase (dilution 1:1 000, Promega, USA) was added onto the slides after blocking with 10 g/L acetylated BSA. The nitroblue tetrazolium and 5-bromo 4-chloro 3-indole phosphate (NBT-BCIP, Promega, USA) were used as the substrate to develop the signals in bluish-violet color. For detection of intact cell using dot blot hybridization, the NCM specimens were first rinsed rapidly with chloroform, followed by treating at 80 °C under vacuum for 2 h and subsequently treated basically as aforementioned procedures for the slides.

Immunocytochemistry

The slide specimens of respective groups were treated with 3 g/L Triton X-100/PBS for 10 min, 30 mL/L H_2O_2 5 min, 0.01 mol/L citrate buffer (pH 6.0) at 95 °C for 10 min, washed with 1× PBS after each step. The slides were treated with 100 mL/L normal goat serum for 20 min, followed by incubation with the primary mAbs against EGFR (Sigma, USA) for E1 and C1 groups, and against p38 kinase and caspase-3 (Invitrogen, USA) for E2 and C2 groups at a dilution of 1:100 at 4 °C overnight. The HRP-labeled or alkaline phosphatase-labeled goat anti-mouse serum was added onto the slides for 1 h as the secondary antibody. The slides were thoroughly washed with PBS after treatment with respective antibodies. The DAB/H_2O_2 was used as the substrate to develop the positive signals in brownish color, while NBT/BCIP was used as the substrate to develop bluish-violet color. The specific primary antibodies were replaced by PBS for the negative controls. For detection of immunodot blotting, the NCM specimens were treated using the above procedures except for substitution of 0.5 g/L Tween 20 in TBS (Tris-Cl buffer saline) for PBS.

Cytochemistry

The slides of each group were incubated with phosphate buffer (PB) containing 1.0 mg/mL reduced form of NAD 1 (co-enzyme 1) and 0.5 mg/mL NBT at 37 °C for 1.5 h. The negative control was performed simultaneously except for the addition of PB alone.

Ratio of differentiated cells/proliferating cells

The slides of each group were re-fixed with ice-cold Carnoy' s fixative for 15 min, followed by digestion of intra-nuclear DNA with 1 mol/L HCL in 800 mL/L ethanol for 5 min. The slides were stained with 5 g/L methyl green and pyronin GS (BDH, UK) in an acetate buffer (pH 4.8) for 5-7 min, subsequently washed with D.H_2O and acetone.

Detection of apoptosis rate by TUNEL

The slides of each group were treated with 50 mg/mL levamizol in ethanol for 15 min, followed by digestion with proteinase K and post-fixation with paraformaldehyde. Then the slides were incubated with 1 mg/mL terminal deoxyribonucleotidyl transferase (TdT, Promega, USA), biotin-11-UTP (Sigma, USA) and dNTP in TdT buffer at 4 °C overnight. The following procedures were performed similarly as those for *in situ* hybridization. The negative control was carried out at the same time except for incubation with TdT buffer alone in the total incubation substrate.

Statistical analysis

Each kind of dot blotting was repeated six times. The dot blotting in violet color was scanned at 560 nm by thin-layer chromatography scanner (Shimada, Japan), and that in brownish color was scanned at 420 nm. The signal intensity in slide specimens was calculated as

total integration value in more than 100 cells under oil-microscope. The data were analyzed with SSPS 10. A *P* value less than 0.05 was considered statistically significant.

RESULTS

The sensitivity of each kind of biotin-labeled cDNA probe, including wt p53, c-myc, bcl-2, and iNOS, could approach to 1.0 ng/L as detected by DNA dot blotting. The apoptotic signals in violet color were localized in the nuclei mostly translocated towards cell periphery. The cell apoptosis rate and the ratio of differentiated cells (D)/proliferating cells (P) in each group are shown in Table 1 and Figures 1 A-D.

Table 1 Apoptosis rate and ratio of differentiated cells (D)/proliferating cells (P) in each group

	E1 group	C1 group	E2 group	C2 group
Apoptosis rate	16%[a]	3.0%	54%[c]	4.0%
Ratio of D/P	1.7 (63/37)[e]	0.2 (17/83)	2.3 (70/30)[g]	0.16 (14/86)

Apoptosis rate: [a]$P<0.05$ *vs* C1 and E2 groups; [c]$P<0.05$ *vs* C2 group. Ratio of D/P:[e]$P<0.05$ *vs* C1, [g]$P<0.05$ *vs* C2.

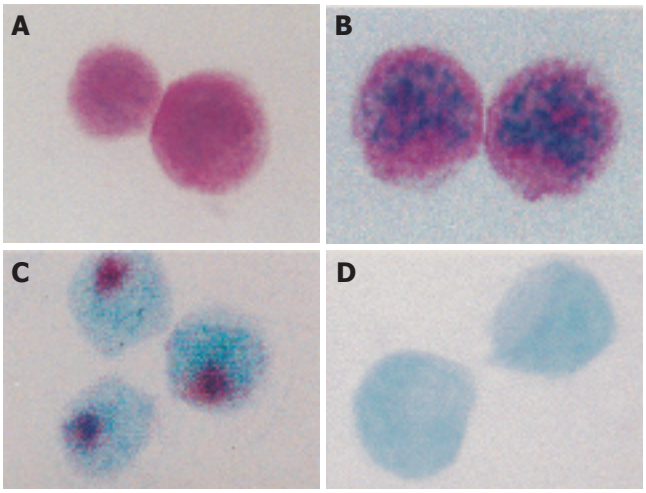

Figure 1 A :HCl denaturation and methyl green-pyronin staining of differentiated Eca-109 cells (×1 000); **B:** HCl denaturation and methyl green-pyronin staining of proliferating Eca-109 cells (×1 000); **C:** TUNEL assay showing apoptotic Eca-109 cells (×1 000); **D:**TUNEL assay showing non-apoptotic Eca-109 cells (×1 000).

The results showed that there was a significant difference in apoptosis whereas no significant difference in differentiation between E1 and E2 groups.The signals of both *in situ* hybridization (gene transcription of c-myc, wt p53 and iNOS) and EGFR-immunoreactivity (IR) were all localized in the cytoplasm. The hybridization signals appeared as violet color granules; the signal intensity of wt p53 and iNOS in E1 group was markedly higher than that in the C1 group, whereas that of c-myc and EGFR in E1 group was significantly lower than that in the C1 group. The scanning values on NCM specimens for each kind of signals are shown in Table 2.

Table 2 Comparison of signal scanning values on NCM between E1 group and C1 group (mean±SD)

Groups	c-myc mRNA	Wt p53 mRNA	iNOS mRNA	EGFR-IR
E1 group	3.38±0.99	2.74±0.83	4.52±0.74	2.37±1.05
C1 group	5.18±1.39	0.38±0.27	2.63±0.13	4.38±0.48

$P<0.05$, E1 *vs* C1 for each signal.

The hybridization signals in violet-colored granules of c-myc, wt p53 and iNOS were localized in the cytoplasm, while that of Fas-IR and FasL-IR were located surrounding the cytomembrane. The signal intensity of bcl-2, c-myc gene expression and Fas/FasL-IR was obviously decreased in E2 group as compared to C2 group, while that of wt p53 and iNOS was markedly increased in E2 group as compared to C2 group. The scanning values of each signal on NCM specimens are shown in Table 3.

Table 3 Comparison of signal scanning values on NCM between E2 group and C2 group (mean±SD)

Groups	bcl-2	c-myc	iNOS	Wt p53	Fas/FasL-I
	mRNA	mRNA	mRNA	mRNA	R
E2 group	1.36±0.54	1.72±0.76	5.47±0.35	4.76±1.28	2.69±0.73
C2 group	3.49±1.53	5.22±1.44	2.65±1.22	0.42±0.28	4.17±0.92

$P<0.05$, E2 *vs* C2 for each signal.

The brownish-colored granules of caspase-3 IR were scattered in the cytoplasm, the signal intensity of E2 group was obviously higher than that of C2 group. In C2 group, the p38-IR staining appeared as yellow-brownish colored granules in the cytoplasm, while in E2 group, the p38-IR staining with stronger intensity was mostly located in the nuclei (the activated p38 kinase translocated from cytoplasm into nuclei). The violet-colored NOS activity located in the cytoplasm was markedly increased in E2 group as compared to C2 group (Table 4).

Table 4 Comparison of total integration of signal intensities for p38-IR, caspase-3-IR and NOS activity between E2 and C2 groups

Group	p38-IR	Caspase-3 IR	NOS activity
E2 group	184	348	302
C2 group	122	207	138

$P<0.05$, E2 *vs* C2 for each signal.

DISCUSSION

It is well known that DNA can be stained by methyl green, and RNA by pyronin in cytochemistry. Sen *et al*[8] demonstrated that the proliferating cells were differentially stained by methyl green in bluish-

green color and the differentiated cells were stained mainly by pyronin in red color, since the nuclear DNA of proliferating cells was less sensitive to hydrolysis with hydrochloric acid as compared to the differentiated cells. In this study, the ratio of differentiated cells/proliferating cells had no significant difference between E1 and E2 groups, the effect of cell differentiation or proliferation inhibition could be demonstrated earlier in E1 group induced with 8-Br-cAMP for 24 h. However, there was a significant difference in the apoptosis rate between E1 and E2 groups.

It was reported that the activation of EGFR, c-myc oncogene, and inactivation of wt p53 tumor suppressor gene could be detected in the development of squamous cell carcinoma of the esophagus[9]. The wt p53 encoded by wt p53 tumor suppressor gene antagonized cell cycle progression to inhibit cell growth with contrary effect to EGFR and c-myc through $p21^{waf1}$, which was elucidated in our previous study[4]. It is known that the EGF receptor in the esophageal cancer, homologous to v-erbB, is a truncated form of EGFR with deletion of extra-cellular ligand domain, and a persistent tyrosine kinase activity displayed to stimulate the cancer cell growth independent of EGF ligand. The c-myc proto-oncogene encodes transcriptional regulator; upregulation of myc enforces cell growth; while abrupt downregulation of myc or withdrawal of any growth cytokine from environmental factors may have an association with cell differentiation and apoptosis[10]. In this experiment, downregulation of myc may be associated with decreased expression of EGFR. The precise mechanism of myc-induced pathways to contribute to apoptotic response is still largely unsolved[11].

It was found that multifunctional gene p53 could be involved in cell differentiation and apoptosis in malignant tumors[12]. Schwartz *et al*[13] reported that the osteoblasts in an osteosarcoma cell line could be induced by p53 to produce osteocalcin product. Tsumamoto *et al*[14] indicated that NO could induce cell differentiation in the rat retinal ganglion cells. Our previous study showed that NO and NOS could induce the retinoblastoma HXO-Rb44 cells towards differentiation with enhanced enolase expression[5]. The wt p53 could be upregulated by NO[15]; and apoptosis of human carcinoma cells could be induced by inducible NOS expression[16,17]. The exogenous wt p53 at higher level could inhibit proliferation of K562 cells and induce apoptosis; but could induce the cell differentiation at lower p53 level[18]. Similarly, the NO, product of NOS, in a small amount could involve cell protection, while a great amount of NO could cause cytotoxicity or apoptosis[19]. Interestingly, in this study, we observed that downregulation of EGFR and c-myc and upregulation of wt p53 and iNOS in E1 group (after treatment with 8-Br-cAMP for 24 h) might be associated with differentiation; and further downregulation of c-myc and upregulation of wt p53 and iNOS in E2 group (after treatment with 8-Br-cAMP for 48 h) might be associated with apoptosis in Eca-109 cells.

Our previous study demonstrated that the decreased ratio of bcl-2/bax expression was associated with inhibition of cell apoptosis. The downregulation of anti-apoptotic bcl-2 could cause the cells sensitive to apoptosis, and p53 could inhibit the bcl-2 expression and promote expression of pro-apoptotic Fas; besides, bcl-2 could participate in NO-mediated and p53-mediated apoptosis[14]. The Fas has been shown as a target gene for transcription and activation by p53[20]. The combination of Fas with FasL could participate in apoptosis of tumors, such as ovarian cancer, etc.[21]. In this experiment, the decreased Fas/FasL ratio implicated that the decreased Fas with increased FasL might be induced by 8-Br-cAMP after 48 h of treatment.

Among the mitogen-activated protein kinase (MAPK) family, the p38-MAPK has been reported to be involved in apoptosis, while ERK-1 oppositely stimulated cell growth; and the p53 could be activated by p38 through N-terminal serine in p53 phosphorylated by p38-MAPK[22]. Kim *et al*[23] indicated that NO-induced p38 kinase activity was an induction signal for apoptosis of chondrocytes in association of p53 accumulation, caspase-3 activation and differentiation status. The caspase-3 is a downstream effector member in the caspase family, playing a role in the final common pathway of apoptosis. It was reported that Fas could induce apoptosis through caspase effector pathway directly, not necessary to be gene-mediated[24]. Our results suggested that 8-Br-cAMP-induced Eca-109 cell apoptosis might mainly be mediated through downregulation of bcl-2 by wt p53 and upregulation of wt p53 by p38 kinase; or wt p53-mediated Fas/NO effector pathway may finally come to the common pathway of activated caspase-3. Hence, upregulation of wt p53 may play an important role, synergistically in combination with regulation of related gene expressions to form a regulatory network involved in Eca-109 cell differentiation and apoptosis. Understanding of the regulatory network may contribute to providing novel strategy and bright insight for cancer therapy.

Abstract

AIM: To study the pathogenetic processes and the role of gene expression by microarray analyses in expediting our understanding of the molecular pathophysiology of pancreatic adenocarcinoma, and to identify the novel cancer-associated genes.

METHODS: Nine histologically defined pancreatic head adenocarcinoma specimens associated with clinical data were studied. Total RNA and mRNA were isolated and labeled by reverse transcription reaction with Cy5 and Cy3 for cDNA probe. The cDNA microarrays that represent a set of 4 096 human genes were hybridized with labeled cDNA probe and screened for molecular profiling analyses.

RESULTS: Using this methodology, 184 genes were screened out for differences in gene expression level after nine couples of hybridizations. Of the 184 genes, 87 were upregulated and 97 downregulated, including 11 novel human genes. In pancreatic adenocarcinoma tissue, several invasion and metastasis related genes showed their high expression levels, suggesting that poor prognosis of pancreatic adenocarcinoma might have a solid molecular biological basis.

CONCLUSION: The application of cDNA microarray technique for analysis of gene expression patterns is a powerful strategy to identify novel cancer-associated genes, and to rapidly explore their role in clinical pancreatic adenocarcinoma. Microarray profiles provide us new insights into the carcinogenesis and invasive process of pancreatic adenocarcinoma. Our results suggest that a highly organized and structured process of tumor invasion exists in the pancreas.

Key words: Pancreatic adenocarcinoma; cDNA microarrays; Cancer-associated genes

INTRODUCTION

Pancreatic carcinoma is the 12th most common cause of cancer death in China, which is one of the most aggressive form of human tumors and is virtually incurable. Its incidence and mortality rates are almost identical, even after receiving surgical resection and adjuvant chemo-radiotherapy, the overall 5-year survival rate is only 4.1%[1]. The etiology of pancreatic carcinoma is still unknown. There is clearly a need for novel and more effective diagnostic and therapeutic methods.

Oncogenesis and development of neoplasm is a complex multiphase process, which involves overexpression of oncogenes or inactivation of tumor suppressor genes, mutation or depletion of normal genes, pleiotropic effects and immunologic function. The genes are involved in vital processes of life, such as gene expression accommodation, immunology or cell differentiation, which are arranged in some gene clusters, in which all the members are being controlled in unity[2]. In the process of oncogenesis, there may exist some different clusters of tumor-related genes. Hence, it is important to find such unique gene clusters involved in carcinogenesis, invasion and metastasis processing.

Current focus of molecular profiling is the large-scale analysis of gene expression using new DNA array technology[3]. This powerful technology is being used to study many biological processes. The experimental or clinical goals range from insights to pathogenesis, cancer diagnosis and prediction of clinical outcome for identification of therapeutic targets. In this way, DNA array analysis is providing the first glimpse of a substantial improvement in our understanding of cancer biology and diagnosis. Identifying and sequencing a set of full-length cDNAs that represent all human genes would help in both gene discovery and functional analysis. It offers a

great opportunity to study the pathogenetic processes and molecular pathophysiology of pancreatic carcinoma.

In this study, we analyzed nine pancreatic adenocarcinomas using the cDNA microarray containing 4 096 human genes with the aim of understanding expression patterns and searching for carcinogenesis-related gene clusters and novel useful markers for the malignant potential of pancreatic carcinoma at the molecular level.

MATERIALS AND METHODS

Patients and tissue specimens

We analyzed samples of pancreatic head adenocarcinoma from nine patients (five males, four females, 51-71 years) who underwent pancreaticoduodenectomy at Changhai Hospital, Shanghai, China, between November 1999 and May 2000. All samples were collected with informed consent and Ethics Committee approval. Samples were grossly dissected and snap-frozen in liquid nitrogen within 10 min of removal and stored at -80 °C. Initial diagnosis of each sample from the frozen section was later confirmed by detailed analysis of paraffin-embedded sections. Following the fourth Japanese edition of the Classification of Pancreatic Carcinoma (Japan Pancreas Society, 1993), the nine tumors were staged, including two stage I, two stage II, four stage III and one stage IVa. We isolated and purified total RNA from pooled, noncancerous, male adult human pancreas tissues and used as a reference "normal" sample for each microarray experiment.

RNA isolation

Tumor and normal tissue samples were ground into a fine powder in a 10-cm ceramic mortar (RNase-free) and total RNA was extracted according to the original single-step extraction procedure with slight modifications. Ground tissue was homogenized in Solution D containing 1% ß-mercaptoethanol. After centrifugation, the supernatant was extracted twice with an equal volume of phenol: chloroform (1:1) and once with an equal volume of acidic phenol:chloroform (5:1), discarding the organic phase each time. The aqueous phase was then precipitated by an equal volume of isopropylalcohol at 4 °C, centrifuged to pellet the RNA and dissolved in deionized (Milli-Q) H_2O. mRNA was purified using an Oligotex-dT mRNA Midi Kit (Qiagen, Inc., Carlsbad, CA, USA), following the manufacturer's instructions. The RNA concentration was measured by using spectrophotometry, and its integrity was assessed by electrophoresis on formaldehyde-agarosegel.

Microarrays

The construction of the microarrays was carried out following Stanford University's method[4]. The microarrays consist of 4 096 sequences, including full-length and partial complementary DNAs (cDNAs) representing novel, known and control genes provided by United Gene Holdings, Ltd. The known genes were selected from NCBI UniGene set and cloned into a plasmid vector. The novel genes were obtained through systematic full-length cloning efforts carried out at United Gene Holding, Ltd. The control spots of non-human origin in 4 096 chip included the rice U2 RNA gene (8 spots), hepatitis C virus (HCV) coat protein gene (8 spots), and spotting solution alone without DNA (32 spots). The cDNA inserts were amplified by PCR using universal primers and then purified. All PCR products were examined by electrophoresis on an agarose gel to ensure the quality and identity of amplified clones as expected. Then the amplified PCR products were dissolved in a buffer containing 3× SSC solution. The solutions with amplified PCR products were spotted onto silylated slides (CEL Associates, Houston, TX, USA) using a Cartesian PixSys 7 500 motion control robot (Cartesian Technologies, Irvine, CA, USA) fitted with ChipMaker Micro-Spotting Technology (TeleChem International, Sunnyvale, CA, USA). Glass slides with spotted cDNA were then hydrated for 2 h in 70% humidity, dried for 0.5 h at room temperature, and UV cross-linked at a dose of 65 mJ/cm. They were further treated with 2 g/L sodium dodecyl sulfate (SDS) for 10 min, distilled H_2O for 10 min, and 2 g/L sodium borohydride ($NaBH_4$) for 10 min at room temperature. The slides were dried again and made ready for use.

Probe preparation and hybridization

The fluorescent cDNA probes were prepared through reverse transcription of the isolated mRNAs and then purified. The RNA samples from healthy individuals were labeled with Cy3-dUTP and those from cancerous patients with Cy5-dUTP. The two color probes were then mixed, precipitated with ethanol and dissolved in 20 μL of hybridization solution. Microarrays were pre-hybridized with hybridization solution containing 0.5 mg/mL denatured salmon sperm DNA at 42 °C for 6 h. Fluorescent probe mixtures were denatured at 95 °C for 5 min, and the denatured probe mixtures were applied onto the pre-hybridized chip under a cover glass. Chips were hybridized at 42 °C for 15-17 h. The hybridized chips were then washed at 60 °C for 10 min each in solutions of 2× SSC and 2 g/L SDS, 0.1× SSC and 2 g/L SDS, and 0.1× SSC, and then dried at room temperature.

Data analysis

The chips were scanned with a ScanArray 3000 (GSI Lumonics, Billerica, MA, USA) at two wavelengths to detect emission from both Cy3 and Cy5. The acquired images were analyzed using ImaGene 3.0 software (BioDiscovery, Inc., Los Angeles, CA, USA). The intensities of each spot at the two wavelengths represent the quantity of Cy3-dUTP and Cy5-dUTP, respectively, hybridized to each spot. Ratios of Cy3-Cy5 were computed for each location on each microarray. Overall intensities were normalized with a correction coefficient obtained using the ratios of 40 housekeeping genes (available at http://www.biodoor.com/).

We used the threshold value to define significant relative expression changes, which set at 2.0 for overexpression and at 0.50 for underexpression on the

basis of both the experimental variability in our data and the manufacturer's established performance criteria. Data filtering with this algorithm identified the genes overexpressed at least by twofold and underexpressed at least by 50% across, more than 66.7% (6/9) of all specimens. To minimize artifacts arising from low expression values, only the genes with raw intensity values for both Cy3 and Cy5 of >600 counts were chosen for differential analysis.

RESULTS

Sensitivity and reproducibility of the microarray system

The purity and concentration of isolated RNA were analyzed first by using UV spectrophotometer at absorbance wavelengths of 260 and 280 nm (A_{260} and A_{280}). The average A_{260}/A_{280} ratio was higher than 1.9. Furthermore, the integrity of the RNA sample was verified by electrophoresis on 10 g/L agarose gel stained with ethidium bromide. The quality of the RNA was assessed by the visualization of the 28S and 18S ribosomal RNA bands. The bands were distinct and sharp, without being diffused and smeared. The results indicated that mRNA preparation expressed continuous polyadenylated transcripts between 0.9 and 4.0 kb in length.

In order to access the "noise" in the differential expression assay, we employed self-comparison experiments. A sample of mRNA from a single fetal liver tissue was divided into two equal aliquots and labeled with Cy3-dUTP and Cy5-dUTP, respectively. The labeled samples were then mixed together and hybridized to the microarray. The results revealed that approximately 1% of the 4 096 cDNA clones showed more than 2.0-fold difference in signal intensity between the two channels. Furthermore, this "noise" in the data was shown upon analysis to occur at random array positions in each microarray experiment. Figure 1 shows the scatter plots of the within-slide normalization experiment. The Cy3/Cy5 log ratios from the different print tip groups were centered around zero, indicating that the types of systematic errors were minimized. The spots in the experiments showed a highly concordant distribution pattern. Besides, hybridization experiments with probes prepared from human mRNA produced little or no signal at the positions of the negative controls (data not shown).

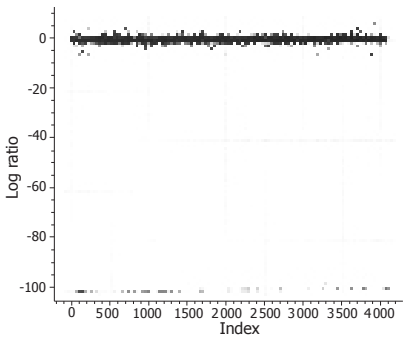

Figure 1 Scatter plots of average ratio/spot label distribution.

Gene expression analysis in patients with pancreatic adenocarcinoma

The hybridizations for each individual were repeated twice. Of all the 4 096 human genes analyzed through microarray experiments, a total of 184 genes (4.5%) revealed differential expression in more than 60.66% (6/9) of the pancreatic adenocarcinoma specimens using a fold ratio of >2 as criteria for cut-off. Of 184 genes, the expression of 87 genes (47.3%) was markedly increased in pancreatic adenocarcinoma tissues as compared with the normal pancreas tissues (Figure 1). In addition, the expression of 97 genes (52.7%) was significantly decreased in pancreatic adenocarcinoma tissues as compared with normal pancreatic tissues (Figure 2). The 184 genes corresponded to 173 genes represented in the GenBank and 11 novel sequences which have not been found in the GenBank. Scatter plots with cancerous tissues showed a wide distribution pattern (Figure 2), suggesting that genes are expressed differentially in cancer cells when compared with the normal cells. Scatter plot of the values of Cy3 and Cy5 fluorescent signals also revealed a pattern of tight distribution and clustered in an almost 45° diagonal line as expected.

In the 11 novel genes screened by our microarray experiments, an overexpressed clone in pancreatic adenocarcinomas was identified. The average Cy5/Cy3 ratio of the clone is 4.92. As we have reported recently[5], this clone is the full-length cDNA of the human gene S100P (GenBank accession number AF539739). The sequence is of 1 297 bp and encodes a protein identical to previously characterized human S100P, but it is much longer than the previously reported 439 bp. The cDNA is near full-length as confirmed by Northern blot analysis. We examined its distribution in tissues by using Northern blot and RT-PCR analysis, and found that it was abundantly expressed in many tissues including placenta, unlike the expression pattern of other S100 family genes.

DISCUSSION

DNA microarray technology has offered us a new insight into the secrets of life by monitoring the activities and

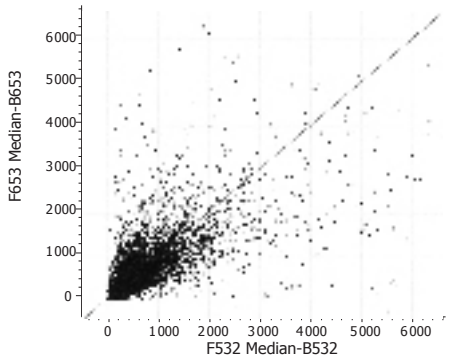

Figure 2 Microarray scatter plot for pancreatic adenocarcinoma mRNA labeled with Cy5 and normal pancreas mRNA labeled with Cy3. The "sameness line" drawn at a 45° angle denotes a 1:1 ratio of signal intensity between the Cy3 dye (*Y* axis) and the Cy5 dye (*X* axis) at each position on the array.

profiles of thousands clones simultaneously. The gene expression profiles can led us to mapping a cross-section of genetic activities and biological entity[6].

In this experiment, the genes identified as differentially expressed in microarrays revealed a wealth of information that pancreatic adenocarcinomas are complex tumors, as evidenced by the wide range of investigations[7-9]. However, these findings not only provide novel insight into the biology of pancreatic carcinoma, but also serve to identify numerous new targets for development into serologic markers or therapeutic target. The differentially expressed genes in pancreatic adenocarcinomas included oncogenes and tumor suppression genes, cell-cycle-related genes, signal transduction factors, extracellular matrix and skeleton related genes, transcription factors, DNA damage and repair related genes and apoptosis-related genes (Tables1 and 2).

The screened genes with good concordance in these pancreatic adenocarcinoma patients may have the potential to become candidates for tumor markers and the molecular target for gene therapy, whereas genes that show concordance in a patient subset may reflect different disease stages or physiological and genetic differences between the patients.

Griffin *et al*[10] reported that more than 70% of pancreatic adenocarcinomas possessed consistent chromosome abnormalities. The most frequent whole chromosomal gains were chromosomes 20 and 7, and

the chromosomal losses were much more frequent in chromosomes 18, 13, 12, 17, and 6. Structural abnormalities were frequently involved in chromosomes 1p, 6q, 7q, 17p, 1q, 3p, 11p, and 19q. From our microarrays, we found that the overexpressed genes in pancreatic adenocarcinomas are mainly located in chromosomes 1, 2q, 7q, 9q, 12, 14q, 15q, and 21q, and the downexpressed genes are mainly located in chromosomes 1, 2, 3, 7q, 8q, 15q, 17, 19, and 22q, which are similar to the previous reports. This phenomenon suggests the existence of acquired genomic alterations in pancreatic carcinomas.

Among the genes overexpressed in pancreatic adenocarcinomas, RAB22B and Rho GDP dissociation inhibitor (Rho GDI) are the members of Ras superfamily, whose Cy3/Cy3 ratios are 3.53 and 4.504, respectively. As it is well known that many pancreatic carcinoma cells show "addiction" to K-ras mutation, while normal cells appear resistant to suppression of K-ras-mediated signaling by antisense K-ras RNA expression adenoviral vector[11]. So, overexpressed RAB22B may be the result of K-ras mutation in pancreatic adenocarcinoma. The Rho family proteins were found to reorganize cytoskeletons and regulate the cell migration via the activation of effector proteins. GTP-bound Rho is an active form, whereas the GDP-bound form is inactive. Rho GDI can block the conversion between the GTP- and GDP-bound forms. Expression of Rho family molecules has recently been reported in breast, lung, pancreas and colon carcinomas, and testicular germ cell tumors[12]. Moreover, three guanine nucleotide exchange factors (RCC1-like G

exchanging factor, eukaryotic translation elongation factor 1-δ, eukaryotic translation elongation factor 1-β2) were downexpressed in our microarrays, which implied that GDP-bound forms might be related to tumorigenesis of pancreatic adenocarcinoma. Furthermore, VHL gene, which has been confirmed as a tumor suppressor gene[13], was also downexpressed in pancreatic adenocarcinoma.

The result showed that pancreatic carcinoma cells are much more active than normal cells in many steps of multiple pathways of signal transduction. The stable state of normal somatic cells depends on the dynamic equilibrium of apoptosis and proliferation. Apoptosis-related genes were downexpressed in cancer. These findings revealed that the phenotypical similarities among different cancers are also reflected at the molecular level.

Gene expression profiling of pancreatic carcinoma has also provided new insights into the process of tumor invasion. In pancreatic carcinoma tissue, many invasion and metastasis related genes, such as ECM and cell skeleton related genes (type I collagen, type III collagen, type IV collagen, decorin, secreted phosphoprotein 1, vimentin, tissue inhibitor of matrix metalloproteinase 1, fibronectin 1,α2-actin, tubulin, tropomyosin 1, *etc.*), showed high expression level, reflecting the cellular components of the host stromal response seen in the presence of infiltrating carcinoma. Moreover, the urokinase-type plasminogen activator receptor (uPAR) was found highly expressed in pancreatic adenocarcinomas, which is a key molecule in the regulation of cell-surface plasminogen activation and, as such, plays an important role in many normal as well as pathologic processes[14]. Memarzadeh *et al*[15] concluded that uPAR is a useful prognostic marker for biologically aggressive forms of endometrial cancer. These phenomena suggest that poor prognosis of pancreatic carcinoma may have a solid molecular biological basis, and also indicate that a highly organized and structured process of tumor invasion exists in the pancreas.

The downregulated genes in the patients with pancreatic adenocarcinoma are also divided into distinct functional categories. Reduced expression was observed in genes encoding products that function in the apoptosis, immune system, cell regulation, DNA injury and repair processing and GTP/GDP signaling, which were in agreement with the previous reports[16,17].

In conclusion, the application of cDNA microarray technique for analysis of gene expression patterns is a powerful strategy to identify novel cancer-associated genes, and can rapidly explore their role in clinical pancreatic adenocarcinomas. Microarray profiles provide us new insights into the carcinogenesis and invasive process in pancreatic adenocarcinoma. Our results suggest that a highly organized and structured process of tumor invasion exists in the pancreas.

Abstract

AIM: To investigate the influence of IL-1B-511 gene polymorphism on IL-1B mRNA expression and gastric acid output in individual with or without *Helicobacter pylori (H pylori)* infection.

METHODS: IL-1B mRNA expression and gastric acid secretion in 117 health volunteers were assayed using semi-quantitative RT-PCR and gastric juice assay, respectively. Pepsinogen (PG) I and II of 255 subjects (including 117 health volunteers) were also examined.

RESULTS: T/T genotype individuals with *H pylori* infection had a more decreased PG I/II ratio. In gastric antrum mucosa, the individuals with *H pylori* infection had higher IL-1B expression than those without *H pylori* infection, but there was no obvious difference among each genotype. In gastric corpus, the individuals with *H pylori* infection had a significantly higher IL-1B expression than those without *H pylori* infection. IL-1B-511T/T genotype was markedly higher as compared with the other two genotypes. Both maximal acid output and basic acid output were similar among each genotype in IL-1B-511 gene locus, regardless of *H pylori* infection.

CONCLUSION: IL-1B-511 T allele does not decrease gastric acid output, although it has a stimulated influence on IL-1B expression. Consequently, the pathway, through which IL-1B plays a central role in gastric cancer development, might not depend on low acid, but on the other regulation mechanisms.

Key words: IL-1; Polymorphism; Stomach neoplasm; Gastric acid; *Helicobacter pylori* (*H pylori*)

INTRODUCTION

Gastric cancer development is a multifactor and multi-step process. Clinical and epidemiological studies have suggested that environmental effects and dietary habits, such as smoking, alcohol consumption, low intake of fruits or vegetables and *Helicobacter pylori (H pylori)* infection, were the primary causes for the occurrence of carcinogenesis[1,2]. Furthermore, decades of researches have built up a variety of evidence that genetic risk factors also play an important role in cancer development[3]. Recently, through a case-control study, El-Omar *et al*[4] discovered that there was a strong relationship between IL-1 gene polymorphism and gastric cancer in the Polish population. The association between IL-1B-511 T allele and gastric carcinoma or atrophic gastritis was discovered by Machado *et al*[5] and Furuta *et al*[6] respectively. The results of several studies are in agreement with ours on Chinese population[7].

The epidemiological studies mentioned above were based on a hypothesis that IL-1B-511 and -31 gene polymorphisms contributed to stomach cancer development through T allele upregulating IL-1B mRNA expression, and then inhibiting directly gastric acid secretion. Low gastric acid was reported as a risk factor for cancer, because it resulted in a change of the colonized place of *H pylori* from gastric antrum to the corpus[8,9]; unfortunately, corpus-predominant gastritis with bacterial overgrowth was at increased risk of atrophic gastritis (with several biomarkers, such as pepsinogen (PG)I, II or I/II ratio)[6,10] and even gastric cancer. Both increased intragastric pH value and *H pylori* infection could significantly enhance N-nitroso compounds concentration, which is a putative promoter of carcinogenesis and tumor progression[11]. Svendsen *et al*[12] discovered 5 gastric cancer patients among 114 patients with low gastric acid secretion in a long-term follow-up (mean 8.4 years) study. However, this model was only supported by animal studies[4,13]. It is unknown now whether IL-1B gene polymorphism increased IL-1β protein level and resulted in human hypochlorhydria and atrophic gastritis *in vivo*. In the present study, we investigated the effects of IL-1B-511 genetic polymorphism on IL-1β mRNA expression and gastric acid secretion in the gastric mucosa of human beings with or without *H pylori* infection.

MATERIALS AND METHODS

Subjects

A total of 255 students (121 females and 132 males) from the Sun Yat-Sen University of Medical Sciences were enrolled in this study (Table 1). All subjects belonged to the ethnic group of Han and their age ranged from 19 to 24 years (mean 21.4±1.5 years). None of them had the histories of systemic lupus erythematosis, diabetes mellitus, rheumatoid arthritis, and inflammatory bowel disease. None of the subjects had received treatment for *H pylori* infection. Subjects with a family history of gastric cancer were also excluded.

Table 1 Relationship between IL-1B-511 genotypes and *H pylori* status

Loci	Genotype	*H pylori*+ (*n*=96)	*H pylori*– (*n*=159)	Total (*n*=255)
IL-1B-511	C/C	34	63	97
	C/T	46	75	121
	T/T	16	21[1]	37 (14.1%)
IL-1B-31	C/C	72	120	192
	C/T	22	37	59
	T/T	2	2[2]	4 (1.6%)

[1]*H pylori*+ *vs H pylori*–: x^2=0.6; [2]*H pylori*+ *vs H pylori*–: x^2=0.3

After genotyping of IL-1B gene and test of *H pylori* antibody IgG, 117 subjects were randomly selected for the second step study on IL-1B-511 locus, but IL-1B-31 T/T genotype frequency is too low to be researched (Tables 1 and 2). Three biopsy specimens were collected from the antrum (two specimens for RNA extraction and another one for urease test) and two biopsy specimens from corpus for RNA extraction. In each genotypical group, no statistical difference in *H pylori* prevalence, sex, and age was observed (Table 2).

Table 2 Common characteristics of 117 subjects (*n*, mean±SD)

	IL-1B-511 genotype (*n* =117)		
	T/T (*n* =37)	C/T (*n* =40)	C/C (*n* =40)
H pylori+	14	15	18[1]
Sex (F/M)	16/21	18/22	19/21[2]
Age (yr)	21.9±1.5	22.1±1.6	22.3±1.6[3]

[1]x^2=0.6; [2]x^2=0.1, [3]F=1.4

Examination of pepsinogen I and II

Using ELISA assay, PG I and II of 255 subjects were examined. Blood samples were obtained after 10-h fasting, and then coagulated at room temperature for 30 min to extract serum. Finally, the ELISA assay was performed according to the manufacturer's instructions (Orion Diagnostica Company). All analysis was done in duplicate and with an internal standard. The mean absorbance (A_{450}) of each specimen was tested at 450 nm.

DNA extraction

DNA was isolated from peripheral blood using the NaI method[14]. Briefly, heparinized whole blood (100 mL) was added to twofold volume of 6 mol/L NaI and fourfold volume of chloroform:isoamyl alcohol (24:1) and centrifuged at 5 000 r/min for 5 min. The aqueous layer was removed and isopropanol was added to the pellet to deposit DNA (centrifugation at 5 000 r/min for 5 min). Extracted DNA was rinsed 2-3 times with 700 mL/L alcohol and resuspended in 40 μL TE buffer (pH 8.0).

Genotyping of IL-1B-511 and -31 loci polymorphism

Polymorphism of IL-1B-511 and -31 that encodes IL-1B was genotyped by polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP)

A fragment containing the AvaI polymorphic site at position -511 of the IL-1B gene was amplified using PCR. The oligonucleotides, 5'-GCCTGAACCCTGCATACCGT-3' and 5'-GCCAATAGCCCTCCCTTCT-3', flanking this region were used as primers. AluI polymorphic site at position -31 was amplified using primers: 5'-AGAAGCTTCCACCAATACTC-3' and 5'-ACCACCTAGTTGTAAGGAAG-3'. PCR was carried out as described previously by Zeng *et al*[7] PCR fragments were separated by electrophoresis on 30 g/L agarose with ethidium bromide staining. The C allele was designated, if two bands of 92 and 63 bp were obtained, and T allele was designated, if a single band of the undigested 155 bp was obtained. The genotype was designated as follows: C/C, 2 bands of 92 and 63 bp; C/T, 3 bands of 155, 92, and 63 bp; T/T, a single band of 155 bp.

Detection of IL-1B mRNA expression

The biopsy specimens (5-10 mg) were mixed with 1 000 μL TRIzol (Invitrogen) and then homogenized for RNA extraction. RNA was resuspended in 40 μL TE buffer (RNase-free).

RNA solution (5 μL) was diluted 10-fold and $A_{260}/_{280}$ ratio was examined. The total RNA was calculated as follows: $RNA_{total}=A_{260}\times40\times N$.

IL-1B amplification was performed using the primers: IL-1B primers, P1 5'-gatgaagtgctccttccaggac-'3, P2 5'-tggagcaacaagtggtgttctcca-'3 (480 bp); and GAPDH primers, P1 5'-cacagtccatgccatcactg-'3, P2 5'-tactccttggaggccatgtg-'3 (480 bp).

RT-PCR amplification was performed in a volume of 50 μL containing 2× AccessQuick™ Master mixture (Promega Company). The final PCR aliquot (10 μL) was analyzed by electrophoresis on 30 g/L agarose with ethidium bromide staining.

Measurement of gastric acid secretion

Gastric acid secretion was detected in 117 subjects following pentagastrin injection. For this, all subjects received no medication (e.g. antiacid, etc.) for 24 h and no food for 12 h before the test. On the morning of the test, a tube was passed into the stomach through the nose. The tube was securely fastened and subjects were made to lie

on their left-side. The gastric juices were then collected by applying continuous suction (at 30-50 mmHg below atmospheric pressure) to the tube.

Statistical analyses

Hardy–Weinberg equilibrium at individual loci was assessed using χ^2 test in the statistics program SPSS (version 12.0, Chicago, IL, USA). Comparison of genotype frequencies between cases and controls was assessed by χ^2 test. ANOVA or *t*-test was used for analysis of means. All *P* values were two-sided and considered statistically significant at $P<0.05$.

RESULTS

Analysis of pepsinogen I and I/II ratio in different IL1-1B-511 genotypes

In *H pylori*-positive cases, T/T genotype individuals had markedly decreased PGI/II ratio as compared with the other genotypes ($F = 3.7$, $P = 0.03$). On the contrary, no significant difference in PGI/II ratio was observed among the genotypical groups without *H pylori* infection. PGI level was similar in the three genotypes of infected subjects or non-infected subjects, although PGI level was lower in *H pylori*-positive subjects than that in negative subjects (Table 3).

Table 3 PG I and I/II ratio in different genotypes with or without *Helicobacter pylori* (*H pylori)* infection (mean±SD)

		IL-1B-511 genotype		
		C/C (*n* = 97)	C/T (*n* = 121)	T/T (*n* = 37)
H pylori+	PGI	38.5 ± 6.7	40.3 ± 7.2	38.0 ± 6.7
(*n*=96)	PGI/II	4.9 ± 0.4	5.0 ± 0.4	4.7 ± 0.31
H pylori–	PGI	23.6 ± 4.3	24.0 ± 5.0	23.5 ± 3.5
(*n*=159)	PGI/II	5.0 ± 0.3	4.9 ± 0.3	4.9 ± 0.4

$F = 3.7$, $P = 0.03$ ($P_{T/TvsC/T} = 0.008$, $P_{T/TvsC/C} = 0.04$).

Relationship between IL-1B-511 gene polymorphism and IL-1B mRNA expression

In *H pylori*-negative individuals, the levels of IL-1B mRNA expression were markedly decreased in the gastric antrum, and similar among each genotype. However, in *H pylori*-positive subjects, IL-1β mRNA expression was significantly increased, but there was no difference among C/C, C/T, or T/T genotype (Figures 1 and 2)

Furthermore, in the individuals without *H pylori*-infected corpus, no significant difference was detected in the expression of IL-1β mRNA among the genotype in IL-1B-511 single nucleotide polymorphism. In *H pylori* infection corpus, however, the level of IL-1β mRNA was higher. Individuals with T/T genotype had remarkably increased IL-1B mRNA than those with C/C or C/T genotype. No difference in IL-1B mRNA levels was observed between C/C and C/T genotypes. Meantime, we discovered a carrier of both IL-1B-511 T/T and –31 T/T genotypes, which had the highest IL-1B gene expression among all the subjects (Figures 1 and 2).

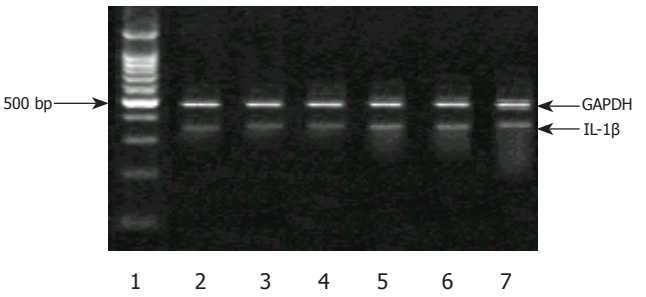

Figure 1 Expression of IL-1βmRNA in antrum Lane 1: a standard DNA ladder, lane 2: C/C genotype without *H pylori* infection, lane 3: C/T genotype without *H pylori* infection, lane 4: T/T genotype without *H pylori* infection, lane 5: C/C genotype with *H pylori* infection, lane 6: C/T genotype with *H pylori* infection, lane 7: T/T genotype with *H pylori* infection.

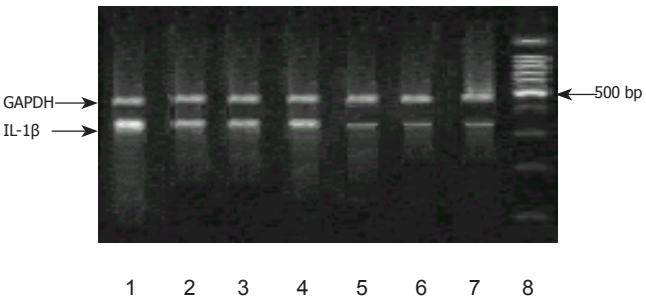

Figure 2 Expression of IL-1βmRNA in corpus. Lane 8: a standard DNA ladder, lane 7: C/C genotype without *H pylori* infection, lane 6: C/T genotype without *H pylori* infection, lane 5: T/T genotype without *H pylori* infection, lane 4: C/C genotype with *H pylori* infection, lane 3: C/T genotype with *H pylori* infection, lane 2: T/T genotype with *H pylori* infection, lane 1: T/T genotype of -511 and -31 with *H pylori* infection.

IL-1B-511 genotype and gastric fluid analysis

In basic condition (basic acid output), gastric acid secretion was similar between *H pylori*-negative and -positive subjects (5.1±1.0 *vs* 5.2±1.1 mmol/h, $t = 0.48$), and also among three different genotypes (six groups comparison, $F = 0.2$, Figure 3). After a pentagastrin stimulation, there was no significant difference for maximal acid output between *H pylori*-negative and -positive subjects (18.3±2.3 *vs* 18.4±2.0 mmol/h, $t = 0.1$), and among three different genotypes (six groups comparison, $F = 0.7$, Figure 4).

pH values of basic gastric juice and stimulated gastric fluid were 4.8±1.1 and 1.4±0.4, respectively. There was a slight increased pH value in *H pylori* infection subjects. Nevertheless, the individuals with T/T genotype did not show a much weaker ability to secrete hydrogen ion (Figure 5, $F = 0.13$ and 0.35).

DISCUSSION

Several studies revealed that hypochlorhydria induced

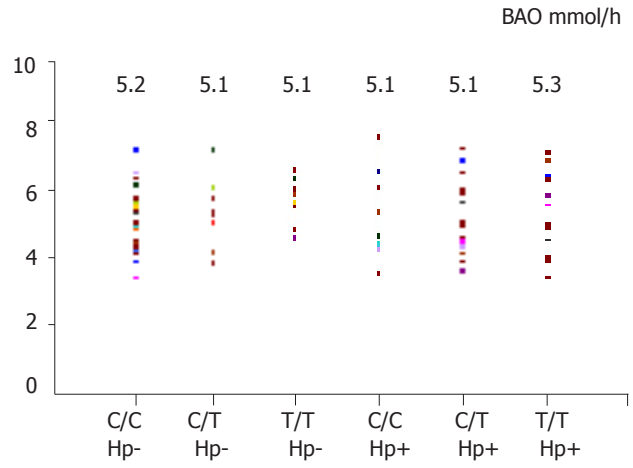

Figure 3 BAO in different genotype or *H pylori* status

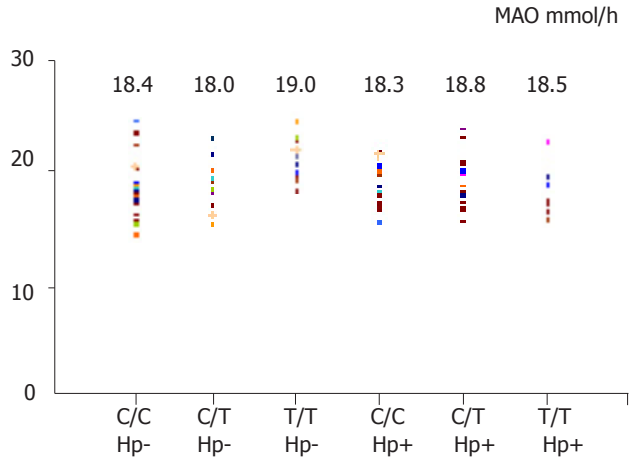

Figure 4 MAO in different genotypes or *H pylori* status

by overexpression of IL-1B was regarded as a bridge to link IL-1 gene polymorphism to gastric cancer[4–7]. The ability of mucosa to secrete gastric acid has been considered as a critical factor to decide clinical outcomes and bacterial description of *H pylori* infection[14,15]. *H pylori* implanted predominantly in the antrum mucosa, a

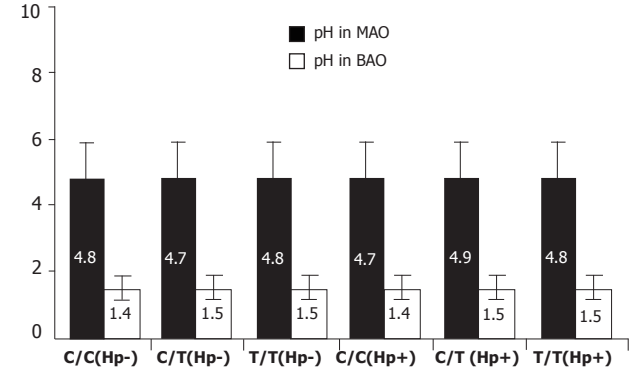

Figure 5 pH value of BAO and MAO in different genotypes or *H pylori* status.

place with a higher pH value, contrarily increased acid environment of corpus mucosa that resulted from a large number of B lymphocytes provides a habitat for *H pylori* to grow. However, for some special individuals with genetic hypochlorhydria, *H pylori* has a chance to migrate from antrum to the corpus. As a result, a large ulcer area resulted in a decreased acid level, which accumulates gastric atrophy or stomach carcinoma development[9]. Schepp *et al*[16] reported that rat parietal cells express IL-1 receptors mediating inhibition of H+ production. The antisecretory effect of IL-1B may contribute to hypoacidity secondary to acute *H pylori* infection or during chronic colonization by *H pylori* preferring the fundic mucosa. Another study reported that the efficacy of IL-1B to inhibit parietal cell H+ production was 100-fold and 6 000-fold higher as compared to proton pump inhibitors and H2 antagonists, respectively[17]. Recently, it has been identified that IL-1B exerts a potent function of gastric acid secretion through the other molecules and protein kinase pathway[18,19].

Until recently, however, no research has provided unambiguous and direct proofs suggesting that lower acid output resulted from higher IL-1B level in the human body except from a rodent model.

In this study, we discovered that T/T genotype individuals infected with *H pylori* had a more decreased PGI/II ratio as compared with the other genotypes, which is partly consistent with the results reported by Furuta *et al*[6] suggesting that IL-1B-511 gene polymorphism might be a risk factor for gastric carcinoma. IL-1B mRNA expression in subjects without *H pylori* infection was not remarkable, and was similar in each genotype, showing that there might be a very low level of IL-1B mRNA expression in normal mucosa. In contrast, the results are more complex in *H pylori*-positive individuals. There was a remarkable upregulation in the antrum, but no relationship with genotype was observed. In the corpus mucosa, however, the level of IL-1B mRNA was markedly higher than that in the antrum mucosa. Furthermore, IL-1B-511 T/T genotype individual had a mild increased IL-1B mRNA level as compared with C/T and C/C genotype. So, these results indicated that this mutation of IL-1B-511 C→T might upregulate IL-1B mRNA expression in corpus but not in the antrum, as these results are consistent to the results reported by Hwang *et al*[20]

The association of IL-1B-31 locus and IL-1B expression is not investigated because genetically mutated subject is too small (about 1%) to be collected. Fortunately, we found one female subject with *H pylori* positive and IL-1B-511 T/T and -31 T/T genotypes simultaneously had a markedly increased IL-1B mRNA level in corpus but not in the antrum. These results suggested a cooperative effect between –511 and –31 locus in IL-1B mRNA expression. These findings are also in agreement with the previous results reported by El-Omar *et al*[4] and Hwang *et al*[20]

We discovered that in basic or pentagastrin stimulation condition, gastric acid secretion was similar between *H pylori*-negative and -positive subjects. Acid secretion function did not show a marked heterogeneity among

three different genotypes of IL-1B-511. This data denoted that higher IL-1B level does not make a strong impact on gastric acid output. So, previous hypothesis that *H pylori* infection leads to IL-1B mRNA overexpression in IL-1B-511 T/T genotype, thereby directly inhibits gastric acid secretion is impossible, at least *in vivo*, in low gastric cancer prevalence region.

Hence, we inferred that the other pathways (such as chronic inflammatory process[21]), but not low acid secretion regulated by IL-1B (a pre-inflammatory factor), lead to mucosal atrophy. Our results, also taking into consideration the reports of several studies, suggested that IL-1B gene polymorphism was a susceptibility factor to gastric carcinoma in population-based studies. Furthermore, Lundell *et al*[21,22] have reported that acid-suppressive therapy maintained for 3 years facilitates neither the development of gastric glandular atrophy of the corpus mucosa nor the occurrence of intestinal metaplasia in *H pylori*-infected GERD patients. Fox *et al*[23] argued that coca leaf chewers (added with slaked lime or ash) did not have a higher prevalence of *H pylori* infection, or a higher rate of progression to gastric atrophy. So, we propose a new hypothesis that IL-1B gene polymorphism acts as a gastric cancer risk factor via upregulating IL-1B expression but downregulating acid secretion.

The individuals included in our study had a strong physiological captivity of acid output in the gastric mucosa as their age ranged from 19 to 24 years. This might be the reason that acid secretion levels were not seen significantly different between upregulated IL-1B mRNA and unchanged IL-1B mRNA groups. But using younger population in the present study is not unreasonable. As we know *H pylori* infection and genetic background play crucial roles in carcinogenesis beginning from early age. Further studies, however, should focus on larger age-range subjects or on other races to identify our results.

Abstract

Papillary carcinoma arising from the extrahepatic bile duct often shows superficial ductal spread. We report herein the case of a patient with extensive superficial spread of non-invasive papillary cholangiocarcinoma, which was depicted with peroral cholangioscopy. A 65-year-old woman presented with the sudden-onset of severe epigastric pain. Ultrasonography revealed acute acalculous cholecystitis. Endoscopic retrograde cholangiography found small protruding lesions around the confluence of the cystic duct, suggestive of a cholangiocarcinoma. As the contour of the middle and upper bile ducts it was slightly irregular on the cholangiogram, the presence of superficial ductal spread was suspected. Peroral cholangioscopy revealed small papillary lesions around the confluence of the cystic duct and fine granular mucosal lesions in the middle and upper bile ducts and the right hepatic duct, suggesting a superficially spreading tumor. A right hepatectomy with bile duct resection was performed and no residual tumor was found. Histological examination revealed a non-invasive papillary carcinoma arising from the cystic duct with extensive superficial spread. Our experience of this case and a review of the literature suggest that a fine granular or fine papillary appearance of the ductal mucosae on cholangioscopy indicates superficial spread of papillary cholangiocarcinoma, for which peroral cholangioscopy is an efficient diagnostic option.

INTRODUCTION

Papillary carcinoma arising from the extrahepatic bile duct often shows superficial ductal spread[1]. Peroral cholangioscopy, introduced in the 1970s by Rosch *et al*[2] and Nakajima *et al*[3], provides direct visualization of the biliary ducts. We report herein the case of a patient with extensive superficial ductal spread of non-invasive papillary cholangiocarcinoma, which was depicted with peroral cholangioscopy.

CASE REPORT

A 65-year-old woman presented with the sudden-onset of severe epigastric pain. No jaundice was observed on physical examination, and the serum total bilirubin level was 0.6 mg/dL (reference range: 0.3-0.9 mg/dL). The serum levels of carcinoembryonic antigen and carbohydrate antigen 19-9 were 0.7 ng/mL (reference range: 0-6 ng/mL) and 6 U/mL (reference range: 0-37 U/mL), respectively.

Ultrasonography revealed acute acalculous cholecystitis, for which percutaneous cholecystostomy was performed. Endoscopic retrograde cholangiography found small protruding lesions around the confluence of the cystic duct, suggestive of a cholangiocarcinoma (Figure 1). Smear cytology of the ductal bile aspirated during endoscopic retrograde cholangiography revealed that exfoliated cells were categorized into Papanicolaou class II. As the contour of the middle and upper bile ducts was slightly irregular on the cholangiogram, the presence of superficial ductal spread was suspected. In order to confirm this, peroral cholangioscopy using a fiberoptic endoscope (CHF-B20QY, Olympus, Tokyo, Japan) was performed, and both small papillary lesions around the confluence of the cystic duct (Figure 2) and fine granular mucosal lesions, brownish in color, in the middle and upper bile ducts were revealed, suggesting a superficially spreading tumor. Such mucosal lesions were also seen in the right hepatic duct (Figure 3).

After laparotomy, a bile duct resection with regional lymphadenectomy was performed. As the resection margin at the right hepatic duct was positive for *in situ* carcinoma on frozen-section examination, a right hepatectomy was additionally performed and no residual tumor was found. Histological examination of the resected specimen revealed a non-invasive papillary carcinoma arising from the cystic duct, with superficial spread extending up to the right anterior sectoral duct (pathologic T1N0M0, Stage IA, according to the tumor-node-metastasis staging system[4]).

Fine granular mucosal lesions on peroral cholangioscopy (Figure 3) corresponded to papillary *in situ* carcinoma histologically, whereas the flat mucosae between the fine granular mucosal lesions, which appeared normal on cholangioscopy (Figure 3), corresponded to non-papillary *in situ* carcinoma. The patient remains healthy, with no evidence of recurrence 7 years after the resection.

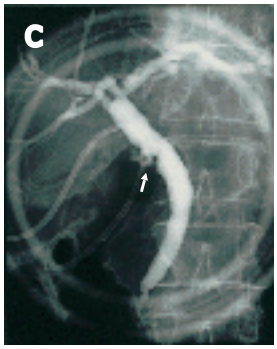

Figure 1 Endoscopic retrograde cholangiography. The cystic duct is poorly opacified with small protruding lesions around the confluence of the cystic duct (arrow). An 8-Fr pig-tail catheter **(C)** is inserted into the gallbladder.

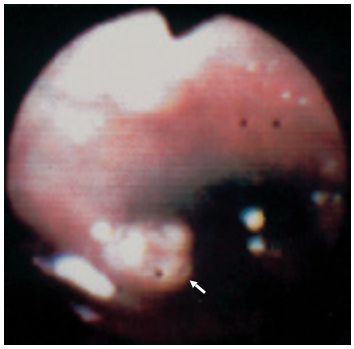

Figure 2 Peroral cholangioscopy shows a small papillary lesion (arrow) around the confluence of the cystic duct.

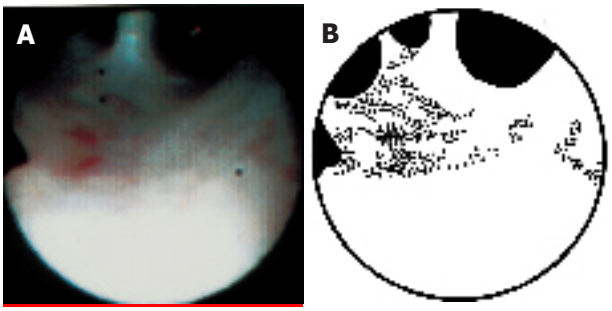

Figure 3 Peroral cholangioscopy of the interior of the right hepatic duct. **A:** Fine granular mucosal lesions, brownish in color, are scattered, suggesting the presence of papillary *in situ* carcinoma. The flat mucosae between the fine granular lesions, which appear normal on cholangioscopy, corresponded to non-papillary *in situ* carcinoma histologically. The lower part of this figure is fogged owing to halation. **B:** Schematic representation. The dotted areas indicate the fine granular lesions.

DISCUSSION

Nimura and Kamiya[5,6] demonstrated, by means of percutaneous transhepatic cholangioscopy, that a fine granular or fine papillary appearance of the ductal mucosae indicates superficial spread of cholangiocarcinoma. In the current case, the fine granular mucosal appearance on cholangioscopy corresponded to papillary *in situ* carcinoma histologically. It is very likely that a fine granular or fine papillary mucosal appearance on cholangioscopy is pathognomonic of superficial ductal spread of papillary cholangiocarcinoma.

The ductal resection margin status is an established prognostic factor in patients with extrahepatic cholangiocarcinoma[7,8]. Although intraductal ultrasonography is helpful in discerning T category of biliary malignancies[9], the extent of the superficial spread of cholangiocarcinoma is difficult to determine preoperatively on imaging studies[5,10,11]. In the current case, although peroral cholangioscopy detected papillary *in situ* carcinoma in the form of fine granular lesions, it did not detect the non-papillary *in situ* carcinoma between the lesions, suggesting that cholangioscopy is incapable of detecting flat ductal spread of *in situ* carcinoma. Intraoperative frozen-section examination is indispensable in assessing the ductal resection margin status.

In conclusion, a fine granular or fine papillary appearance of the ductal mucosae on cholangioscopy suggests superficial spread of papillary cholangiocarcinoma, for which peroral cholangioscopy is an efficient diagnostic option, unless the superficial lesions are flat.

Abstract

Internal herniation of the small bowel is a relatively rare cause of intestinal obstruction. Left paraduodenal hernia resulting from abnormal rotation of the midgut during embryonic development is the most common form of congenital internal hernia. We report our experience in the diagnosis and management of a young male with left paraduodenal hernia presenting as recurrent intestinal obstruction. Correct preoperative diagnosis of left paraduodenal hernia had been difficult due to non-specific clinical presentations, but the advent of modern imaging technology makes early and correct diagnosis possible. Due to the risk of obstruction and strangulation, surgical treatment is indicated; however, timely intervention increases the likelihood of a favorable outcome.

Key words: Internal hernia; Paraduodenal hernia; Small bowel obstruction

INTRODUCTION

congenital internal hernias, paraduodenal hernias are the most common and account for 25%-53% of all cases[2]. Paraduodenal hernias result from abnormal rotation of the midgut during embryonic development and can be divided into two subtypes, left and right paraduodenal hernias, according to their distinct pathogenesis and the resultant anatomical derangement. Correct preoperative diagnosis of paraduodenal hernia was once difficult, because of its non-specific presentations; however, with the advent of modern imaging technology, more information can be gained regarding the anatomical characteristics of the underlying lesion and allow for better treatment planning. We present our experience in the diagnosis and management of a patient with left paraduodenal hernia presenting as recurrent intestinal obstruction, as well as a brief review of the literature.

CASE REPORT

The patient was a slim 24-year-old male who visited our emergency room because of intermittent epigastric abdominal pain associated with bilious vomitus during the previous few hours. He had no history of previous abdominal surgery, but had a similar episode with pain and vomiting about 6 mo before. He had lost about 10 kg during that period. Physical examination revealed a non-tender, mildly distended abdomen with hyperactive bowel sounds. The only remarkable finding on plain abdominal film was loops of a dilated small bowel. Initial abdominal computed tomography (CT) revealed a mass lesion of soft tissue density located between the stomach, the pancreas, and the transverse colon (Figure 1A). For better elucidation

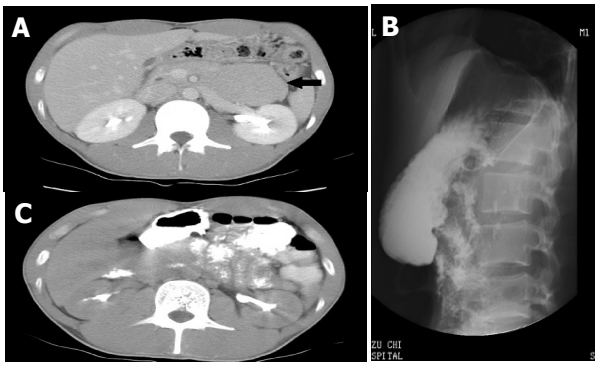

Figure 1 A: Computed tomography (CT) showing a soft tissue mass between the stomach, the pancreas, and the transverse colon (arrow); **B:** Upper gastrointestinal series showing a cluster of jejunum interposing between the stomach and the spine; **C:** The mass proved to be a cluster of intestinal loop after ingestion of contrast medium.

of the character of the mass lesion, we performed an upper gastrointestinal series with small intestinal follow-through, which revealed loops of jejunum clumping over the left upper quadrant of the abdomen (Figure 1B). The mass lesion proved to be a cluster of jejunum on follow-up CT (Figure 1C). The patient underwent surgery with a tentative diagnosis of left paraduodenal hernia with small bowel obstruction. Exploratory laparoscopy and laparotomy revealed that the jejunum did not emerge from the usual position at the base of transverse mesocolon; instead, only loops of the small bowel were visualized behind a thin layer of peritoneum (Figure 2A). Further exploration revealed that the jejunum exited from an aperture of about 15 cm caudal to the usual location of Treitz's ligament. The initial 10 cm of intraperitoneal jejunum ran parallel and was adherent to both the inferior mesenteric artery (IMA) and the inferior mesenteric vein (IMV), which constitute the anterior rim of the orifice (Figure 2B). A 25 cm long segment of jejunum had herniated through the orifice into the space behind the descending mesocolon. We manually reduced the herniated bowel loops after opening the anterior wall of the hernial sac by dividing the adhesion between the jejunum and the IMV. We then closed the orifice of the hernial sac around the jejunum with interrupted 3-0 silk sutures (Figure 2C). The patient tolerated the procedure well and recovery was uneventful postoperatively. Follow-up upper gastrointestinal series revealed the smooth passage of contrast medium without evidence of abnormal aggregation of the small bowel.

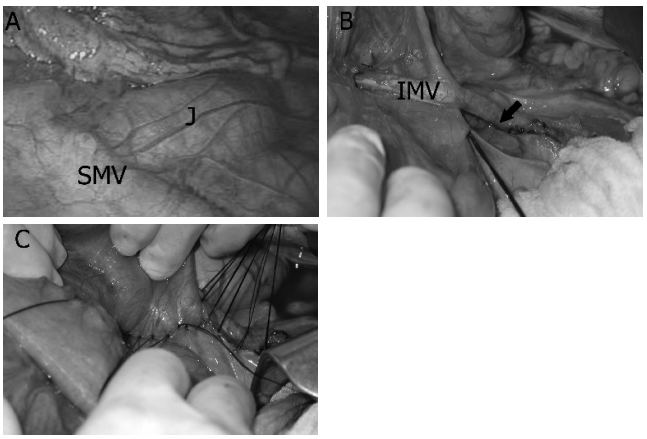

Figure 2 **A:** Loops of small bowel behind the mesocolon. Treitz's ligament was not seen. SMV: superior mesenteric vein, J: jejunum; **B:** the orifice through which the small bowel herniated (arrow). IMV: inferior mesenteric vein; **C:** completion of the repair.

DISCUSSION

Left paraduodenal hernia is about three times more frequent than its right counterpart, and is reported to occur three times more often in men[3]. As mentioned previously, left paraduodenal hernia usually results from abnormal rotation of the midgut. In the 5th wk of embryonic development, the rapidly elongating midgut herniates into the umbilical cord. Later, the herniated midgut undergoes a counter clockwise rotation of 90° around the superior mesenteric artery (SMA), leaving the prearterial limb on the left side. The herniated intestinal loop, first the prearterial then the postarterial limb, returns to the abdominal cavity by the 10th week. During this process, the intestinal loop undergoes another 180° countercloc kwise rotation. In the end, the prearterial limb lies left to the SMA and the postarterial limb lies superior and right to the SMA[4]. Under normal circumstances, fusion of the mesocolon with the peritoneum of the body wall follows this process. Failure of the fusion to take place in time leaves a potential space (the fossa of Landzert) behind the mesocolon. A leftparaduodenal hernia results from invagination of the small intestine into this unsupported area through an opening bound anteriorly by the IMV and is established as the descending colon that seeks its normal attachment[2].

Although the left paraduodenal hernia is congenital, most patients are recognized between the 4th and 6th decades of life, and the mean age at the time of diagnosis is 38.5 years[3]. The most common presentations are those associated with small bowel obstruction and are nonspecific[5], ranging in severity from recurrent vague abdominal pain, nausea, and vomiting in partial, reversible obstruction to acute abdomen in cases of incarceration and strangulation.

Physical examination is usually unrevealing except for such nonspecific findings as abdominal tenderness, distension, and the occasional presence of a mass. Correct preoperative diagnosis has been difficult in the past, due to these ambiguous presentations; therefore, it is mandatory to maintain a high index of suspicion in patients with pertinent unexplained complaints. Under emergent settings, diagnosis is only possible at the time of surgery. In the absence of an abdominal emergency, however, a variety of diagnostic tools is available to help establish the correct diagnosis before surgery. Because of the ambiguous clinical presentation of this disease, a CT scan may be the initial tool of investigation. A characteristic finding is a cluster of small bowel loops between the stomach and pancreas[6,7]. In case that the trapped loops are collapsed and oral contrast is not used, the hernia contents may be mistaken for a soft tissue mass. A high index of suspicion is again required to avoid inadvertent invasive diagnostic procedures such as CT-guided biopsy, which may be disastrous under such circumstances. An upper gastrointestinal series with small bowel follow-through demonstrates contrast-filled loops of small bowel clustering over the left upper aspect of the abdomen, as is seen in our patient. Abdominal ultrasonography might also aid in the diagnosis of paraduodenal hernia. Suggestive findings include a cluster of bowel loops or a well-defined mass. Peristalsis of the bowel loops can be appreciated and made more obvious with the ingestion of water[8].

In earlier reports, the diagnosis and treatment of left paraduodenal hernia tended to be delayed and the result of treatment seemed to be less satisfactory[5]. With the diagnostic tools available today, correct diagnoses are

possible even in the absence of acute symptoms, and treatment can commence promptly. Once diagnosed, left paraduodenal hernia should be surgically repaired because 50% of them cause intestinal obstruction[5,9]. The procedure consists of a manual reduction of the hernia contents followed by repair of the defect. If the herniated intestine is difficult to reduce because of its bulky size or adhesions within the sac, an incision can be made in the avascular portion of the hernial sac to the right of the inferior mesenteric vessels to enlarge the opening[2]. During this procedure, it is important to consider the relationship of the inferior mesenteric vessels to the sac opening and to take care to avoid injury to these structures. Although Bartlett indicated that these vessels can be divided without compromising blood supply to the colon[1], they should be preserved whenever possible. Intestinal resection is necessary in cases of strangulation and gangrene. In addition to the conventional "open" approach, successful laparoscopic repair of left paraduodenal hernia has been reported by Uematsu *et al*[10].

In conclusion, although relatively uncommon, left paraduodenal hernia should be included in the differential diagnosis of small bowel obstruction in patients who are relatively young, who have repetitive attacks, and who lack any history of previous abdominal surgery. The combination of a high index of suspicion, familiarity with this disease entity, and modern imaging technology make preoperative diagnosis easier today. Timely surgical intervention effectively relieves the patient's complaints and prevents further complications.

Abstract

Primary splenic angiosarcoma is a very rare, aggressive neoplasm with a high metastatic rate and dismal prognosis. This neoplasm usually presents with abdominal pain, splenomegaly, anemia, and thrombocytopenia. Splenic angiosarcoma with bleeding gastrointestinal metastases is extremely rare. The literature contains only two case reports. This study reported a 44-year-old male patient with splenic angiosarcoma with sustained repeated gastrointestinal bleeding due to small bowel metastases. Salvage surgery was performed by splenectomy and resection of the metastatic small bowel tumors. The post-operative course was uneventful; the patient survived with the disease and had no GI bleeding, 7 mo after surgery.

Key words: Gastrointestinal bleeding; Metastasis; Small bowel; Splenectomy; Splenic angiosarcoma

INTRODUCTION

Primary splenic angiosarcoma is a very rare neoplasm with a high metastatic rate and dismal prognosis. Langhans[1] first identified this disease in 1879. Presentations of splenic angiosarcoma are extremely variable and frequently cause diagnostic difficulties. The disease usually manifests with abdominal mass, abdominal pain, splenomegaly, and anemia. Distant metastases can occur in the liver, lung, lymph node, and bone, and soft tissue[2]. To our knowledge, splenic angiosarcoma with bleeding gastrointestinal (GI) metastases is extremely rare. The literature contains only two case reports[3,4]. The present case is the first report of splenic angiosarcoma metastasis to the small bowel. This work describes the experience of the authors in the management of the splenic angiosarcoma with bleeding GI metastases.

CASE REPORT

A 44-year-old male patient was admitted to Chang Gung Memorial Hospital on July 1, 2004, complaining of severe lower back pain and progressively weakness in his bilateral lower legs for 1 mo. Subconjunctiva hemorrhage and gingival bleedings were noted during initial examination mild pale conjunctiva, hepatomegaly, and splenomegaly. The hematogram measured hemoglobin at 108 g/L and platelet at 137 000/cm^3. Prothrombin and activated partial thromboplastin times were normal. Magnetic resonance imaging of the spine identified abnormal enhancement at multiple bodies in the thoracic, lumbar, and sacral spines, which were assumed to be metastatic lesions. Unfortunately, the patient developed hematochezia 9 d after admission. Persistent passage of tarry stools resulted in severe anemia (the lowest hemoglobin level was 43 g/L) and an episode of syncope. The patient received transfusions of packed RBC to a total of 12 U, before surgery. Both endoscopy and colonscopy failed to detect the site of bleeding. Abdominal computed tomography showed a diffusely heterogeneous density infiltrating the whole spleen (Figure 1) and did not detect any GI tumors. The scan of Tc-99m RBC revealed evidence of active bleeding in the left mid-abdominal region. The patient then underwent an exploratory laparotomy on July 17, 2004. During surgery, the spleen was enlarged with multiple dark-red nodules on its surface (Figure 2). Intra-operative endoscopy failed to identify any site of bleeding. The serosa of the small intestine was intact and multiple small hemorrhagic patches (number >5) were observed at the jejunum and ileum (Figure 3). Splenectomy and resection of the small intestine containing hemorrhagic patches were then performed.

Macroscopically, the surgical specimen of the spleen measured 14 cm×10 cm×9 cm with a weight of 400 g, and the splenic parenchyma was diffusely scattered with multiple, irregular sized and dark-red color nodules. Mucosal tumors (size <1 cm) were identified at the resected small intestine. Microscopically, the spleen revealed neoplastic sinusoidal endothelial cells with

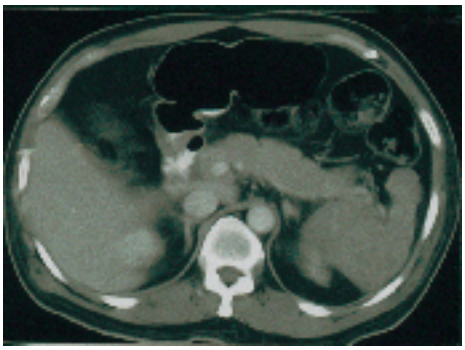

Figure 1 Abdominal computed tomography identifies an enlarged spleen with a heterogeneous density involving the whole spleen.

Figure 3 Multiple small hemorrhagic patches are identified at the jejunum and ileum.

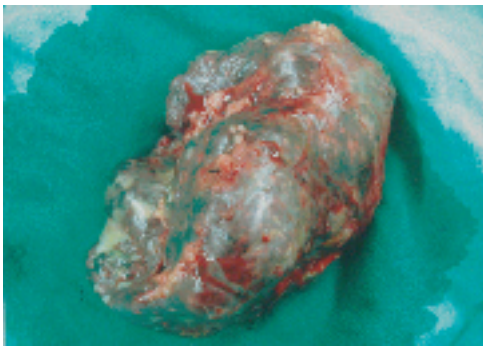

Figure 2 The splenic parenchyma is diffusely scattered with multiple, irregular sized and dark-red nodules.

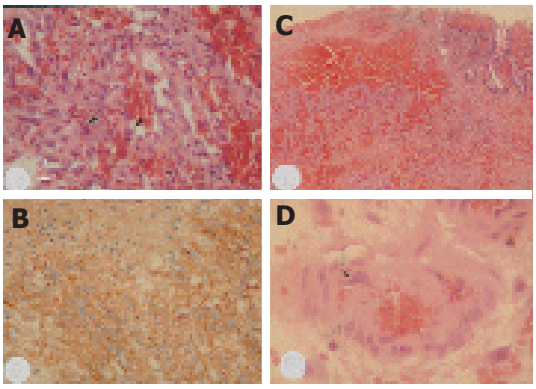

Figure 4A Photomicrography of the spleen reveals neoplastic sinusoidal endothelial cells with marked cytological atypia (arrowhead) lining the congested sinusoid spaces (hematoxylin and eosin staining, 200×); **B:** immunohistochemical staining of the neoplastic cells is positive for factor XIII associated antigen (immunostain, 200×); **C:** histological examination of the specimen of small intestine shows metastatic neoplastic cells primarily distributed within the submucosal layer and focally extending to the mucosal layer (hematoxylin and eosin staining, 100 ×); **D:** photomicrography of the intestinal vessel reveals presence of individual neoplastic cells (arrowhead) within the vascular lumen (hematoxylin and eosin staining, 400×).

marked cytological atypia lining the congested sinusoid spaces (Figure 4A). The tumor cells were immunoreactive to factor XIII associated antigen (polyclonal, 1:500, Calbiochem Novabiochem, CA, USA, Figure 4B). The neoplastic cells of the small intestine only involved the mucosal and submucosal layers (Figure 4C); the muscular layer and serosa were intact and free of malignancy. They formed anastomosing network of sinusoids lined by pleomorphic endothelial cells, similar to those seen in the spleen. In addition, individual tumor cells were identified within the small vessels (Figure 4D). The diagnosis of primary splenic angiosarcoma with metastases of bones and small intestine was confirmed.

The patient had an uneventful post-operative course. He received external beam radiation therapy for his bone pain postoperatively. He did not experience GI bleeding again and survived with the disease 7 mo after surgery.

DISCUSSION

PATIENTS WITH splenic angiosarcoma may occur at any age[2,5–7]. The mean age of the reported patients was 50-60 years[2,5,6]. The pathogenesis of splenic angiosarcoma remains unknown. Reported causes are exposed to ionizing radiation[8] or chemotherapy for lymphoma[9]. However, some authors believed that splenic angiosarcoma develops from a previously existing benign counterparts of the splenic tumors such as hemangioma or hemangioendothelioma[7,8]. In this case, no such risk factors were noted.

Splenomegaly with left-side upper abdominal pain occurs in over 70% of patients with splenic angiosarcoma[2,5]. Anemia and thrombocytopenia are the frequent findings of hematogram and are reported in more than 70% of cases[5,6]. Spontaneous splenic rupture presenting with acute abdominal pain has been reported in 13%-32% of patients[2,5,10]. Other systemic symptoms such as body weight loss, gum bleeding, fatigue, weakness, fever, chest pain, and GI bleeding have also been observed[2,5].

Metastases of the splenic angiosarcoma are frequent, occurring in 69–100% of cases[2,5]. The most common metastasis sites are the liver, lung, lymph node, bone, bone marrow, and soft tissue. To the best of our knowledge, the present patient is the first case report of splenic angiosarcoma metastasis to the small bowel.

Table 1 Primary splenic angiosarcoma with bleeding gastrointestinal metastases

Author/yr	Age/sex	Site of GI metastasis	Treatment	Status and time of follow-up
Chung[3] 1999	54/M	ND	Splenectomy	DOD, 10 mo
Jimenez-Heffernan[4] 1999	71/F	Colon (splenic flexure)	Splenectomy, left hemicolectomy, radiation	DOD, 9 mo
Hsu, present	45/M	Small bowel	Splenectomy, resection of small bowel metastases, radiation	AWD, 7 mo

AWD; alive with disease; DOD, dead of disease; GI, gastrointestinal; mo, months; ND, not described.

Malignancies of the small bowel can be either primary or metastatic. Primary small bowel malignant tumors are rare with the incidence of about 1 per 100000 and a prevalence of 0.6%[11]. Secondary neoplastic involvement of the small bowel is more frequent than primary small bowel neoplasm by hematogenous spread, direct invasion or intraperitoneal seeding[12]. Metastatic malignant tumors from the colon, ovary, uterus, and stomach generally invade the small bowel via direct invasion or intraperitoneal spread. The breast cancer, lung cancer, and melanoma usually metastasize to the small bowel hematogenously. Based on the operative and histopathologic findings, this case is the first report of small bowel metastases from the splenic angiosarcoma via hematogenous route.

The prognosis for splenic angiosarcoma is typically very dismal with a 6-mo survival for only 20% of cases[2,4]. Notably, survival of pediatric patients was reported as extremely poor ranging from less than 1 mo to 2 years[13]. However, Falk *et al*[5] had reported that two adults survived at the last follow-up, 1 with disease at 8 years and the other disease-free at 10 years. Survival is favorable for early diagnosis with splenectomy before rupture[4,10]. Montemayor and Caggiano[14] also found that patients with splenic angiosarcoma had longer survival, if splenectomy was performed prior to rupture compared to after rupture (14.4 *vs* 4.4 mo).

Table 1 shows only three cases including this case that have experienced GI bleeding due to GI metastasis from the splenic angiosarcoma (Table 1). In patients with either primary or metastatic GI angiosarcoma, repeated GI bleeding and the need for blood transfusion made them hospitalization-dependent and debilitated. These patients frequently die of uncontrolled GI bleeding[15]. The survival of these patients in Allison's study ranges from 1 wk to 3 years after resection of the foci[15]. No consensus yet exists regarding the need to treat patients with disseminated metastases aggressively. Nevertheless, salvage surgery (resection of small bowel metastases) combined with splenectomy to control bleeding and confirm diagnosis was justified in the present case. The patient survived with the disease, 7 mo after surgery without evidence of GI bleeding.

In conclusion, splenic angiosarcoma with bleeding GI metastases is extremely rare. This case is the first report of metastatic small bowel malignancy from the splenic angiosarcoma. Salvage surgery to control bleeding due to the GI metastases is justified in this case.

Abstract

The author presents three cases of esophageal rupture during the treatment of massive esophageal variceal bleeding with Sengstaken-Blakemore (SB) tube. In each case, simple auscultation was used to guide SB tube insertion, with chest radiograph obtained only after complete inflation of the gastric balloon. Two patients died of hemorrhagic shock and one died of mediastinitis. The author suggests that confirmation of SB tube placement by auscultation alone may not be adequate. Routine chest radiographs should be obtained before and after full inflation of the gastric balloon to confirm tube position and to detect tube dislocation.

INTRODUCTION

Esophageal rupture is a well-known but rarely reported fatal complication of the management of bleeding esophageal varices with the Sengstaken-Blakemore (SB) tube[1]. Described below are three cases of fatal esophageal rupture with striking radiographs showing the gastric balloon of the SB tube inflated in the thoracic cavity. A routine pre-inflation chest radiograph should have prevented esophageal perforation due to malposition of the SB tube in these cases.

CASE REPORTS

Case 1

A 38-year-old man was admitted with massive hematemesis. On physical examination, his blood pressure, pulse rate, respiratory rate, and temperature were 86/50 mmHg, 126 bpm, 24/min, and 37.3 °C, respectively. Pale conjunctivae, icteric sclera, splenomegaly, and spider angiomata were also observed. Resuscitation was started with normal saline, packed red cells and platelet concentrates. When stabilized, an emergency esophago-gastroduodenoscopy was performed, which revealed active bleeding from ruptured esophageal varices.

Despite aggressive therapies with fluids, blood components and full-dose terlipressin, the patient deteriorated into coma due to hemorrhagic shock. He was moved to the intensive care unit (ICU) for insertion of an SB tube. Endotracheal intubation was accomplished to secure airway before the procedure. A chest radiograph taken soon after tracheal intubation and inflation of the gastric balloon to 300 mL showed a radiolucent area behind the heart (Figure 1). The gastric balloon was immediately deflated and the SB tube removed (2 h after insertion). A repeated chest radiograph revealed massive left hemothorax. As the patient was deemed unfit for surgery, he was treated conservatively. The patient died when a further episode of massive hematemesis developed 44 h after admission.

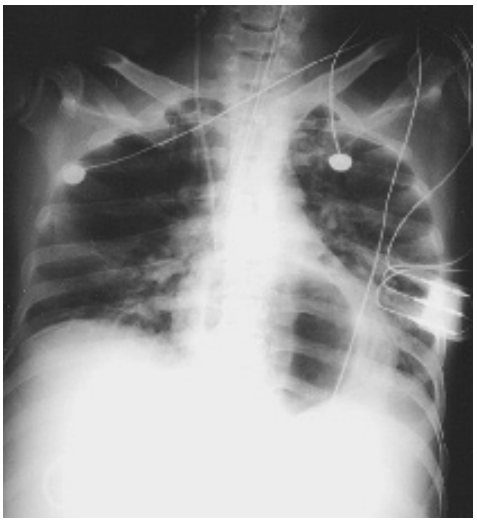

Figure 1 Chest radiographs indicating gastric balloon of SB tube, behind the heart shadow.

Case 2

A 49-year-old man was admitted to the ICU due to uncontrolled hematemesis from ruptured esophageal varices and hepatic encephalopathy. Physical examination showed that he was in deep coma (Glasgow coma scale of E2M1V1) and severe hypotension (BP 60/40 mmHg). Rapid endotracheal intubation followed by insertion of an SB tube was performed without difficulties. However, a chest radiograph ordered to check tube positions demonstrated a radiolucent circle (the gastric balloon) within the left hemithorax (Figure 2). The patient died of shock-related multiple organ failure on the third day of admission.

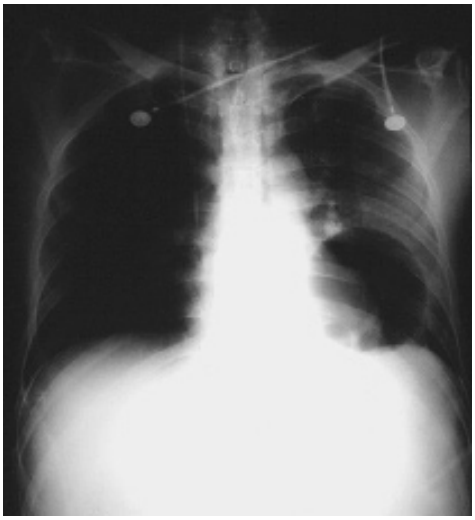

Figure 2 Chest radiographs indicating gastric balloon of SB tube, within the left lower hemithorax.

Case 3

A 43-year-old male alcoholic was treated in the ICU for convulsions due to decompensated hepatic cirrhosis with grade IV encephalopathy. He was tracheally intubated with a Glasgow coma scale of E2M2VT. His vital signs were within the normal limits. However, he suffered a massive hematemesis on the third day of admission, which was the result of ruptured esophageal varices. An SB tube was inserted and a chest radiograph later showed a radiolucent area within the lower mediastinum (Figure 3). The patient developed fever, leukocytosis and shock in the following days and a chest computer tomography (CT) revealed findings compatible with mediastinitis. He died of sepsis 12 d after the admission.

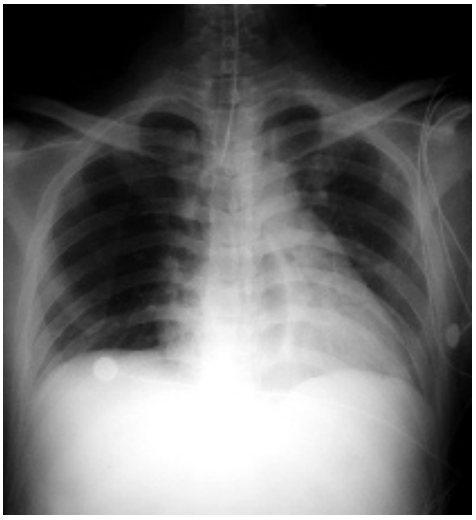

Figure 3 Chest radiographs indicating gastric balloon of SB tube, in the lower mediastinum.

DISCUSSION

The management of acute bleeding episodes from ruptured esophageal varices consists of volume replacement, pharmacological, mechanical (balloon tamponade), and surgical modes of arresting hemorrhage. While balloon tamponade using SB tube is effective in achieving initial hemostasis, it has a significant complication rate. The most common complications of esophageal balloon therapy for varices include aspiration, esophageal perforation, and pressure necrosis of the mucosa[2]. The exact incidence of complications is difficult to determine, as it varies with the skill and experience of the surgical team, the duration of treatment, and the status of the patient. Aspiration of secretions is the most common complication of balloon tamponade, occurring in approximately 10%-20% of cases[3].

As described in past literature, cases with esophageal perforation can occur as a result of difficult SB tube insertion[4], retching and vomiting[5], and repeated endoscopic sclerotherapy[6]. In each of our cases, the SB tube was inserted without documented difficulties. Intragastric position was confirmed with auscultation. A radiographic localization of the SB tube before full inflation of the gastric balloon was ignored. The diagnosis of esophageal perforation in each case was confirmed by a follow-up chest radiograph taken after full inflation of the gastric balloon. Though uncommon, esophageal rupture due to SB tube misplacement carries a high incidence of mortality from hemothorax or septic mediastinitis, as demonstrated in our patients.

In conclusion, following insertion of the SB tube, confirmation of tube placement by auscultation alone may not be adequate. Routine chest radiographs should be obtained before and after full inflation of the gastric balloon to confirm correct tube position and to detect tube dislocation as soon as possible.

Abstract

Although multiple options for the treatment of liver tumors have often been described in the past, including liver resection, radiofrequency ablation with or without hepatic pump insertion, laparoscopic liver resection and the use of chemotherapy, the potential of immunotherapy and gene manipulation is still largely unexplored. Immunological therapy by gene manipulation is based on the interaction between virus-based gene delivery systems and dendritic cells. Using viruses as vectors, it is possible to transduce dendritic cells with genes encoding tumor-associated antigens, thus inducing strong humoral and cellular immunity against the antigens themselves. Both chemotherapy and radiation therapy have the disadvantage of destroying healthy cells, thus causing severe side-effects. We need more precisely targeted therapies capable of killing cancer cells while sparing healthy cells. Our goal is to establish a new treatment for solid liver tumors based on the concept of cytoreduction, and propose an innovative algorithm.

Key words: Liver; Tumors; Surgery; Dendritic cell; Cytoreduction; Immunotherapy; Gene manipulation

HEPATIC TUMORS

Although relatively uncommon in Western countries, hepatocellular carcinoma (HCC) is probably the most common solid cancer in the world, with an estimated incidence of at least one million new patients per year[1,2]. The optimal treatment for HCC is surgical excision with a curative intent, but only 5-15% of newly diagnosed patients undergo potentially curative resection[3]. Patients with disease confined to the liver may not be candidates for resection because of multifocal disease, or an inadequate hepatic functional reserve capacity related to co-existent cirrhosis may contraindicate resection. As there are few other curative treatment options for patients with unresectable liver disease, HCC is one of the most lethal human malignancies, with a mortality rate of 94%[4].

The liver is second only to lymph nodes as a site of metastases from other solid cancers[5], and may be the only site of metastatic disease particularly in patients with colorectal adenocarcinoma[6]. However, fewer than 10-15% of patients with liver metastases are candidates for resection for the same reasons as those regarding HCC. The majority of patients with primary or metastatic hepatic malignancies who are not candidates for complete surgical resection therefore require novel treatment modalities to control and potentially cure their disease[2,7].

Cirrhosis may be another variable that places such patients at the highest risk[2]. Patients in class C of the Child-Pugh Classification (Table 1) have the highest mortality and morbidity rate following all treatments, particularly surgical procedures[8,9], and so most centers have shifted away from open liver surgery and are attempting other approaches. The treatment of hepatic tumors in cirrhotic and non-cirrhotic patients is a major decision-making issue for oncologists and surgeons, and the high mortality rate of open liver surgery in cirrhotic patients has spurred physicians to seek new modalities[10].

We here outline the immunological and genetic techniques available for the treatment of liver tumors, and propose a new immunologico-clinical algorithm using immunological therapy to debulk the mass, kill micrometastases, and allow a lower dose of chemotherapy to achieve better cytoreduction.

Table 1 Child-Pugh classification

	A	B	C
Ascites	None	Controlled	Uncontrolled
Bilirubin (mmol/L)	<2.0	2.0-2.5	>3.0
Encephalopathy	None	Minimal	Advanced
PT (s prolonged)	<4.0	4.0-6.0	>6.0
INR	<2.0	2.0-3.0	>3
Albumin (g/L)	>3.5	3.0-3.5	<3.0

WHAT IS THE ROLE OF SURGERY?

Open surgery

Complete surgical resection of primary or secondary liver tumors is the gold standard of surgical therapy[2,8,9], but it has fallen out of favor because of complications related to bleeding and liver failure. Furthermore, the time of the associated hospitalization is not cost-effective in the context of the new health plan insurance capitation systems.

Underlying anatomical and physiological limitations may exclude the use of complete surgical resection but, when complete or partial resection is plausible, the approach of choice is either the traditional open technique (wedge resection, segmentectomy or major lobectomy) or the laparoscopic technique. Laparoscopic liver surgery has become feasible with the improvement in laparoscopic techniques and the development of new and dedicated technologies[9]. There are benefits common to all endoscopic procedures, and the choice of the approach to hepatic resection is usually made by both the surgeon and the patient.

Laparoscopic surgery

The laparoscopic method is useful in oncological therapy, as it allows abdominal exploration and the visualization of the tumor itself. Specimen collection is another key benefit, and can range from a lymph node biopsy in the peritoneum or retro-peritoneum, to scraping the peritoneum in the abdominal wall. Laparoscopy allows direct visualization of the organs and biopsy. The liver is a large organ, and can therefore be visualized quite well, particularly the anterior section, although it is laparoscopically more difficult to visualize the posterior section of the retroperitoneal area of the right lobe. Anatomically, the left side of the liver is not hard to mobilize by dissecting the left triangular ligament and flipping the left side of the liver over the midline, but it is more complicated to achieve the same result on the right side where segments VI and VII (the lateral segments) and segment VIII are harder to visualize posteriorly, and so intraoperative ultrasound has been introduced to improve the visualization of tumors in these segments[9].

Radiofrequency ablation

This is a thermal technique designed to cause localized tumor destruction by heating the tumoral tissue to temperatures of more than 50 °C. The methodology has been previously described by our group[8,11], and has been found to be safe and effective in the treatment of single tumors of <5 cm with curative intent, or the cytoreduction of multiple or larger tumors.

Percutaneous ethanol injection (PEI)

This is usually performed under transabdominal ultrasonographic guidance, and consists of intra-tumorally injecting 5-10 mL of ethanol twice a week. Patient compliance has been a problem because of the number of injections required and the associated pain. As PEI requires multiple treatment sessions and is associated with a high local recurrence rate, it should only be considered in the case of tumors with a diameter of less than 1.5 cm.

Cryosurgery

This has been used to treat patients with unresectable primary and metastatic liver tumors for the last 20 years. Most of the scientific data concerning local tumor recurrences and complications after cryosurgery comes from patients treated for colorectal cancer liver metastases[8].

CLINICAL ALGORITHM FOR SOLID LIVER TUMORS

The pros and cons of liver surgery and the new clinical algorithm used for the treatment of liver tumors will be briefly discussed[8], considering only the patients with Child –Pugh class A or B cirrhosis, because those with advanced liver cirrhosis (Child–Pugh class C) would probably receive no survival benefit and would be at a disproportionately increased risk of interventional therapy. The patients in the two groups will belong to one of the following four categories: (1) Those with stage I, primary liver tumors will be evaluated for liver resection or radiofrequency ablation (RFA); (2) Those with stage II and III primary liver tumors will undergo complete resection, if anatomically possible, or partial resection with RFA, or RFA alone; the patients with vascular invasion will also receive a hepatic arterial pump (HAP); (3) The patients with stage IV primary liver tumors or liver metastases of other than colorectal origin (endocrine, breast) will only be treated with RFA and a HAP; (4) The patients with colorectal metastases will undergo complete resection if possible, or partial resection with RFA, or RFA alone, and all will receive a HAP.

After a median follow-up of 20 mo in patients with unresectable liver disease, the addition of adjuvant HAP therapy to cryoreduction decreased all recurrences from 77% to 49% and decreased liver recurrences from 67% to 38%. This, and other multi-approaches (RFA and HAP therapy) to the treatment of partially resectable or unresectable liver disease, is promising and deserves further investigation.

IMMUNOTHERAPY AND NEOPLASTIC LIVER DISEASE

Most cancer patients are currently treated with some combination of surgery, radiation therapy and

chemotherapy, but both chemo- and radiation-therapy have the disadvantage of destroying healthy cells and this causes severe side effects. The possibility of destroying more cancer cells by increasing the chemotherapeutic dose or radiation exposure is limited by the non-specific organ toxicity of these therapies and the relatively old age of most patients. We therefore need more precisely targeted therapies capable of killing cancer cells while sparing healthy cells.

One possible answer is immunological therapy, which is not only more specific and less toxic, but may also induce memory responses that could yield long-term tumor immunosurveillance and reduce the incidence of relapses, thus increasing long-term disease-free survival. Immunological therapy may be adoptive[10,12] in which case the patients' white blood cells are coupled with a naturally producing growth factor to enhance their cancer fighting capacity, or passive[13], with immunity being acquired as a result of the transfer of antibodies from a healthy donor. However, the possibility of successfully implementing these therapies rests on the existence of tumor-specific antigens, and suitable antigens have been hard to come by because of the complex process required to validate them[14–18].

Immunotherapy refers to any approach aimed at mobilizing or manipulating a patient's immune system to treat or cure disease[19], and immunological therapy by means of gene manipulation is based on the interaction between virus-based gene delivery systems and dendritic cells (DCs). Using viruses as vectors, it is possible to transduce DCs with genes encoding tumor-associated antigens (TAA), thus inducing a robust immune response[20,21].

A number of studies have established the role played by DCs in the immune system, and provided a rationale for using them as natural adjuvants for cancer immunotherapy[20-22]. Previous studies have concentrated on identifying the proliferating progenitors of DCs within the small CD34+ sub-fraction of cells in human blood[23]. These cells can be stimulated by cytokines (particularly by GM-CSF and TNF-alpha) to differentiate into DCs *in vitro* over a period of 1 wk[24]. It has also been more recently found that the combination of GM-CSF and IL-4 facilitates the generation of significantly larger numbers of DCs from monocytes/macrophages, which have equal or greater stimulatory activity in mixed lymphocyte reactions, and a greater capacity to present soluble protein antigens than CD34+ cell-derived DCs[23,24].

Gene manipulation

Gene manipulation transmits new genes/DNA into target cells infected with the viral vector, and has been most widely used to treat genetic diseases. The vector unloads its genetic material containing the therapeutic human gene into the target cell, which is finally restored to its normal state as a result of the generation of a functional protein encoded by the therapeutic gene[24,25]. The technique can be used in cancer to activate self and non-self antigens and enhance T cell responses. Some of the different types of viruses used as gene therapy vectors are listed in Table 2.

There are also various non-viral options for gene delivery. The simplest method is to introduce therapeutic DNA directly into target cells, but its application is limited by the fact that it can only be used with certain tissues and requires large amounts of DNA. Another non-viral approach involves creating a liposome (an artificial lipid sphere with an aqueous core), which is capable of shuttling the therapeutic DNA through the target cell's membrane, and a further delivery system is based on electroporation[25-28].

Problems in applying gene therapy

Whenever a foreign body (antigen, bacteria, *etc.*) enters the human tissue, the immune system is prompted to attack the invader, and so there is a risk of stimulating an immune response and reducing the effectiveness of gene manipulation. Furthermore, the immune system's enhanced response to previously encountered invaders makes it difficult for gene therapy to be repeated.

Viruses are the carriers of choice in most gene therapy studies, but they can give rise to a number of potential problems relating to toxicity, immune and inflammatory responses, gene control, and targeting. The main concern is that, once inside the patients, the viral vector may somehow recover its ability to cause disease, which is why we decided to use virus vectors with little or no replicative capacity, such as adeno-associated viruses (AAV)[29-31].

Viral delivery of antigen genes into dendritic cells

There are various ways of inserting antigen genes and proteins into DCs via protein pulses or viral vector loading[27-32]. Recombinant retroviruses, adenoviruses, and poxviruses can all efficiently transduce DCs[29-31],

Table 2 Commonest viruses used as gene therapy vectors

Retroviruses	Adenoviruses	Adeno-associated virus (AAV)	Herpes virus
8kb, RNA enveloped	35 kb, DNA, non-enveloped	5 kb, single stranded DNA, non-enveloped	61 kb, double-stranded DNA
Activate proto-oncogene by insertional mutagenesis	Episomal, transient	Stable integration, high infectivity	Infect mainly neurons
Cause lymphoma	Highly immunogenic, causing inflammation and anaphylactic shock	Non-pathogenic; requires helper viruses such as Adenoviruses for replication and packaging in mammalian cells.	Cause cold sores or blisters in the genital areas
Inactivation of transgene *in vivo*	One case of death	Long-term expression *in vivo*	Cutaneous skin lesions

but they all have well-known and serious disadvantages. Retroviruses can integrate chromosomally, but any residual contaminating wild-type virus can lead to significant disease and malignancy in the host. Furthermore, as they can also integrate gonadally and alter the germ line, their use may be restricted by the FDA[30,31].

Adenoviruses carry many genes in addition to the transgene, and the viral particle contains several proteins; the delivered antigen gene would therefore be only one of the many genes/proteins and epitopes to which a CTL response would be generated.

Unlike these viruses, AAVs are non-pathogenic, and various studies have shown that they are effective gene delivery vectors for both immortalized tissue culture cells and primary hematopoietic cells[33-36]. The helper-dependent parvovirus AAV can latently infect cells via stable chromosomal integration. Early studies demonstrated that 15-30% of immortalized cells could be latently infected with wild-type AAV, and the AAV genome was chromosomally integrated[21]. After the mapping of AAV genes and their functions[32-34], recombinant AAV virus vectors proved to have a similar capacity in immortalized tissue culture cells[33,34], and the recombinant AAV transduction of primary hematopoietic stem cells was achieved in 1988[35].

We have demonstrated that AAVs can be highly efficiently (>90%) used to transduce antigen genes into primary human monocytes (Mo) and Mo-derived DCs[36,37]. Unlike cells transduced using adenoviruses, retroviruses and other pathogenic viruses, AAV-transduced cells are not usually significant targets of the host immune system[37]. The use of the rAAV-based DC loading of human papillomavirus type 16, E6, and E7 antigen genes leads to robust and rapid antigen-specific, MHC class I-restricted CTL responses with one stimulation (one DC addition) and a 7-10 d co-incubation period[37,38]. Our data therefore strongly suggest that AAVs may be effective vectors for manipulating DCs[20,36,39].

DISCUSSION

Experimental algorithm for solid liver tumors

The key to the new evolution toward immunotherapy is to set up an algorithm for patients who will not respond to surgery. As shown in Figure 1, the liver tumor of selected patients is staged and the patients are directed to follow the clinical[8] or immunological algorithm. The experimental option is designed by taking specimens, with the tumor being preferably harvested laparoscopically or by means of the open technique. The next step is to insert modified antigens with carriers into the neoplastic cells. At this point, the choice is whether to inject them with DCs after leukopheresis, or by means of a virus (AAV). Both injections can be performed laparoscopically, thus allowing minimally invasive surgery, the introduction of the antigen inside the area of the tumor, and the initiation of a cell-mediated reaction designed to ensure immunological cytoreduction or debulking. An ultrasound-guided needle is placed into the abdomen, and a biopsy of the tumor can be taken.

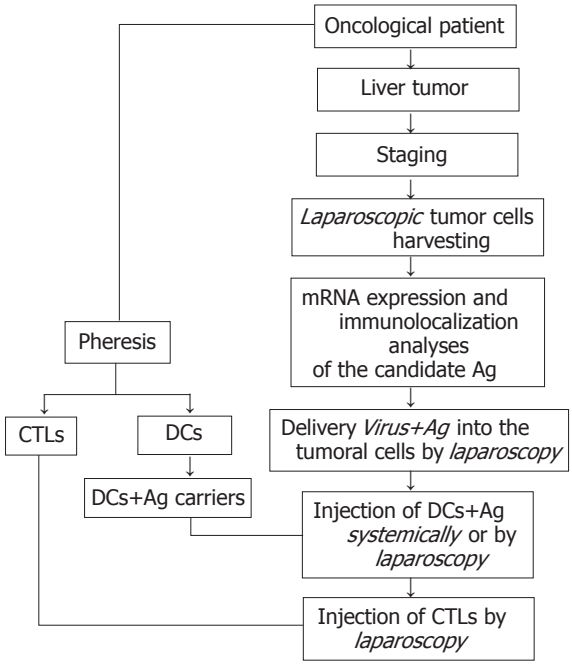

Figure 1 Relationships between laparoscopic surgery and immunotherapy for treatment of primary and secondary liver tumors. CTLs: cytotoxic T lymphocytes; DCs: dendritic cells; Ag: antigen.

As laparoscopy is a widely used surgical technique, most surgeons can easily adopt the procedure of injecting antigens, CTLs and DCs directly into the primary or secondary tumor in order to increase tumor immunogenicity and kill the remaining tumor cells by means of a local injection of CTLs and DCs for better cytoreduction. A port should be placed inside the internal jugular or subclavian artery in order to allow the retrieval of blood for leukopheresis; this port can be accessed quite easily using an external needle.

Improving cytoreduction: our new approach

The most widely used treatment is tumor resection, and so the main role of surgeons and oncologists is to decrease tumor bulk or mass in order to improve survival or allow the possibility of chemotherapy. Some liver tumors are so large that they are either inoperable or require such extensive surgery as to increase the incidence of death, but the introduction of cryoablation, alcohol injection, and radiofrequency ablation means that surgeons can reduce the amount of tumor in the liver, thus allowing chemotherapy to work on fewer tumor cells. The theory is that shrinking the tumor should lead to better chemotherapeutic results. Chemotherapy usually not only kills the tumoral cells remaining after radiofrequency, but also eliminates the satellite cells present in the liver or liver vessels together with good and normally replicating cells. We strongly believe that immunological therapy could become the new standard treatment for liver tumors. It not only debulks the tumor mass while destroying the tumor by means of a cell-mediated response, but its cell-

specific nature should enable it to kill satellite lesions and micro-metastases more efficiently (thus leading to better cytoreduction) without killing normal cells, and allow the use of low-dose chemotherapy to avoid or reduce undesirable side effects. Furthermore, the possible activation of memory responses could lead to much-needed long-term tumor immunosurveillance, which should reduce the incidence of relapses.

CONCLUSIONS

Evidence of practical immunotherapy treatment

Our initial clinical results suggest that there is an urgent need to explore further therapeutic options for liver tumors. This study introduces several innovations and a methodology that will help establish critical clinical assays for assessing immune responses targeting liver tissue, and verify the relationship between host response and liver tumor regression/progression.

Relevance to liver cancer research

We believe that immunological therapy can improve our overall understanding of how the host immune system interacts with primary and secondary liver cancer tissue, and will further elucidate useful methods for assessing this potential interaction.

Relevance to tumor immunology/immunotherapy

The importance of breaking host tolerance in order to achieve a tissue-specific mediated response and facilitate a favorable response to antitumor immunotherapy has recently been stressed in the literature[40]. For this reason, we believe that the use of a mini-invasive surgical approach, the immunotherapy and a clinical treatment will have a significant impact on liver tumors.

Costs and applications

Immunological therapy seems a very promising treatment for liver tumors. However, its specificity and cost makes it indicated for patients with tumors that cannot be resected by any of the different ablation methods, and small tumors in cirrhotic patients who are unsuitable candidates for standard surgery.

Improved cytoreduction

We believe that immunological therapy could become a new standard treatment of liver tumor for mainly three reasons: (1) it can debulk the tumor mass, while destroying the tumor by means of a cellular response; (2) it should be able to control the satellite lesions and micro-metastases more efficiently because of its more cell-specific nature, thus improving cytoreduction, avoiding the killing of normal cells, and reducing the use of chemotherapy and therefore its side effects; and (3) the possible activation of memory responses could lead to much-needed long-term tumor immunosurveillance, and thus reduce the incidence of relapses.

Abstract

The common characteristic criteria of all functional gastrointestinal (GI) disorders are the persistence and recurrence of variable gastrointestinal symptoms that cannot be explained by any structural or biochemical abnormalities. Functional dyspepsia (FD) represents one of the important GI disorders in Western countries because of its remarkably high prevalence in general population and its impact on quality of life. Due to its dependence on both subjective determinants and diverse country-specific circumstances, the definition and management strategies of FD are still variably stated. Clinical trials with several drug classes (e.g., proton pump inhibitors, H2-blockers, prokinetic drugs) have been performed frequently without validated disease-specific test instruments for the outcome measurements. Therefore, the interpretation of such trials remains difficult and controversial with respect to comparability and evaluation of drug efficacy, and definite conclusions can be drawn neither for diagnostic management nor for efficacious drug therapy so far. In view of these unsolved problems, guidelines both on the clinical management of FD and on the performance of clinical trials are needed. In recent years, increasing research work has been done in this area. Clinical trials conducted in adequately diagnosed patients that provided validated outcome measurements may result in better insights leading to more effective treatment strategies. Encouraging perspectives have been recently performed by methodologically well-designed treatment studies with herbal drug preparations. Herbal drugs, given their proven efficacy in clinical trials, offer a safe therapeutic alternative in the treatment of FD which is often favored by both patients and physicians. A fixed combination of peppermint oil and caraway oil in patients suffering from FD could be proven effective by well-designed clinical trials.

INTRODUCTION

Symptoms of upper gastrointestinal distress are of world-wide interest and very common in the general population. In developing countries the important form of dyspepsia is organic dyspepsia, whereas the problem of functional dyspepsia (FD) seems to be mainly confined to industrialized Western countries though convincing data for underdeveloped countries are still lacking[1]. It is estimated that the annual prevalence of recurrent upper abdominal discomfort in the United States and other Western countries is approximately 25%, about 2% to 5% of all primary care consultations are related to dyspeptic symptoms[2]. For many patients the symptoms are of short duration or mild severity[3] and are therefore self-manageable. Less than half of these patients consult their general practitioner[2]. Moreover, patients with upper gastrointestinal problems frequently suffer from recurrent affections. However, several long-term studies showed that high percentages of patients with dyspeptic symptoms at entry report similar symptoms of dyspepsia after some years[3,4]. Repetitive diagnostic measures and medical treatments with low success rates lead to high costs and frustrating results. Thus, FD represents not only a clinical challenge but also a major socio-economical problem. In recent years, a lot of efforts have been made by national and international consensus meetings to work out precise definitions as well as adequate management strategies for dyspepsia. Still unsolved problems and new perspectives for both research work and disease management in clinical practice are summarized and discussed in more detail in this review.

Definition of functional dyspepsia

Several definitions of dyspepsia have been proposed in the past decades[5] demonstrating the difficulties in categorizing

dyspepsia as a clearly pathologically defined entity based on the variability of symptoms. According to the proposition of an international committee meeting in Rome in 1991, the term "dyspepsia" refers to pain or discomfort centered in the upper abdomen[6] while discomfort refers to a subjective negative (or aversive) feeling that is distinct from pain. Discomfort may include several specific bothersome but non-painful symptoms, such as early satiety, fullness, bloating and nausea (the so-called Rome criteria). In Rome I and more recent Rome II reports[1,7-9], the symptoms of heartburn, acid regurgitation, and belching are excluded from the definition of dyspepsia because they are more likely related to gastroesophageal reflux disease (GERD) and aerophagia[1,9]. It is important to distinguish subjects with uninvestigated dyspepsia from patients with dyspepsia after adequate diagnostic procedure. Patients who have neither definite structural or biochemical explanation for their symptoms are considered to have FD. Thus, FD is defined as a persistent or recurrent dyspepsia for at least 12 wk in the preceding 12 mo if there is no evidence for organic disease (including upper endoscopy) that could cause the symptoms. The Rome II definitions of FD also exclude patients who report a relief of symptoms by defecation or symptoms associated with the onset of a change in stool frequency or stool form[9]. In the latter case, irritable bowel syndrome (IBS) is the diagnosis by definition. Coexistence of FD and IBS can be considered if there is pain or discomfort in the upper abdomen that is unrelated to bowel pattern and if there is other pain or discomfort that is related to bowel pattern[7].

Management of dyspepsia

Due to geographical, cultural, educational, social, and psychological aspects, universally applicable guidelines on diagnostic and therapeutical measures are difficult to implement[1,10]. Management strategies should be individualized and developed for each major community taking into account the prevalence of risk factors for gut diseases such as prevalence of *H pylori* infection, use of non-steroidal anti-inflammatory drugs, dietary habits, tobacco smoking and alcohol consumption[1,10]. Beyond these patient-related factors, the available financial and technical resources in each particular country may dictate the individual steps in the management of dyspepsia[1].

Nevertheless, useful recommendations regarding the management of dyspepsia are concluded in a recent systematic review of the literature[11]. To date, five management strategies can be offered to the physicians treating dyspeptic patients: (1) wait and see-strategy without diagnostic and therapeutic interventions; (2) empiric medical therapy with any subsequent investigation reserved for treatment failures; (3) immediate diagnostic evaluation in all cases; (4) testing for *H pylori* infection and reserving endoscopy for *H pylori*-positive cases to look for organic diseases (test-and-scope strategy); and (5) testing for *H pylori* infection by serology or urea breath test and treating all positive cases with *H pylori* eradication therapy (test-and-treat strategy).

For adult patients in Western countries with new onset of dyspepsia, endoscopy is the gold standard approach providing a firm diagnosis and facilitating decisions on treating or excluding organic diseases. In elderly patients or in those with alarm symptoms such as weight loss, immediate endoscopy is strongly advised. In respect of cost-effectiveness, a repeated endoscopy in those with an initially negative result should be avoided. An alternative management strategy in young dyspeptic patients under 45 years is non-invasive testing for *H pylori* infection and antibacterial treatment of positive cases[10-12]. Because of many substantial disadvantages such as antibiotic resistance, overtreatment, or undertreatment, there is ongoing discussion about the benefit of this strategy.

Management of functional dyspepsia

Patients with FD typically present an array of painful and non-painful symptoms demonstrating the multifactorial nature of this syndrome[13,14]. In order to identify pathophysiological abnormalities with subsequent targeted treatment and to promote more homogeneity, patients can be subdivided into ulcer-like, dysmotility-like and unspecified dyspepsia subgroups based on the concept of a cluster of symptoms[13,15]. Several studies have shown that this arbitrary classification seems to be unsustainable because of the considerable overlap of the subgroups, the lack of stability over time, and the inconsistent responses to therapy[13,16]. Currently, the existence of subgroups among dyspeptic patients is neither endorsed nor categorically disproved[7,8,13].

Another approach to a subdivision of patients with FD is the sus pected association with *H pylori* infection. Between 30% and 60% of patients suffering from FD have *H pylori*-induced gastritis. However, *H pylori* infection is also common in the asymptomatic background population[17,18]. Even most recent trials with prolonged follow-up, analyzing the association between *H pylori* status and specific symptom profiles in FD have produced inconsistent and conflicting results. To date, there is no convincing evidence for the relief of specific dyspeptic symptoms after an eradication therapy[5,13,19,20]. Thus, a benefit of anti- *H pylori* therapy in FD is not established [5,11,19].

Drug therapy for functional dyspepsia

The wide range of therapies reflects the uncertainty about the pathogenesis and the lack of satisfactory treatment. The pathophysiology of FD remains inadequately understood, even though various mechanisms may play a role in the development of symptoms. As yet, there is no cure for this disorder and available treatments are aimed at the relief of symptoms. Even though the efficacy of some currently established treatments (e.g., antisecretory agents or prokinetics) has been proven in placebo-controlled trials, these treatments yield sufficient relief of symptoms only in a proportion of patients[5].

In ulcer-like (pain predominating) functional dyspepsia, H_2-receptor antagonists have produced inconsistent response rates[21]. Patients with dysmotility-like symptoms

(upper abdominal discomfort predominating) may benefit from prokinetic drug treatment[22-24]. Proton pump inhibitors appear to be efficacious especially in patients with ulcer-like pain and accompanying reflux symptoms. The majority of controlled clinical trials have shown only minor advantages of these drugs compared to placebo[25,26].

Thus, efforts should be made to identify and develop new effective treatments. Various herbal medications are used in many countries for the treatment of patients with FD. While some clinicians believe that clinical experience appears to support the use of these remedies, randomized controlled studies supporting the efficacy of these treatments have been lacking in the past decades. Recently, several well-designed placebo-controlled clinical trials have provided evidence for the efficacy of herbal preparations used in the treatment of dyspepsia[27]. Particularly, patients with dysmotility-like dyspeptic symptoms, such as postprandial sensations of fullness, premature feelings of repleteness, non-acid eructation, or epigastric pain, experience a notable amelioration of their complaints[28,29].

Problems with evaluating drug efficacy in functional dyspepsia

Clinical trials in functional GI disorders remain a challenge due to a variable placebo response ranging 20-60%[30], marked spontaneous fluctuations of symptoms and a lack of widely accepted primary response variables. In addition, patients recruited at tertiary referral centers may represent a highly selected population that is less likely to respond to therapy[31]. It is likely that patients with FD present to general practitioners when their symptoms are worse. Therefore, spontaneous improvement may partially explain at least part of the placebo response[18].

Beside these well-known problems, the differences in the design of clinical drug trials in FD call for caution when interpreting their results. A systematic analysis of more than fifty eligible published placebo-controlled clinical trials testing prokinetics[32-35], cytoprotectives[36,37] or anti-ulcer agents[38-40] and other drugs[36,37] used in the treatment of functional dyspepsia revealed that single substantial items for the consistency of clinical studies such as inclusion and exclusion criteria for trial design and outcome measures are common but differ quite definitively in specific determinations[41]. Particularly, it is of importance how investigators deal with symptomatic GERD and other organic diseases. In 50% of the analyzed studies other upper GI disorders such as esophagitis and duodenal or gastric ulcer were not excluded; only 27% of the trials exclude or account for patients with overt irritable bowel syndrome as an overlapping functional disorder. The study design varies from parallel group, cross-over to multiple cross-over design[41]. The majority of analyzed trials fail to fulfill the indispensable requirement for efficacy evaluation and comparability of drug classes, i.e. use of clearly defined patient groups according to the consensual definition of FD and the use of validated outcome measures regarding described symptoms, their severity, and quality of life yielded with validated categorical and visual analog scales (VAS). Thus, the authors concluded that convincing conclusions for efficacious drug therapy in the treatment of FD cannot be drawn.

Promising outcome measures for clinical trials

Although some research work has been done to develop validated outcome measures of symptoms[42] which can be used in FD, no generally accepted scales are available. Categorical scales (often referred to as Likert Scales) and VAS (horizontal line, usually 10 cm with endpoints on which the patient must place a mark) have been extensively applied[29,39,43-45] and qualified as most eligible measurement scales by their reproducibility and ability to detect changes in a wide variety of clinical trials of different diseases. The usefulness of a reasonable combination of a categorical scale and a VAS is demonstrated by the dyspeptic discomfort score (DDS) which records the existence, frequency and severity of the symptoms of functional dyspepsia[28,29]. Integrating the dyspeptic, intestinal and extraintestinal autonomic discomforts assessed by means of numerical scales, the DDS seems to consider the entire complexity of this syndrome. Nevertheless, the DDS has not been validated yet.

A noteworthy measurement instrument to be mentioned is the clinical global impression (CGI) scale consisting of three items, namely severity of illness, global improvement and efficacy index. The first and second items are rated on a point scale while the third is a rating of the interaction of therapeutic effectiveness and adverse reactions. Originally conceived for schizophrenic studies, the CGI scale facilitates prognosis, survey and assessment of drug efficacy during the treatment period[28,29,44].

During the last years, attention has been drawn to the fact that in diseases without obvious biological or clinical markers such as functional dyspepsia, the use of quality of life instruments and psychometric documentation as an outcome measure can reflect treatment efficacy evaluated by its impact on symptoms as well as on patient well-being and functioning[41,46]. The underlying philosophy is that quality of life is affected by the severity of disease-specific symptoms. Hence, the reciprocal conclusion can be drawn by any change of symptom severity. Recently, validation data of the new disease-specific Nepean dyspepsia index (NDI)[46,47] and the quality of life in reflux and dyspepsia patient (QOLRAD) questionnaire[48] measuring frequency, intensity, and bothersomeness of upper gastrointestinal symptoms have been presented. The remarkable feature of the NDI is the consideration not only of a subject's ability to perform or engage in an aspect of life but also the enjoyment of that aspect of life. In a systematic review of full-length publications during 1980-2002 reporting studies in patients with FD and measuring health-related quality of life, none of the studies used dyspepsia-specific health-related quality of life instruments[49]. However, recently a first methodologically well-designed clinical study proving efficacy of the study drug by use of the NDI was reported by Holtmann and colleagues[50], which demonstrates a

statistically significant and clinically relevant superiority of a fixed combination of peppermint oil and caraway oil (PCC) in comparison to placebo. The reported outcome confirms the results formerly obtained with this herbal preparation in placebo-controlled clinical trials[28,44] and in a double-blind equivalence study with the prokinetic drug cisapride[29], measured by VAS, CGI and the DDS.

Recommendations for future trials

In view of the mentioned weaknesses in present trials, the most essential recommendations are summarized as follows.

According to the consensus for a diagnosis of FD, a minimum set of diagnostic measures including upper endoscopy, an abdominal ultrasound and basic laboratory is obligatory[6]. At the time of enrolment for a treatment study, eligible patients must have persistent symptoms that are of a sufficient degree to seek medical attention. Any definite structural abnormalities of the upper GI tract, explaining the symptoms, e.g., peptic ulcer confirmed by endoscopic evidence and biochemical agents such as daily use of NSAID or high dose aspirin must be excluded. To avoid an overlap with gastroesophageal reflux disease, patients in whom heartburn or acid regurgitation are the predominant symptoms or patients suffering from irritable bowel syndrome and other known organic diseases that might explain the dyspepsia symptoms must not be enrolled.

Despite some well recognized problems such as the occurrence of period-by-treatment interactions of cross-over trials resulting in ambiguous interpretation of data, the randomized, double-blind, placebo-controlled parallel group design is strongly advocated as the trial design of choice.

It is not to deny that even among physicians there is great variation in the definitions of common dyspeptic symptoms. In addition, terminology and possibly also the sensations experienced vary between cultures and countries. Therefore, it is advisable that clinical investigators use definitions of symptoms suggested by the Rome Working Party report and accommodated to common parlance in the respective study population.

As validated outcome measures like the NDI and the QOLRAD questionnaire are now available, their use is strongly recommended regarding described symptoms, their severity, and aspects of quality of life. In order to support the results obtained with these validated disease specific questionnaires, categorical scales, VAS and the CGI could be used as secondary outcome measures. Promising outcome measures such as DDS, should be validated soon in order to broaden the range of appropriate devices for evaluating drug efficacy in functional dyspepsia.

Further research using well-validated outcome instruments for measurement of individual symptoms as well as their severity and their impact on quality of life may perhaps result in a valid symptom-related categorization of functional dyspepsia that may be used to improve treatment strategies.

Causally determined by the aforementioned unsolved problems concerning the definition and management of FD as well as the listed weaknesses in trial methodology of present treatment studies, convincing conclusions for efficacious drug therapy cannot be drawn yet. However, it is very likely that effective drug therapies are av-ailable. Further research on well-validated measurement instruments for outcome data permitting comparability of drug classes may perhaps result in better insights with respect to effective treatment strategies. Quite recently, new perspectives have been arising from presented efficacy of a fixed peppermint oil/caraway oil preparation in a methodologically adequate clinical trial.

ACKNOWLEDGMENT

This paper is dedicated to Professor Jürgen Hotz, a friend, colleague, and academic teacher, who passed away in 2002.

Abstract

AIM: To investigate the growth suppression of adenovirus expressing p27^{kip1} on established esophageal tumors in nude mice.

METHODS: Esophageal carcinoma xenografts in nude mice were established by tumor tissue mass transplantation. The successfully constructed recombinant adenoviral vectors carrying p27^{kip1} gene (Ad-p27^{kip1}) were directly injected into the esophageal tumors in nude mice. Compared to control group, the growth curve of tumor was drawn and the growth inhibition rate of tumor was calculated. The histology of tumors was examined by hematoxylin and eosin (H&E) staining. The expression of p27^{kip1} and survivin was detected in tumors by immunohistochemical technique.

RESULTS: The growth of tumors in gene therapy group with Ad-p27^{kip1} was obviously suppressed compared to control group (0.42±0.08 g *vs* 1.17±0.30 g, t=6.39, P<0.01), the inhibition rate of tumor growth reached 64.1%. Pathological detection showed that the tumors in nude mice were poorly differentiated esophageal squamous carcinoma. In addition, the expression of p27^{kip1} was increased, while the expression of survivin was decreased in tumors after being transfected with Ad-p27^{kip1}.

CONCLUSION: p27^{kip1} gene therapy mediated by adenovirus vector has a significant inhibitory effect on esophageal carcinoma *in vivo*. Up-regulated p27^{kip1} expression and down-regulated survivin expression may be its important mechanisms.

Key words: p27^{kip1} gene; Esophageal carcinoma; Xenograft; Nude mice; Survivin gene

INTRODUCTION

p27^{kip1} is an anti-oncogene with the function of negative regulation of cell cycle[1], and is also involved in the inhibitory reaction of cytokines, induction of cell differentiation and apoptosis, increase of cell adherence and regulation of resistance to drugs for noumenal tumors[2-6]. Our earlier investigation indicates that p27^{kip1} gene transfer mediated by adenovirus can obviously inhibit the growth of esophageal carcinoma cells[7]. Whether this gene therapy has the same effectiveness *in vivo* is worth further investigation. In this study, we explored the growth suppression of adenovirus expressing p27^{kip1} on established esophageal tumor in nude mice in order to find a new strategy for esophageal carcinoma therapy.

MATERIALS AND METHODS

Materials

The esophageal carcinoma cell strain EC109 and 4-week-old nude mice (Balb/C) of both sexes bred under specific pathogen-free conditions were purchased from Cancer Institute, Chinese Academy of Medical Sciences. pCMV5p27^{kip1} was presented by Dr. Gang Wang, Urinary Surgery Research Institute of the First Hospital of Beijing Medical University. pAACCMVpLpA and pJM17 were presented by academician Zu-Ze Wu, No. 2 Research Institute of Academy of Military Medical Sciences. DH$_{5a}$ was presented by Dr. Xu Peng, Heart Disease Department of the First Hospital of Beijing Medical University. Recombinant adenovirus was constructed by Molecular Biology Laboratory of Taihe Hospital. p27^{kip1}cDNA and adenovirus PCR primer were designed and synthesized by Saibaisheng Biological Company (Beijing, China). RPMI 1640 medium was purchased from Gibco BRL (NY, USA). Polyclonal goat antibody of survivin was purchased from Santa Cruz Biotechnology (CA, USA). Monoclonal mouse antibody of p27^{kip1}, ultra sensitive S-P kit, and 3,3-diaminobenzidine (DAB) kit were purchased from Fuzhou Maixin Biotechnology Co. Ltd (Fuzhou, China).

Construction of recombinant adenovirus Ad-p27^{kip1}

The process was the same as described in our previous work[7].

Cell culture

Human esophageal carcinoma cell strain EC109 was maintained in RPMI 1640 medium supplemented with 100 mL/L fetal calf serum (FCS), 100 kU/L penicillin, 100 mg/L streptomycin, 2 mmol/L L-glutamine, and 50 mL/L CO_2 in a humidified incubator at 37 ℃. The medium was changed every 2-3 d.

Establishment of esophageal carcinoma xenografts

EC109 cells growing exponentially were selected. The final concentration was adjusted to 10^7 cells/mL. Nude mice (Balb/C) of 4 wk old received injections into the dorsal midline in a 100 mL volume to establish tumors. The transplanted tumors were reproduced among the animals continually when the original grafts were growing well. Then esophageal carcinoma xenografts were established by transplanting the tumor tissue mass into the subcutaneous tissue of 36 nude mice. They were ready for use when the tumor diameter reached about 0.7 cm.

Therapeutic effect of intratumoral injection of Ad-p27^{kip1} into established tumors

The animals were randomized into three groups, and each group had seven mice with comparable tumor size within and among the groups. Intratumoral injection of Ad-p27^{kip1}, Ad-LacZ (1.0×10^{10} pfu) or PBS was made every other day for totally four times. The growth curve of tumor was drawn and the growth inhibitory rate of tumor was calculated after the animals were killed at wk 4. Tumor sizes were calculated by the formula: tumor volume = 1/2 ×length×width^2. The growth inhibitory rate of tumor was calculated by the formula: inhibitory rate = (tumor mass of control group–tumor mass of experimental group)/ tumor mass of control group.

Histology

The tumor tissues were fixed in 10% neutral formalin and embedded in paraffin. Sections of 5 μm thickness were used for morphological and immunohistochemical examinations. Paraffin sections were stained with hematoxylin and eosin (H&E) to demonstrate esophageal carcinoma tissue components.

Expression of p27^{kip1}

The paraffin sections were washed with phosphate-buffered saline (PBS, pH 7.4) and incubated in 3% hydrogen peroxide for 10 min to block endogenous peroxidase. After being heated for 10 min in 0.01 mol/L citrate buffer (pH 6.0) using a microwave oven, the sections were incubated with normal animal serum for 10 min and then with monoclonal mouse antibody of p27^{kip1} overnight at 4 ℃. Biotinylated antimouse immunoglobulin and streptavidin conjugated to horseradish peroxidase were subsequently applied. Finally, DAB was used for color development, and hematoxylin was used for counterstaining. As a negative control, the sections were processed in the absence of primary antibody. A scoring method was used to quantitate the p27^{kip1} expression in samples examined. A mean percentage of positive tumor cells was determined in at least five areas at 400-fold magnification. Samples with scores less than 50% were defined as low expression, otherwise as high expression[8]. These scorings were performed in a blinded fashion.

Expression of survivin

The sections carrying survivin protein were stained according to SP immunohistochemical staining method as aforementioned. The primary antibody was polyclonal goat antibody of survivin (dilution 1:200). The mean percentage of positive cells for the expression of survivin was determined in at least five areas at 400-fold magnification, and the samples with less than 10% positively stained cells were defined as negative. Samples with 10-29% positively stained cells were defined as +, 30-59% as ++, and 60% or more than 60% as +++[9].

Statistical analysis

The data were expressed as mean±SD. The difference between each group was analyzed by *t*-test. $P<0.05$ was considered statistically significant.

RESULTS

Growth suppression of established esophageal carcinoma xenografts by intratumoral injection of Ad-p27^{kip1}

Intratumoral injection of Ad-p27^{kip1} into established tumors induced partial growth suppression. The growth of tumors in gene therapy group with p27^{kip1} was obviously suppressed, being significantly different from that in control group and Ad-LacZ group ($P<0.01$). The growth inhibitory rate (IR) of tumor reached 64.1% (Figures 1 and 2, Table 1).

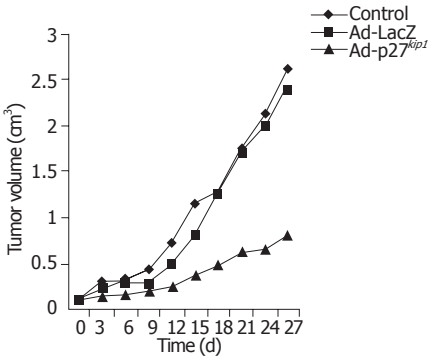

Figure 1 The growth curves of tumor.

Histological evaluation

The result of hematoxylin and eosin staining showed poorly differentiated esophageal squamous carcinoma (Figure 3).

Table 1 Tumor mass of three groups treated with Ad-p27^{kip1}, Ad-LacZ (1.0×10^{10} pfu) or PBS at wk 4

Groups (%)	Tumor mass (g)								IR
	1	2	3	4	5	6	7	mean±SD	
Control	1.02	0.93	1.31	1.47	0.86	1.63	0.95	1.17±0.30	
Ad-LacZ	0.72	1.36	1.12	0.87	0.92	1.23	0.85	1.00±0.23	
Ad-p27^{kip1}	0.32	0.46	0.35	0.43	0.57	0.38	0.40	0.42±0.08^{b}	64.1

$t = 6.39$, $^{b}P<0.01$ *vs* control group. IR: inhibition rate.

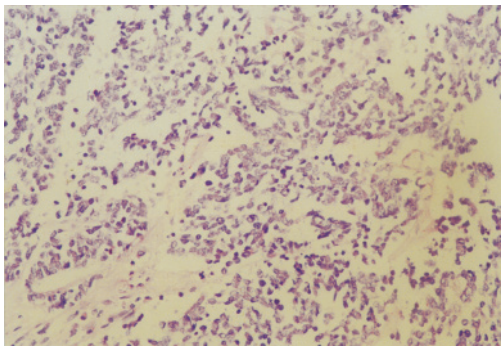

Figure 3 Hematoxylin and eosin (H&E) staining of established esophageal carcinoma xenografts (×200).

Expression of p27^{kip1}

Immunohistochemical staining showed that the expression of p27^{kip1} was increased in established esophageal carcinoma xenografts after being transfected with Ad-p27^{kip1} (Figure 4).

Expression of survivin

Survivin was prominently found in control group by immunohistochemistry and decreased in established esophageal carcinoma xenografts after being transfected with Ad-p27^{kip1} (Figure 5).

DISCUSSION

p27^{kip1} has been mapped to the short arm of chromosome 12 at the 12p12-12p13.1 boundary containing two introns and two exons[10]. Mutations of gene p27^{kip1} occur rarely in human tumors and the decrease in p27^{kip1} expression in tumor tissues is due to post-transcriptional degradation[11]. p27^{kip1} protein belongs to the family of proteins called cyclin-dependent kinase inhibitors (CDKIs). These proteins play an important role as negative regulators of cell cycle-dependent kinases during the progression of cell cycle. p27^{kip1} regulates the progression from G_1 into S phase by binding to and inhibiting the cyclin E/Cdk2 complex, which is required for entry into the S phase. It also interacts with various other cyclin complexes and is therefore designated as a universal CDKI[12-16]. p27^{kip1} expression decreases in esophageal cancer and may correlate with the histologic differentiation. Reduction of p27^{kip1} is considered to be an independent prognostic indicator of esophageal cancer[17-20].

In this study, we found that the growth of established esophageal carcinoma xenografts was obviously depressed and the inhibitory rate reached 64.1% after transfection with Ad-p27^{kip1}. The result of immunohistochemical staining demonstrated that Ad-p27^{kip1} could efficiently express p27^{kip1} in esophageal carcinoma. Ad-p27^{kip1} constructed in the present study is a kind of replication defective adenoviral vector, which has only one opportunity for infection in target cells without any dup-lication ability to fulfill the functions of adenoviral carrier, thus avoiding damage of adenovirus itself to target cells and reaching gene conversion.

We also observed that the expression of survivin was decreased in tumors of nude mice, indicating that p27^{kip1} might downregulate survivin expression. Survivin is a newly identified gene in inhibitors of apoptosis protein (IAP) family and is characterized by a unique structure with a single baculovirus IAP repeat and no zinc-binding domain known as Ring finger[21-23]. Survivin is an oncogene, which has been implicated in inhibition of apoptosis and control of mitotic progression. It is not usually detectable in normal adult tissues, but is prominently expressed in almost all common human cancers and most transformed cell lines. It is a short-lived protein degraded by ubiquitin proteasome pathway and interferes with the activation of caspases, called "cell death executioners"[24-28]. Disruption of survivin-microtubule interactions results in loss of survivin's anti-apoptosis function and increase of caspase-3 activity, a mechanism involved in cell death during mitosis. Survivin functions as a dimer and is regulated in a cell-cycle-dependent manner, peaking at G_2/M, nearly not detectable at G_1, and is associated with the mitotic spindle, centromeres, and the midbody in dividing cells[29-31]. p27^{kip1}, a down-regulating survivin may be associated with G1 blocking of p27^{kip1}, which has been identified in our previous studies[7].

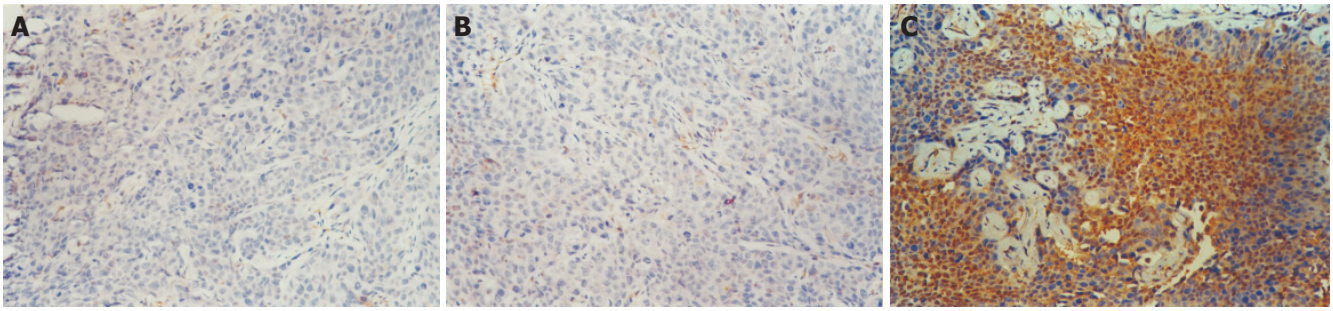

Figure 4 Result of immunohistochemical staining of tumors in nude mice. **A:** control group. p27^{kip1} protein located in cytoplasm of a few cells showing low expression; **B:** Ad-LacZ group. The result showed low expression also; **C:** Ad-p27^{kip1} group. p27^{kip1} protein located in cytoplasm and nucleus showing high expression (×200).

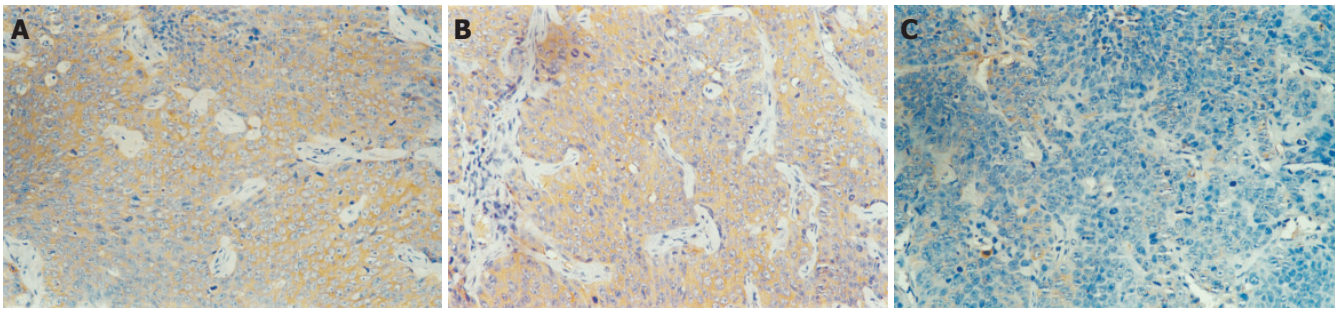

Figure 5 Result of immunohistochemical staining of tumors in nude mice. **A:** control group. Survivin protein located in cytoplasm showing high expression; **B:** Ad-LacZ group. The result showed high expression also; **C:** Ad-p27^{kip1} group. Survivin protein located in cytoplasm of a few cells showing low expression (×200).

In conclusion, p27^{kip1} gene therapy mediated by adenovirus vector has significant inhibitory effect on esophageal carcinoma *in vivo*. Upregulated p27^{kip1} expression and downregulated survivin expression may be its important mechanisms.

Abstract

AIM: To study the clinical significance of minimal ascites, which was only defined by the CT and whose nature was not determined preoperatively, in the relationship with the peritoneal carcinomatosis.

METHODS: The medical records and the dynamic CT films of 118 patients with gastric cancer were reviewed. Factors associated with peritoneal carcinomatosis were analyzed in 40 patients who had CT-defined ascites of which the nature was surgically confirmed.

RESULTS: Only 12.5-25% of the CT-defined minimal ascites, whose volume was estimated to be less than 50 mL, were associated with peritoneal carcinomatosis. When the estimated CT-defined ascitic volume was 50 mL or more, peritoneal carcinomatosis was identified in 75–100%. When CT-defined lymph node enlargements were not found beyond the regional gastric area, perigastric invasions were not suspected, and the size of tumor was less than 3 cm, peritoneal carcinomatosis seemed significantly less accompanied at the univariate analysis. However, except for the minimal volume of CT-defined ascites in comparison with the mild or more, other factors were not confirmed multivariately.

CONCLUSION: In the patients with gastric cancer, CT-defined minimal ascites alone is rarely associated with peritoneal carcinomatosis, if it does not accompany other signs suggestive of malignant seeding. Therefore, consideration of active curative resection should not be hesitated, if CT-defined minimal ascites is the only delusive sign.

INTRODUCTION

Gastric cancer, quite uncommon in the developed countries, is still the second leading cause of cancer death in the world[1]. Surgical resection is the only effective therapy to secure curability of this fatal disease. Therefore, overestimation of the stage to render surgery being given up is critically hazardous, as it could deprive a patient of a chance for cure.

The two most frequent conditions in which gastric cancer is regarded incurable are when distant metastasis and malignant peritoneal seeding are demonstrated[2]. Dynamic CT is an excellent modality in clinical staging for gastric cancer and reliably detects metastasis to distant organs such as liver or lung[3,4]. However, the accuracy of dynamic CT in assessing malignant peritoneal involvement is somewhat questionable[4]. The presence of ascites, intestinal wall thickening, contrast-enhanced density in peritoneal adipose tissues, or implanted peritoneal, mesenteric or omental nodules are commonly stated CT findings suggestive of peritoneal carcinomatosis[5,6]. Among these, ascites is assumed to be the most frequently occurring clue for malignant seeding[5].

The nature of ascites is easily disclosed by aspiration cytology as long as the quantity of intra-abdominal fluid enables paracentesis[7,8]. Even small amount of ascites could be recovered for analysis by ultrasonography-guided needle aspiration[9,10]. However, dynamic CT has now become extremely sensitive and may occasionally detect subtle and equivocal amount of ascites in the pelvis, too little for preoperative aspiration-based examination. Without a cytological study or other strong evidences of peritoneal carcinomatosis, the significance of CT-defined minimal ascites might be ambiguous.

In clinical practice, some degree of hesitation is unavoidable in proceeding to surgery, when peritoneal seeding is equivocally suspected. The aim of this study is to make obvious whether the minimal ascites, which was

only defined by CT and whose nature was not practically feasible to characterize preoperatively, is related to genuine peritoneal carcinomatosis. We intend to draw a reasonable perception about 'minimal' ascites in view of clinical significance.

MATERIALS AND METHODS

Patients

Between January 2002 and December 2002, 118 consecutive patients were diagnosed for gastric cancer based on the histological examination of a gastroscopic biopsy and were also examined by dynamic CT at Boramae hospital. Their medical records and CT films were retrospectively reviewed. Out of these, 11 patients did not complete all necessary diagnostic and therapeutic procedures and were excluded from the study. One patient with massive ascites caused by decompensated hepatic cirrhosis was also excluded. Finally, a total of 106 patients remained for an initial analysis (BRM02) for overall frequency of ascites, peritoneal carcinomatosis, and distant metastasis.

The nature of ascites was often unexplored in the patients with metastatic diseases, because curative surgery was not indicated for them and thus characterization of ascites was practically unnecessary. Therefore, when analyzing the clinical implications of CT-defined ascites, we excluded 17 metastatic cases. In the remaining 89 cases (BRM02-NoMeta), the relationships between CT-defined ascites, surgery- or aspiration-recovered ascites, and peritoneal carcinomatosis were analyzed.

Thereafter, we tried to find factors predicting the absence of peritoneal carcinomatosis in the patients with CT-defined ascites, whose nature could not be evaluated preoperatively. To obtain sufficient number of cases for statistical analysis, we extended the study subjects to the cases of Boramae Hospital and of Seoul National University Hospital during the periods between March 1998 and December 2002. We reviewed 2 365 CT reports of the cases who had undergone open abdominal surgery, so whose ascitic natures were confirmed. In this screening step based on the reports, we collected 40 operated cases in which the patients had CT-defined ascites of undetermined nature at preoperative phase and had no definite evidence of distant metastasis or apparent peritoneal seeding (BRM-SNU group). Their medical records and CT films were reviewed in detail.

Radiologic analysis

Dynamic CT studies were performed with Somatom plus-4 scanner (Siemens Medical System, Erlangen, Germany). The abdomen and pelvis were scanned with helical technique and the image was reconstructed at 1-cm-thick sections. Patients were asked not to drink or eat anything for 8 h before CT examination. A total of 500-1 000 mL of tap water was given by mouth, immediately before scanning. A total of 80-120 mL of iopromide contrast medium (Ultravist370®, Schering, Berlin, Germany) was administrated by Mark V dedicated CT injector (Medrad, Pittsburgh, PA, USA) at a flow rate of 3 mL/s, through 18-gauge angiographic catheter placed in the antecubital vein.

Ascites was defined at CT images by at least two experienced radiologists, when the reasonably low radiologic density of 10 or less Hounsfield number was found within the pelvic cavity outside intra-abdominal or pelvic organs. Volume of ascites was estimated by the ruler grids applied on CT images. For example, the area of ascites was measured about 3.5 cm^2 in Figure 1A and 16 cm^2 in Figure 1B and these respectively corresponded with the estimated volumes of 3.5 mL (3.5 $cm^2 \times 1$ cm) and 16 mL (16 $cm^2 \times 1$ cm), because the interval between the serial images obtained in the study was 1 cm. When fluid densities were detected in more than one image, the volumes at each image were added up.

'Minimal' ascites was defined, when the volume of ascites was estimated to be less than 50 mL, and ascites of 50-300 mL was defined as 'mild'. Because we focused on the small amount of ascites which could not be easily evaluated by conventional measures at the preoperative stage, definition about moderate to severe ascites was not considered.

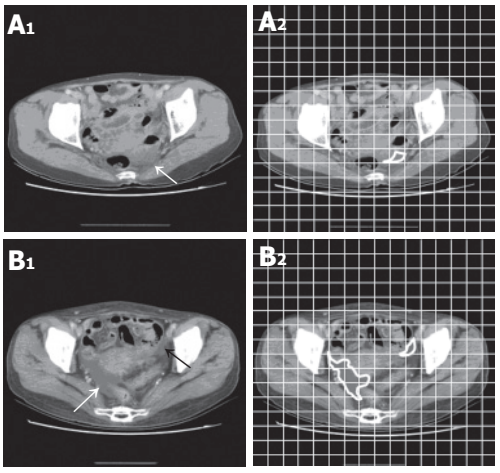

Figure 1 To estimate the volume of ascites by applying grids. Arrows indicate ascitic density (**A1-2**-**B1-2**).

Obliteration of a fat plane between the stomach and adjacent organs or apparent infiltration shown in the CT images was regarded as tumor invasion. Lymph nodes were considered significantly enlarged, when the long diameter was more than 1 cm. The lymph nodes were classified as 'regional' when they were located along the lesser or the greater curvatures of stomach, or at the left gastric, common hepatic, celiac, or splenic arteries. Other intra-abdominal nodes beyond these regions, such as the hepatoduodenal, retropancreatic, mesenteric, or para-aortic area, were defined as distant lymph nodes.

Statistical analysis

Data were analyzed by SPSS (11.5th version) software. Chi-square test was used for categorical data analysis, and the

univariate analysis and the multivariate logistic regression modeling were employed for assessing the predictive factors for the absence of peritoneal carcinomatosis in patients with CT-defined ascites.

RESULTS

Overall proportion of CT-defined ascites, peritoneal carcinomatosis and distant metastasis in the patients with gastric cancer (BRM02 group)

One hundred and six patients committed to the initial analysis consisted of 70 men and 36 women with a mean age of 63.3 years. The stage of gastric cancer at diagnosis was stage I, 23.6%; stage II, 7.5%; stage III, 34.0%; and stage IV, 34.9%. Patients with early gastric cancers were 27.4%.

Of the BRM02 patients, 22 (20.7%) had ascites defined by CT images. Based on the estimated volume of ascites, 12 patients belonged to the category of minimal ascites and 10 patients had mild or more ascites (11.3% and 9.4% of all patients, respectively).

Twenty patients out of the 106 BRM02 group (18.9%) were found to have peritoneal carcinomatosis that was confirmed by preoperative aspiration cytology or laparotomy no matter, whether they had CT-defined ascites or not. Seventeen patients (16%) had metastatic diseases to distant organs. Among these, four patients (3.8%) were confirmed to have both distant metastasis and malignant peritoneal seeding (Table 1).

Clinical realities of CT-defined ascites in the metastasis-free patients (BRM02-NoMeta)

Out of the remaining 89 patients (BRM02-NoMeta) after excluding those with metastatic diseases, 8 had minimal ascites, and 7 had mild ascites. There were no patients having ascites greater than mild category in the metastasis-free group. The nature of ascites was explored by surgery, in all 8 cases with minimal ascites, and in 5 out of 7 cases with mild ascites. The remaining two patients' ascites were proven malignant by aspiration cytology, and surgery was not performed.

Ascites defined by CT images were not always identified as peritoneal fluid on surgery. As for the CT-defined minimal ascites, ascitic fluid was recovered at the surgical field in only one (12.5%) of the cases. However, as CT-estimated ascitic volume was higher, surgical correlation improved. In the cases of 'mild' ascites which had more volume than 'minimal', the concordance rate between CT-defined ascites and surgery- or aspiration-recovered ascites was as high as 85.7% (6 out of 7). On the other hand, 5 (6.8%) out of 74 patients who had no CT-identified ascites preoperatively demonstrated ascites at the time of surgery (Table 2A).

The relationship between CT-defined ascites and peritoneal carcinomatosis was analyzed (Table 2B). Among the patients who did not show ascites at the CT images, seven (9.5%) had peritoneal carcinomatosis on surgery. Seven out of sixteen (43.8%) patients with peritoneal carcinomatosis did not demonstrate radiological signs of ascites at the preoperative CT. In the patients with CT-defined 'minimal' ascites, only 25% were concluded by surgery to have peritoneal carcinomatosis. This was contrast to the cases with CT-defined 'mild' ascites, in which all of the CT-defined ascites turned out to have occurred in the association with peritoneal carcinomatosis.

The presence of surgery- or aspiration-recovered ascites was not always accompanied with malignant peritoneal seeding, too. Four out of twelve patients (33.3%) with surgically or cytologically recovered ascites did not accompany peritoneal carcinomatosis, and 8% of ascites-free patients were actually positive for malignant peritoneal seeding (Table 2C).

Factors favoring absence of peritoneal carcinomatosis

[1]Presence of ascites was not examined because operation was immediately ceased following observation of malignant omental cakes.

in the patients with CT-defined ascites which was not yet determined whether malignant or not.

We tried to search factors favoring absence of peritoneal carcinomatosis in the gastric cancer patients with CT-defined ascites in the larger number of cases. The sex and age distributions in these 40 patients (BRM-SNU) were not statistically different from those of the initial 106 gastric cancer patients (BRM02).

Majority of CT-defined ascites, of which the nature could not be preoperatively characterized, had volumes of less than 10 mL with a left-skewed pattern (Skewness = 2.768, Figure 2). The range of volume was 1-300 mL; the mean was 34.8 mL and the median was 9.9 mL. Thirty-two cases were categorized as 'minimal' ascites and the rest eight were 'mild' ascites. Age and sex were not related to the volume of CT-defined ascites (data not shown), but the stage of cancer seemed lower in the patients with minimal ascites than those with mild ascites (Table 3).

The CT-defined 'minimal' ascites were associated with peritoneal carcinomatosis in only 12.5% and demonstrated surgically recovered ascites in only 9.4% (Table 4). These data confirmatively reproduced the results obtained from the fewer cases in BRM02 (Table 2). Contrary to the CT-defined 'minimal' ascites, the CT-defined 'mild' ascites were accompanied with peritoneal carcinomatosis in as high as 75%, and were proved to have genuine fluid collection in 62.5%.

In addition to the ascitic volume, several other factors suggestive of negative peritoneal carcinomatosis were tested by the univariate analysis in the patients with CT-defined minimal or mild ascites (Table 5). When enlargement of peritoneal lymph nodes were absent or confined to the regional perigastric area at the CT images, the negative predictive value for peritoneal carcinomatosis was 88.9%. Free of CT-defined perigastric invasion also negatively predicted peritoneal carcinomatosis in 90.9%. None of the patients with tumors with less than 3 cm were accompanied with malignant peritoneal seeding. However, except for the CT-defined 'minimal' ascites in comparison with the more abundant ascites, none of the above factors obtained statistical significance by multivariate analysis as an independent predictor for absence of malignant seeding.

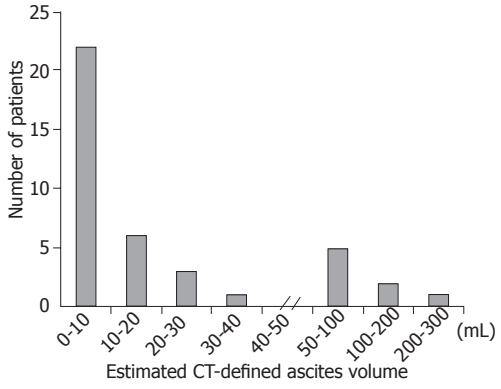

Figure 2 Frequency of patients based on the estimated CT-defined ascites volume.

4	14 (43.8)	6 (75.0)
Total	32 (100)	8 (100)

DISCUSSION

CT has been established as the most popular staging modality in gastric cancer although conventional or endoscopic ultrasonography, or laparoscopy can also be used[3,4,10-14]. The role of CT in detecting distant metastasis has been particularly well recognized; overall sensitivity for assessing liver metastasis reached about 62-89%[4,13,14].

However, CT is less reliable in identifying ascites or peritoneal carcinomatosis; the sensitivity was merely

36-46.7% for ascites and was 13-30% for malignant peritoneal seeding[4,12,14,15]. While the full blown peritoneal carcinomatosis demonstrating all the relevant radiologic features is diagnosed unambiguously, early and tiny malignant implantation cannot be easily decided. Although ascites has been regarded an important sign suggesting peritoneal carcinomatosis[5], the meaning of ascites may become ambiguous, as the dynamic CT detects subtle amounts of peritoneal fluid collection with increased sensitivity.

Then, what is the clinical significance of minimal ascites found in the CT image? Our data showed that minimal amounts of suspicious ascites defined by the dynamic CT were associated by peritoneal carcinomatosis in only 12.5-25%. This data may suggest that the patients need not hesitate to go through surgery, if the CT-defined minimal ascites is the only delusive clue for peritoneal seeding.

In the past, these amounts of minimal ascites might have never been detected by the CT and, therefore, might have never become a clinical issue. It may be argued whether the CT-defined minimal ascites is true or false-positive. However, this kind of question seems clinically out of point. Confirmation of real ascites may hardly be possible. Even surgery cannot be a gold standard in judging the presence of ascites because some blood or irrigated saline might be inevitably mixed with minimal, if any, ascites during surgery. Moreover, peritoneal cavity physiologically contains small amount of serous fluid which has been produced by permeable mesothelium[16], although this disperses diffusely in the peritoneal cavity and is not usually detected by the CT. It remains uncertain, if our CT-defined 'minimal' ascites is exaggerated physiologic fluid, or pathologic ascites.

On the other hand, high index of suspicion may have rendered observers to detect phantom radiologic ascites in the cancer patients. However, an article by Chen *et al*. also reported that small amounts of ascites were detected at the perigastric area in 39% of patients with gastric cancers by endoscopic ultrasonography and they were not significantly correlated with macroscopic peritoneal carcinomatosis[17]. Revealing the mechanism in the development of minimal ascites may be beyond the scope of this study.

No matter whether CT-defined minimal ascites is true or false, the apparent existence of minimal ascites reasonably defined by the dynamic CT may confuse a physician in determining the patient's operability. This may be particularly critical in the patients with marginally poor condition. It is possible that, for example, elderly patients may give up radical surgery, when they are imprudently suggested the worse prognosis, because of the suspicious ascites. Adoption of laparoscopic staging in patients with CT-defined minimal ascites is another issue. Although laparoscopic examination may reveal the nature of minimal ascites more clearly[12], this procedure is not always routinely available at every hospital. In the most common practice setting, a physician cannot help but judge the operability according to the CT finding and other clinical manifestations.

If CT-defined minimal ascites has just low probability of peritoneal carcinomatosis, what additional factors could enhance the possibility of free peritoneum? Of course, it should be explored first whether peritoneal nodules, fat strands, pleated soft tissue, thickening of omental, mesentery and/or bowel wall, or other radiologic clues for malignant seeding were accompanied with or not. As our data suggested, when CT-defined lymph node enlargements were not found beyond the regional gastric area, CT-defined perigastric invasions were not detected, and the size of tumor was less than 3 cm, the probability of true peritoneal carcinomatosis may be very low, at least based on the univariate analysis.

In conclusion, majority of malignancy-undetermined CT-defined minimal ascites that was estimated to be less than 50 mL at the preoperative phase are not significantly related to the peritoneal carcinomatosis. Therefore, if the peritoneal carcinomatosis was not definitely established, passive therapeutic strategy should not be applied to those patients simply because ascites is suspected. Definite meaning of CT-defined minimal ascites may need to be reinterpreted by the final effect on survival after long-term follow-up, and this study is under way.

Abstract

AIM: To evaluate the association between polymorphisms *XRCC1* Arg194Trp and Arg399Gln and *XRCC3* Thr241Met and the risk for chronic gastritis and gastric cancer, in a Southeastern Brazilian population.

METHODS: Genotyping by PCR-RFLP was carried out on 202 patients with chronic gastritis (CG) and 160 patients with gastric cancer (GC), matched to 202 (C1) and 150 (C2) controls, respectively.

RESULTS: No differences were observed among the studied groups with regard to the genotype distribution of *XRCC1* codons 194 and 399 and of *XRCC3* codon 241. However, the combined analyses of the three variant alleles (194Trp, 399Gln and 241Met) showed an increased risk for chronic gastritis when compared to the GC group. Moreover, an interaction between the polymorphic alleles and demographic and environmental factors was observed in the CG and GC groups. *XRCC1* 194Trp was associated with smoking in the CG group, while the variant alleles *XRCC1* 399Gln and *XRCC3* 241Met were related with gender, smoking, drinking and *H pylori* infection in the CG and GC groups.

CONCLUSION: Our results showed no evidence of a rela-tionship between the polymorphisms *XRCC1* Arg194Trp and Arg399Gln and *XRCC3* Thr241Met and the risk of chronic gastritis and gastric cancer in the Brazilian population, but the combined effect of these variants may interact to increase the risk for chronic gastritis, considered a premalignant lesion. Our data also indicate a gene-environment interaction in the susceptibility to chronic gastritis and gastric cancer.

INTRODUCTION

DNA repair pathways are responsible for maintaining the integrity of the genome in face of environmental insults and general DNA replication errors, playing a role in protecting it against mutations that lead to cancer[1]. So, polymorphisms of DNA repair enzymes, which may alter the function or efficiency of the DNA repair, may contribute to an increased risk of environmental carcinogenesis[2]. These low-penetrance susceptibility genes have common variants and interact with environmental factors, contributing as a major factor to the populational incidence of cancer[3]. Several polymorphisms in genes that participate in different DNA repair pathways, such as *XPD*, *XPF*, *ERCC1*, *XRCC1*, *XRCC3*[4], *hOGG1*[5], *XPA*, *XPB*[6] and *XPC*[7], have been identified and related to cancer susceptibility.

The *XRCC1* gene is responsible for a scaffolding protein that directly associates with other proteins such as DNA polymerase β, PARP (ADP-ribose polymerase) and DNA ligase III in a complex, to facilitate the processes of base excision repair (BER) or single-strand break repair[8]. The BER pathway repairs DNA damage caused by a variety of endogenous and exogenous factors, including oxidation, alkylating agents and ionizing radiation[1,9]. The *XRCC1* protein can bind directly to both gapped and nicked DNA, as well as to gapped DNA associated with DNA

polymerase β, suggesting that this protein might be independently involved in DNA damage recognition[10]. Two polymorphisms, more often found in *XRCC1'* conserved sites, lead to a C→T substitution at codon 194 in exon 6 and to a G→A substitution at codon 399 in exon 10 of the gene, leading to the amino acid alterations arginine (Arg) to tryptophan (Trp) and arginine (Arg) to glutamine (Gln), respectively. These changes in conserved protein sites may alter the BER capacity, increasing the chances of DNA damage[4].

The Arg399Gln variant is more frequent and has been associated mainly with head and neck[11], colorectal[12], gastric[13], esophageal[14,15], breast[16] and lung[17,18] cancers. The Arg194Trp polymorphism has been related to colorectal[12], gastric[13], head and neck[19] and skin[20] cancers.

Protein *XRCC3* functions in the DNA double-strand break (DSB) and cross-link repair[21] and interacts and stabilizes Rad51[22], one of the key components of the homologous repair (HR) pathway. The HR pathway uses a second intact copy of a homologous chromosome as a template to copy the information lost at the DSB site, resulting in a high-fidelity process and preventing chromosomal aberrations[9]. The main polymorphism in this gene involves the change of threonine (Thr) to methionine (Met) at codon 241 in exon 7[4]. Little is known about the functional consequences of this variation, although some studies observed a positive relation between the Thr241Met polymorphism and an increased risk for skin[23], bladder[24], breast[25] and lung[26] cancers.

So far, the investigations about interactions between *XRCC1* and *XRCC3* polymorphisms and environmental carcinogenesis have produced scarce and conflicting results[27,28,29,30], showing the functional complexity of these variants, that can include their interaction with environmental factors, thus modulating the susceptibility to cancer. Regarding gastric cancer, only a few studies were conducted to investigate its association with *XRCC1* and *XRCC3* variants[13, 27,29,31].

In Brazil, gastric cancer is still one of the most frequent types of cancer. The estimate for 2005 points to the fourth place in incidence and mortality, with about 23 000 new cases and 12 000 deaths[32]. However, multiple factors are thought to play a role in gastric carcinogenesis, including diet[33], lifestyle[34], pathological changes in the stomach such as chronic gastritis[35], and genetic alterations[36,37], besides the infection by *Helicobacter pylori*, the first bacterium to be termed as a definitive cause of cancer[38].

Thus, we conducted a study to evaluate the association between the polymorphisms *XRCC1* Arg194Trp and Arg399Gln and *XRCC3* Thr241Met and the risk of chronic gastritis and gastric cancer in a Brazilian population, as well as the interaction between these polymorphisms and environmental factors involved in gastric carcinogenesis.

MATERIALS AND METHODS

Subjects

This was a case-control study on chronic gastritis and gastric cancer. The case groups comprised 202 patients with a histopathologically confirmed diagnosis of chronic gastritis (100 men and 102 women), with a mean age of 52 years (range 19-86 years), and 160 patients with a histopathologically confirmed diagnosis of gastric adenocarcinoma (118 men and 42 women), with a mean age of 61 years (range 28-93 years). All subjects were recruited from the Hospital de Base in São José do Rio Preto, SP, and from the Pio XII Foundation in Barretos, SP, Brazil. Gastric adenocarcinomas were classified as diffuse or intestinal types, according to the classification proposed by Lauren[39], and the chronic gastritis cases according to the Sidney System[40]. *H pylori* infection was histologically established by the Giemsa staining technique. Two cancer-free control groups with no previous history of gastric disease were matched to the case groups with respect to age, gender and ethnicity. The control group for chronic gastritis (C1) was composed of 202 healthy individuals (100 men and 102 women) with a mean age of 51 years (range 20-85 years), and the control group for gastric cancer (C2) consisted of 150 healthy volunteers (108 men and 42 women) with a mean age of 59 years (range 22-93 years). Epidemiological data on the study population were collected using a standard interviewer-administered questionnaire, with questions about current and past occupation, smoking habits, alcohol intake and family history of cancer. This work was approved by the National Research Ethics Committee and written informed consent was obtained from all individuals.

DNA extraction and genotype analyses

About 5 mL of whole blood were collected from all study participants in sterile EDTA-coated vacutainers. The samples were assigned a unique identifier code. DNA was extracted according to Abdel-Rahman *et al.*[41] and stored at -20 ºC until used for genotyping.

Genotypic analyses of the *XRCC1* gene were carried out by multiplex PCR-RFLP, using primers for codons 399 (F 5' -TTGTGCTTTCTCTGTGTCCA-3' and R 5'-TCCTCCAGCC TTTTCTGATA-3') and 194 (F 5'-GCCCCGTCCCAGGTA-3' and R 5'-AGCCCCAAGACCCTTTCACT-3'), which generate a fragment of 615 and 491 bp, respectively, as previously described[12] with modifications. Briefly, PCR was performed in 25 μL reaction buffer containing 12.5 pmol each primer, 0.2 mmol/L of dNTPs, 3 mmol/L of $MgCl_2$, about 100 ng DNA and 1 U of Taq DNA polymerase. The PCR products were digested overnight with 10 U of *Msp*I at 37 ºC. The wild-type Arg allele for codon 194 is identified by the presence of a 293 bp band, and the mutant Trp allele by the presence of a 313 bp band (indicative of the absence of the *Msp*I cutting site). For codon 399, the presence of two bands of 375 and 240 bp, respectively, identifies the wild-type Arg allele, while the uncut 615 bp band identifies the mutant Gln allele (indicative of the absence of the *Msp*I cutting site). A 178 bp band, resulting from an additional invariant *Msp*I cutting site in the 491 bp amplified fragment, is always present and serves as an internal control for complete enzyme digestion.

Polymorphism of the *XRCC3* gene was deter-

mined by PCR-RFLP, using codon 241 primers (F- 5' GCCTGGTGGTCATCGACTC 3' e R- 5' ACAGGGCTCTGGAAGGCACT GCTCAGCTCACGCACC 3'), as previously described by David-Beabes *et al.*[42]. The 25 µL PCR mixture contained about 100 ng of DNA, 12.5 pmol of each primer, 0.2 mmol/L of dNTPs, 2 mmol/L of $MgCl_2$ and 1 U of Taq DNA polymerase. The 552 bp amplified product was digested overnight with 5 U of *Nla*III at 37 ºC. The wild-type allele Thr was identified by the presence of two 239 and 313 bp bands, while the mutant allele Met was represented by 105, 208, and 239 bp bands.

Statistical analysis

Chi-square or Fisher's exact tests were utilized to compare the groups with regard to genotype frequencies and putative risk factors such as age, gender, ethnicity, smoking, drinking, *H pylori* infection and histological type of adenocarcinoma. To investigate the gene-environment interactions, the odds ratios (OR) and their 95% confidence intervals (95% CI) were calculated, according to a combination of the *XRCC1* and *XRCC3* polymorphisms with putative risk factors. The statistical analyses were performed using Statidisk and GraphPad InStat computer software programs. A probability level (*P*) of less than 0.05 was used as criterion of significance.

RESULTS

Cases and controls did not show any statistically significant difference with regard to age, gender and ethnicity, indicating a well-matched study population. Gastric cancer (GC) patients were more likely to be cigarette smokers or alcohol drinkers than chronic gastritis (CG) patients and controls (C2), and this difference was statistically significant ($P<0.05$), the same occurring with CG patients when compared to controls (C1).

The *XRCC1* and *XRCC3* genotypes and the allele frequency distributions among cases and controls are presented in Table 1. The allele frequencies of polymorphisms 194Trp, 399Gln and 241Met were similar in cases and controls, not showing any statistically significant

differences ($P>0.05$). However, a combined analysis of the *XRCC1* Arg194Trp and Arg399Gln polymorphisms and the *XRCC3* Thr241Met polymorphism (Table 2), and the assessment of the inter- and intra-gene interactions of these three polymorphisms revealed a statistically significant ($P = 0.0372$) association when the three variant alleles interacted in the chronic gastritis group, as compared to the gastric cancer group. Other combinations did not show any significant difference. The banding patterns of *XRCC1* Arg194Trp and Arg399Gln and of *XRCC3* Thr241Met are represented in Figure 1.

Table 3 shows the associations of the different genotypes with the variables gender, smoking, drinking and *H pylori* infection, among the groups. For this analysis, we combined the heterozygous and mutant homozygous genotypes. Allele 194Trp was associated with smoking, with an increased OR for chronic gastritis (4.16, 95%CI = 1.16-16.66), when we compared the CG and C1 groups. The comparison between the CG and GC groups revealed that in men who were smokers and drinkers there was an association with increased OR's for gastric cancer in the individuals with the alleles *XRCC1* 399Gln (3.03,

95%CI = 1.58-5.55; 2.27, 95%CI = 1.22-4.16 and 3.22, 95%CI = 1.75-5.88, respectively) and *XRCC3* 241Met (3.22, 95%CI = 1.66-6.25; 1.88, 95%CI = 1.01-3.57 and 2.63, 95%CI = 1.41-4.76, respectively). Comparing the CG and GC groups further, we found increased OR' s for gastric cancer in the association between *H pylori*-negative subjects and the alleles *XRCC1* 399Gln (0.26, 95%CI = 0.11-0.63) and *XRCC3* 241Met (0.36, 95%CI = 0.15-0.85). An association between smoking and drinking and the polymorphisms 399Gln (2.04, 95%CI = 1.17-3.57 and 2.63, 95%CI = 1.35-5.26, respectively) and 241Met (2.44, 95%CI = 1.42-4.16 and 2.13, 95%CI = 1.10-4.00, respectively) was observed when we compared the CG and C1 groups, with increased OR' s for chronic gastritis. Likewise, when we compared GC and C2, we observed an association between smoking and drinking, with an increased OR for stomach cancer, and alleles 399Gln (3.57, 95%CI = 1.85-6.66 and 5.55, 95%CI = 2.77-10.99) and 241Met (2.70, 95%CI = 1.38-5.26 and 4.34, 95%CI = 2.17-9.09). The other evaluated parameters as age and ethnicity, presented no association with the studied polymorphisms.

DISCUSSION

There is increasing evidence that genetic variation leads to different DNA repair capacities in the human population. So, common polymorphisms can play a role in the individual genetic susceptibility to cancer[43]. Very few studies have investigated the role of polymorphisms of the DNA repair genes *XRCC1* and *XRCC3* in the risk of gastric cancer, and, to our knowledge, so far no study examined both gene polymorphisms in this type of cancer and in chronic gastritis. We conducted the first case-control study to investigate the relationship between the polymorphisms *XRCC1* Arg194Trp and Arg399Gln and *XRCC3* Thr241Met and the risk of chronic gastritis and gastric cancer, in a Southeastern Brazilian population.

Our data showed no association between the *XRCC1* and *XRCC3* polymorphisms and an increased risk for chronic gastritis and gastric cancer. To date, there are three published reports on investigations of the association between *XRCC1* polymorphisms and gastric cancer risk[13,27,31], and only one that examined the influence of an *XRCC3* polymorphism[29], with conflicting results. While Shen *et al.*[13] found the wild-genotype Arg194Arg and the mutant-genotype Arg399Gln in the *XRCC1* gene to be associated with an increased risk of gastric cardia cancer, Ratnasinghe *et al.*[27] observed a significant reduction in the risk of this type of cancer, both in Chinese populations. Similarly, Lee *et al.*[31] did not find any association with the risk of gastric cancer in a Korean population, but suggested that the 194Trp allele might be a protective allele with regard to gastric antral cancer. The only study that investigated the role of the *XRCC3* polymorphism in gastric cancer in a Chinese population found no evidence of an association between this polymorphism and an increased risk of gastric cancer[29].

The differences observed in these reports may be due to the different types of gastric cancer studied (cardia and antrum), which may have a distinct pathogenesis and ethnical differences[31]. In the Brazilian population, most gastric cancers are located in the antral region, as in the Korean population, and are commonly associated with H. pylori infection. We also found that in the gastric cancer group the variant allele frequency of 194Trp was lower (0.06) and those of 399Gln and 241Met were higher (0.33 and 0.31, respectively) than those reported in Asian popula tions[13,27,29,31].

These differences can yet be due to the presence of variants of the common susceptibility polymorphisms, not just a single one, but DNA repair genes or activation and detoxification genes may jointly contribute to the susceptibility of gastric and other cancers. Thus, it is important to include more gene polymorphisms for the same or other DNA repair pathways to verify the gene-gene interactions, as well as the gene-environment interactions that may be important in the etiology of the disease.

When we assessed the association of *XRCC1* Arg194trp and Arg399Gln and *XRCC3* Thr241Met with the risk of chronic gastritis and gastric cancer, we found an increased risk for chronic gastritis when all three variant alleles were present at the same time, supporting the hypothesis of an additive effect of these three polymorphisms. There are no studies on chronic gastritis regarding its association with DNA repair gene polymorphisms, as there are for several metabolizing genes, such as *GSTM1*, *GSTT1* and *CYP2E1*, in Brazilian[44] and Chinese[45] populations. Chronic gastritis, a frequent inflammation of the stomach[46], is considered a premalignant lesion[47]. Gastritis may start after an *H pylori* infection and progress over time from an initially superficial form to more severe forms, including severe atrophic gastritis with intestinal metaplasia[48]. About 10% of patients with gastric atrophy develop gastric cancer within a time period of 15 years[46]. Therefore, a reduced DNA repair capacity due to variant alleles may allow mutations to accumulate in the DNA of the epithelial cells of the stomach, resulting from the inflammatory process caused by *H pylori* or from environmental factors such as dietary habits and lifestyle, increasing the risk of gastric cancer.

Gastric cancer has a complex etiology in which genetic and environmental factors play an important role. In this study, we observed a statistically significant association between variant alleles and demographic and environmental factors such as gender, smoking, drinking and *H pylori* infection.

It is known that *H pylori* infection has a very important role in the development of chronic gastritis and in its development into gastric cancer[48]. Various mechanisms were proposed for *H pylori*-associated carcinogenesis, such as the formation of DNA adducts, the generation of free radicals, and a dysregulation of the gastric epithelial cell cycle[49,50]. So, these factors, associated with a decreased DNA repair capacity, may increase the risk for gastric cancer. Differently from these findings, we found a high frequency of variants 399Gln and 241Met

in *H pylori*-negative gastric cancer patients, as compared to chronic gastritis patients. However, these data must have been influenced by the great number of *H pylori*-negative individuals, as compared to the H. pylori-positive individuals found in the gastric cancer group, probably due to an underestimate of the histological diagnosis in these patients.

In smokers, the presence of *XRCC1* 194Trp was more frequent in chronic gastritis cases, while polymorphisms *XRCC1* 399Gln and *XRCC3* 241Met were more frequent in both the chronic gastritis and the gastric cancer groups, compared with healthy controls. Whether the mechanisms of tobacco carcinogens act in human gastric cancer is currently uncertain. The main carcinogens contained in tobacco smoke include polyaromatic hydrocarbons (PAH), *N*-nitrosamines and aromatic amines. Cigarette smoking increases the number of single-strand breaks and DNA adducts, which, if left unrepaired, can lead to gene mutation[51]. These DNA damages can be repaired by BER, in which the *XRCC1* protein has an important role. Functional studies of *XRCC1* variants observed a significantly elevated level of sister chromatid exchange (SCE) in peripheral blood lymphocytes after *in vitro* exposure to the tobacco-specific NNK in carriers of the 399Gln allele, but the same was not observed for the 194Trp polymorphism[52]. Duell *et al*.[53] reported higher frequencies of SCE for current smokers with the 399Gln polymorphism than for smokers with the Arg/Arg genotype.

Protein *XRCC3* participates in the DSB repair by the homologous repair pathway and the 241Met variant may lead to biological implications for the enzyme's function and/or the interaction with other proteins involved in DNA damage repair. Matullo *et al*.[54] associated the 241Met polymorphism with ^{32}P-DNA adduct levels, indicating a possible role of the *XRCC3* gene in the repair of bulky DNA adducts. Thus, variations in DNA repair capacity caused by polymorphisms of DNA repair genes may modulate the genotoxic effect of tobacco smoking.

Excessive alcohol consumption can also lead to DNA damage through the production of free radical intermediates, such as reactive oxygen species, which are produced during the ethanol metabolism[55]. The frequency of DNA single-strand breaks also increases with chronic exposure to alcohol[56]. We observed an association with alcohol consumption in the patients with chronic gastritis and gastric cancer, and found an increased risk for these diseases when polymorphisms *XRCC1* 399Gln and *XRCC3* 241Met were present.

In conclusion, in the Brazilian population studied, we did not find evidence of a relationship between the polymorphisms *XRCC1* Arg194Trp and Arg399Gln and *XRCC3* Thr241Met and the development of chronic gastritis and gastric cancer. However, intra- and inter-gene interactions may contribute to the development of chronic gastritis, a precursor lesion of stomach cancer. We also verified a gene-environment interaction between the *XRCC1* and *XRCC3* polymorphisms, mainly with the habits of smoking and drinking, in the chronic gastritis and gastric cancer patients. Our study is an important addition to the small number of previously published reports on DNA repair gene variants in gastric cancer and shows the need for further studies in different populations, to elucidate the role of these polymorphisms in carcinogenesis.

ACKNOWLEDGMENTS

We thank Prof. Dr. Antonio José Manzato for assistance with the statistical analysis.

Abstract

AIM: To investigate the relationship between the expression levels of nm23 mRNA, CD44s, and CD44v6, and oncogenesis, development and metastasis of human gastric adenocarcinoma, colorectal adenocarcinoma, intraductal carcinoma of breast, and lung cancer.

METHODS: Using tissue microarray by immu-histochemical (IHC) staining and *in situ* hybri-dization (ISH), we examined the expression levels of nm23 mRNA, CD44s, and CD44v6 in 62 specimens of human gastric adenocarcinoma and 62 specimens of colorectal adenocarcinoma; the expression of CD44s and CD44v6 in 120 specimens of intraductal carcinoma of breast and 20 specimens of normal breast tissue; the expression of nm23 mRNA in 72 specimens of human lung cancer and 23 specimens of normal tissue adjacent to cancer.

RESULTS: The expression of nm23 mRNA in the tissues of gastric and colorectal adenocarcinoma was not significantly different from that in the normal tissues adjacent to cancer ($P>0.05$), and was not associated with the invasion of tumor and the pathology grade of adenocarcinoma ($P>0.05$). However, the expression of nm23 mRNA was correlated negatively to the lymph node metastasis of gastric and colorectal adenocarcinoma ($r = -0.49$, $P<0.01$; $r = -4.93$, $P<0.01$). The expression of CD44s in the tissues of gastric and colorectal adenocarcinoma was significantly different from that in the normal tissues adjacent to cancer ($P<0.05$; $P<0.01$). CD44v6 was expressed in the tissues of gastric and colorectal adenocarcinoma only, the expression of CD44v6 was significantly associated with the lymph node metastasis, invasion and pathological grade of the tumor ($r = 0.47$, $P<0.01$; $r = 5.04$, $P<0.01$). CD44s and CD44v6 were expressed in intraductal carcinoma of breast, the expression of CD44s and CD44v6 was significantly associated with lymph node metastases and invasion ($P<0.01$). However, neither of them was expressed in the normal breast tissue. In addition, the expression of CD44v6 was closely related to the degree of cell differentiation of intraductal carcinoma of breast ($\chi^2 = 5.68$, $P<0.05$). The expressional level of nm23 mRNA was closely related to the degree of cell differentiation ($P<0.05$) and lymph node metastasis ($P<0.01$), but the expression of nm23 gene was not related to sex, age, and type of histological classification ($P>0.05$).

CONCLUSION: Patients with overexpression of CD44s and CD44v6 and low expression of nm23 mRNA have a higher lymph node metastatic rate and invasion. In addition, overexpression of CD44v6 is closely related to the degree of cell differentiation. Detection of the three genes is able to provide a reliable index to evaluate the invasion and metastasis of tumor cells.

INTRODUCTION

Tissue microarray (TMA) technology is a new method used to analyze hundreds of tumor samples on a single slide, allowing high resolution analysis of genes and proteins on a large cohort. TMA is ideally suitable for genomics-based diagnosis and drug target locating. Oncogenesis, development and metastasis of tumor are triggered by many genes and factors. In recent years, research on the molecular mechanism of oncogenesis and metastasis and the diagnosis of the correlated mark of tumor are

important objects in clinical research in oncology. CD44 is one of the transmembrane proteins on the surface of cells. Its distribution is very extensive and can be detected in lymphocytes and fibroblasts[1]. The expression of CD44v, which is related to the progression, metastasis and prognosis of tumor, has been detected in lung cancer, carcinoma of colon, esophageal cancer, carcinoma of breast, carcinoma of urinary bladder, liver cancer, cervix cancer, carcinoma of kidney and reticulosarcoma[2-5]. Nm23 was first found by Steeg in 1988. Lower expression of nm23 is related to the metastasis of tumors, such as carcinoma of breast, lung cancer, gastric carcinoma, malignant melanoma, and ovary cancer, and has been regarded as the gene of transfer inhibition. In order to investigate the relationship between the expression level of nm23 mRNA, CD44s and CD44v6 and the oncogenesis, pathological grade, invasion, and metastasis of tumor, we detected the expression of nm23 mRNA, CD44s, and CD44v6 in tissues of human gastric adenocarcinoma, colorectal adenocarcinoma, intraductal carcinoma of breast and lung cancer, and also in tissues adjacent to cancer using tissue microarray by immunohistochemical (IHC) staining and *in situ* hybridization (ISH).

MATERIALS AND METHODS

Tissue specimens

The following tissue specimens were enrolled in this study: 40 specimens of colorectal adenocarcinoma (including 16 specimens of moderately differentiated colorectal adenocarcinoma, 24 poorly differentiated adenocarcinoma, 14 lymph node metastatic carcinoma, and 17 invasive carcinoma) and 22 specimens of normal colorectal tissue, 40 specimens of gastric adenocarcinoma (including 20 specimens of moderately differentiated gastric adenocarcinoma, 20 poorly differentiated adenocarcinoma, 15 lymph node metastatic carcinoma, and 23 invasive carcinoma) and 22 specimens of normal gastric tissue, 120 specimens of intraductal carcinoma of breast (including 86 specimens of moderately differentiated intraductal carcinoma, 34 poorly differentiated intraductal carcinoma, 30 lymph node metastatic carcinoma and 58 invasive carcinoma) and 20 specimens of normal breast tissue, 72 specimens of lung cancer (including 13 specimens of moderately differentiated carcinoma, 19 poorly differentiated carcinoma, 24 lymph node metastatic carcinoma) and 23 specimens of normal lung tissue. All patients underwent surgery at Xijing Hospital of the Fourth Military University, China in 2003. The resected specimens were fixed in 10% formaldehyde.

Reagents

CD44s and CD44v6 monoclonal antibodies were obtained from MBI. SABC kit was bought from Sina-America Biotechnology Company. nm23 oligonucleotide probe and CSA test kit were purchased from Boshide Biotechnology Company. Biotin labeled anti-digitoxin (DIG) antibody was obtained from Sigma.

Tissue microarray

Samples were fixed in buffered formaldehyde and subsequently paraffin-embedded. Histological sections (5 μm) were prepared from the specimens, and then diagnosed and labeled by the pathologist. Tissue microarray was performed on the instrument of microarray from Beecher, USA. A hole (diameter 0.5 mm) was made on the recipient block (blank paraffin block), then the tissue core was taken on the supply block (labeled tissue block) and put in the hole. The former procedure was repeated and tissue microarray was completed. Histological sections (3-5 μm) were prepared with the instrument of Leica, Germany, and then rediagnosed by the pathologist.

Immunohistochemical analysis

The sections for tissue microarray were dewaxed in water by normal technique, and then the antigen was restored in high pressure (at 121 °C for 10 min). Immunohistochemistry was performed with the SABC kit. The primary antibodies were CD44s and CD44v6 monoclonal antibodies. Staining was performed following the instructions of SABC kit.

Detection of nm23 mRNA expression by in situ hybridization

All reagents and containers were treated by diethylprocarbonate (DEPC). In brief, the sections for tissue microarray were dewaxed in water by normal technique, immersed into 3% H_2O_2 at room temperature for 10 min, and then washed twice with distilled water. Twenty microgram per milliliter of freshly diluted protease K was added and digested for 20 min at 37 °C to expose mRNA nucleic acid segments. Twenty milliliter of glycerine (20%) was added to the dry bottom of the test kits to keep humidity, 20 μL of the pre-hybridization solution was added to each section and kept at 37 °C for 4 h. Then the supernumerary liquid was absorbed without washing, hybridization solution was added as mentioned above. The sections were then covered with protective membrane and put in homeothermia at 40 °C overnight. After the coverglass was removed, the sections were washed twice at 37 °C in 2×SSC for 5 min, once in 0.5×SSC for 15 min, once in 0.2×SSC for 15 min, and kept in 3% BSA at 37 °C for 30 min and in seal solution at 37 °C for 30 min. After being washed with 0.5 mol/L PBS, the biotin labeled anti-digitoxin antibody was added for 60 min at 37 °C, followed by biotin-peroxidase for 20 min at 37 °C and then washed with PBS. Color was showed by DAB. Finally, the sections were restained, dehydrated, pellucidated, and sealed. Negative controls were designed.

Assessment of immunohistochemical staining and in situ hybridization

Specimens were considered positive when >50% of the tissue components were immunohistochemically stained brown-yellow in appropriate cellular compartment. Specimens were considered positive for ISH when >50% of the tissue components were stained blue in appropriate cellular compartment.

Statistical analysis

Statistical analysis was performed with χ^2 test. $P<0.05$ was considered statistically significant.

RESULTS

Relationship between expression of CD44s, CD44v6, nm23 mRNA, and clinical pathology of human colorectal adenocarcinoma

The expression of CD44s in tissues of colorectal adenocarcinoma and normal colorectal mucosa was 42.0% (17/40) and 13.6% (3/22), respectively (Figures 1A and B), and there was a significant difference between them ($\chi^2 = 5.18$, $P<0.05$). In addition, there was a statistical significance between colorectal adenocarcinoma of with and without invasion ($\chi^2 = 10.52$, $P<0.01$), as well as with and without lymph node metastasis ($\chi^2 = 12.48$, $P<0.01$). However, there was no statistical significance between moderately and poorly differentiated colorectal adenocarcinoma ($P>0.05$), indicating that the expression of CD44s was related to the oncogenesis and development of colorectal adenocarcinoma. The expression of CD44v6 in tissues of colorectal adenocarcinoma and normal colorectal mucosa was 55.8% (22/40) and 0% (0/22), respectively (Figure 1C). There was a statistical significance between moderately and poorly differentiated colorectal adenocarcinoma ($P<0.05$) with and without invasion ($P<0.05$), as well as with and without lymph node metastasis ($\chi^2 = 9.22$, $P<0.01$). The results showed that the expression of CD44v6 was related not only to the invasion of colorectal carcinoma, but also to the metastasis. The expression of nm23 mRNA in tissues of colorectal adenocarcinoma and normal colorectal mucosa was 45.0% (18/40) and 40.9% (9/22), respectively (Figure 1D), and there was no statistically significant difference ($P>0.05$). However, the expression of nm23 mRNA in gastric adenocarcinoma with/without lymph node metastasis was 28.5% (4/14) and 53.8% (14/26), respectively. The difference was statistically significant ($\chi^2 = 8.47$, $P<0.05$). In addition, the expression of CD44v6 in colorectal adenocarcinoma was related to the invasion ($P<0.05$), but not to the pathological grade ($P>0.05$, Table 1).

Relationship between expression of CD44s, CD44v6, and nm23 mRNA in human colorectal adenocarcinoma

Expression of CD44s and CD44v6 was associated with invasion and lymph node metastasis of colorectal adenocarcinoma ($r = 0.47$, $P<0.05$). However, expression of nm23 mRNA was not associated with invasion and lymph node metastasis of colorectal adenocarcinoma ($r = -0.49$, $P<0.05$), suggesting that CD44s, CD44v6 and nm23 mRNA could regulate invasion and lymph node metastasis of colorectal adenocarcinoma. In addition, the expression level of nm23 mRNA, CD44s and CD44v6 was not associated with the age and sex of patients ($P>0.05$, Table 1).

Relationship between expression of CD44s, CD44v6, nm23 mRNA, and clinical pathology of human gastric adenocarcinoma

The expression of CD44s in tissues of gastric adenocarcinoma and normal gastric mucosa was 48% (19/40) and 13.6% (3/22), respectively (Figures 2A and B), and there was a significant difference between them ($\chi^2 = 10.29$, $P<0.01$). However, the expression of CD44s was not significantly associated with lymph node metastasis. There was no statistical significance between moderately and poorly differentiated gastric

[a]$P<0.05$ *vs* poorly differentiated colorectal adenocarcinoma; [c]$P<0.05$, [b]$P<0.01$ *vs* without invasion; [e]$P<0.05$, [d]$P<0.01$ *vs* without metastasis.

adenocarcinoma with/without invasion (P>0.05). The expression of CD44v6 in tissues of gastric adenocarcinoma and normal gastric mucosa was 63.3% (25/40) and 0% (0/22), respectively (Figure 2C). There was a statistical significance between moderately and poorly differentiated gastric adenocarcinoma (χ^2 = 9.19, P<0.01) with and without invasion (χ^2 = 22.22, P<0.01), as well as with and without lymph node metastasis (χ^2 = 10.36, P<0.01). The expression of nm23 mRNA in tissues of gastric adenocarcinoma and normal gastric mucosa was 47% (19/40) and 43% (9/22), respectively (Figure 2D) and there was no statistically significant difference between them (P>0.05). However, the expression of nm23 mRNA in gastric adenocarcinoma with/without lymph node metastasis was 26.7% (4/15) and 60% (15/25) respectively, the difference was significant (χ^2 = 18.47, P<0.01, Table 2).

Relationship between expression of CD44v6 and nm23mRNA in human gastric adenocarcinoma

The expression of CD44v6 was associated with lymph node metastasis of gastric adenocarcinoma (r = 5.04). However, the expression of nm23 mRNA was not associated with lymph node metastasis of gastric adenocarcinoma (r = -4.93, Table 2).

Relationship between the expression of CD44s, CD44v6, and clinical pathology of human intraductal carcinoma of breast

The expression of CD44s and CD44v6 in tissues of intraductal carcinoma of breast was 45.8% (55/120) and 53.3% (64/120), respectively (Figures 3A and B), but neither of them was expressed in normal breast tissue. The expression of CD44s and CD44v6 in intraductal breast carcinoma with and without invasion had a significant statistical difference (χ^2 = 9.52, P<0.01; χ^2 = 22.89, P<0.001), as well as with and without lymph node metastasis (χ^2 = 9.41, P<0.01; χ^2 = 8.75, P<0.01). Furthermore, the expression of CD44s was not significantly associated with moderately and poorly differentiated intraductal breast carcinoma (P>0.05). However, the expression of CD44v6 was not only related to invasion and lymph node metastasis of intraductal breast carcinoma, but also related to its pathological grade (χ^2 = 5.68, P<0.05, Table 3).

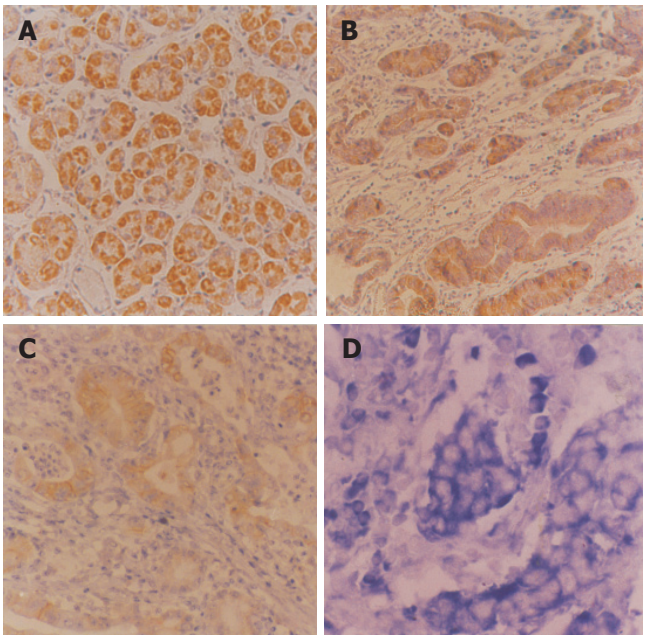

Figure 2 Expression of CD44s in human normal gastric tissue (**A, B**) and expression CD44v6 (**C**) and nm23 mRNA (**D**) in human gastric adenocarcinoma

Relationship between expression of nm23 mRNA and clinical pathology of human lung cancer

The expression of nm23 mRNA in tissues of lung cancer and normal lung tissues was 55.2% (40/72) and 82.6% (19/23), respectively (Figure 4), and there was a significant difference between them (χ^2 = 5.42, P<0.05). The expression of nm23 mRNA in tissues of lung cancer with and without lymph node metastasis was 25.0% (6/24) and 70.8% (34/48), respectively and there was a significant difference between them (χ^2 = 13.61, P<0.001), as well as between moderately and poorly differentiated lung cancer (χ^2 = 9.61, P<0.01), indicating that the expression of nm23 mRNA was associated with the oncogenesis, lymph node metastasis and pathological grade of lung cancer. In addition, the expression of nm23 mRNA in lung cancer was not associated with the age and sex of patients and the pathologic feature of lung cancer (P>0.05, Table 4).

DISCUSSION

CD44s, a hyaluronic acid receptor, is important in regulating invasion and metastasis of tumor[3-7]. Previous studies demonstrated that the expression of CD44s is an important biological marker for predicting metastatic potential. Invasion and metastasis of tumor are a very complicated process, which is regulated by many correlated genes. CD44v6 may take part in the invasion and meta-

stasis of tumor, but it is not the necessary factor for tumor invasion and metastasis. When CD44v6 produces a marked effect, it must be restricted by many factors in vivo. It has been proved that CD44v6 is correlated to tumor invasion and metastasis in experiments of cultured cells and animals. But consistent view has not been reached so far with respect to the relationship between expression of CD44v6 and human tumor invasion and metastasis.

It was reported that CD44v mRNA is expressed in human colorectal carcinoma as detected by RT-PCR[8-10]. Zalewski *et al*.[11] reported that the expression of CD44 is associated with the size of tumor, age, and sex of patients. In our current study, CD44 and CD44v6 were expressed in colorectal carcinoma and normal colorectal tissues respectively, indicating that the expression of CD44 and CD44v6 is associated with the invasion and metastasis of colorectal carcinoma, but not associated with the age and sex of colorectal carcinoma patients. In addition, the expression of CD44v6 was related to the pathological grade of tumor. Other studies reported that the expression of CD44 is not associated with the clinical pathological feature of colorectal carcinoma[12,13]. Whether the expression level of CD44 can be seen as a marker of tumor histopathology requires further research.

Using reverse transcription polymerase chain reaction followed by Southern blotting, Yamamichi *et al*.[14] examined the expression of the standard and variant forms (v6 and v9) of CD44 mRNA in 73 cases of gastric cancer, and found that the expression status of the standard form of CD44 mRNA is correlated with peritoneal dissemination only, and that of CD44v9 mRNA does not significantly correlate with any clinicopathologic factor. Li *et al*.[15] reported that 74% gastric cancers and 80% invasive carcinomas are positive for CD44v6, implying that CD44v6 is also a useful marker of tumor invasion and metastasis. In the present study, the expression of CD44v6 was significantly correlated with tumor differentiation, lymph node metastasis and invasion of tumor. The expression of CD44s and CD44v6 in gastric cancer was much higher than that in normal stomach and was associated with genesis, metastasis and clinically aggressive behavior of gastric adenocarcinoma.

The aberrant activation of two or more genes plays a different role during different stages of genesis, progression and metastasis of malignant tumor. These genes synergically facilitate carcinoma change. Our studies showed that the expression of nm23 mRNA in colorectal adenocarcinoma was negatively correlated with that of

CD44 and CD44v6, which was closely associated with the invasion and metastasis of colorectal adenocarcinoma. These results indicate that nm23 and CD44v6 synergically play positive and negative roles during lymph node metastasis of colorectal, and gastric adenocarcinoma. Further studies are needed to investigate the relationship between nm23 and CD44v6, which is important for tumor metastasis.

Mammary cancer is one of the most common malignant tumors. Although 50% of mammary cancers are surgically curable, 50% patients have metastasis within 5 years after surgery. Kaufmann *et al*.[16] reported that the positive expression rate of CD44v6 is 80% in primary tumor and 100% in focal tumor, but no expression is found in normal mammary tissue. The patients with positive expression of CD44v6 have a poor prognosis. There are still many correlative reports[17–20]. Our results showed that the expression of CD44s and CD44v6 in intraductal carcinoma was related with tumor invasion and metastasis, but not with the age and sex of patients.

Since the gene of nm23 was found, lower expression of nm23 has been found to be associated with high metastatic potential and poor prognosis of human mammary cancer, gastric cancer, lung cancer, melanoma, and ovary cancer. Nm23H1 is more important than nm23H2. Gazzeri *et al*.[21] reported that the expression of nm23H1 is not associated with clinicopathological features of adenocarcinoma, while it is associated with the development of squamous carcinoma. Lai *et al*.[22] reported that the expression of nm23H1 is positively correlated with tumor metastasis and prognosis. The lower the nm23H1 expression is, the poorer the prognosis is. Our studies showed that the expression of nm23 mRNA was correlated with lymph node metastasis (r = -4.93). The expression of nm23 mRNA was gradually reduced in normal lung tissue adjacent to cancer. In conclusion, nm23H1 may take part in the regulation of metastasis as a prohibitive gene, and may become a valuable target in the evaluation of tumor development and prognosis.

Abstract

AIM: To investigate the clinical significance of KL-6 as a tumor marker of HCC in two different ethnic groups with chronic liver disease consecutively encountered at outpatient clinics.

METHODS: Serum KL-6 was measured by the sandwich enzyme immunoassay method using the KL-6 antibody (Ab) as both the capture and tracer Ab according to the manufacturer's instructions (Eisai, Tokyo, Japan). Assessment of alpha fetoprotein (AFP) and protein induced vitamin K deficiency or absence (PIVKA-II) was performed in both groups using commercially available kits.

RESULTS: A significantly higher mean serum KL-6 (556±467 U/L) was found in HCC in comparison with non-HCC groups either with (391±176 U/L; P<0.001) or without (361±161 U/L; P<0.001) liver cirrhosis (LC). Serum KL-6 level did not correlate with either AFP or PIVKA-II serU/Levels. Using receiver operating curve analysis for KL-6 as a predictor for HCC showed that the area under the curve was 0.574 (95%CI = 0.50-0.64) and the KL-6 level that gave the best sensitivity (61%) was found to be 334 U/L but according to the manufacturer's instructions; a cut-off point of 500 U/L was used that showed the highest specificity (80%) in comparison with AFP and PIVKA-II (78% *vs* 72% respectively). Combining the values of the three markers improved specificity of AFP for HCC diagnosis from 78% for AFP alone; 93% for AFP plus PIVKA-II to 99% for both plus KL-6 value (P<0.001). Mean serum alkaline phosphatase level was significantly higher in KL-6 positive (564±475) in comparison with KL-6 negative (505±469) HCC patients (P = 0.021), but such a difference was not found among non-HCC corresponding groups.

CONCLUSION: KL-6 is suggested as a tumor for HCC. Its positivity may reflect HCC-associated cholestasis and/or local tumor invasion.

Key words: Tumor markers; Liver disease; Hepatocellular carcinoma

INTRODUCTION

Hepatocellular carcinoma (HCC) is the 4th most common cancer worldwide, and it is a well-known complication of chronic hepatitis[1,2]. Asymptomatic patients diagnosed as HCC through screening programs are more likely to be candidates for curative treatment and have improved short- and medium-term survival[3,4]. Although serum alpha-fetoprotein (AFP) had been shown to be associated with HCC since 1963[5], unfortunately it is also elevated in a wide variety of non-hepatic malignancies[6,7] and benign hepatic conditions[8,9]. Moreover, it is uncertain whether serum AFP is a useful marker for HCV-related HCC in some ethnic groups e.g., North American patients of African origin[10]. Thus, searching another tumor marker, that together with AFP could improve the diagnostic utility of the later, seemed to be justified. KL-6 was originally found using a murine monoclonal antibody that recognized an undefined sialylated carbohydrate chain on a mucin-like glycoprotein[11] which was also defined as MUC1[12]. The cell membrane MUC1 was found to regulate cell adhesion properties[13]. KL-6 has been first shown to be

elevated in patients with interstitial pneumonia[14]. It was also reported to have a high positive rate in different non-hepatic malignancies and its expression was also correlated with metastatic potential of the primary tumor in some of them[15-17]. It has also been studied as a fibrosis marker in patients with HCV-related chronic liver disease[18] and was found to correlate with the degree of irregular regeneration of hepatocytes[19]. A recent study addressed its clinical significance as a tumor marker in HCV-related HCC[20]. However, all these studies investigated KL-6 in HCV-related disease only so that its actual significance as a marker for screening HCC in patients with different chronic liver disease is not yet fully understood. In this study, we aimed to investigate KL-6 as a tumor marker in consecutive patients with chronic liver disease seen at outpatient settings in two different ethnic groups of possible different risk factors for HCC, so that we could get a wider spectrum of disease in order to assess KL-6 validity for HCC screening.

MATERIALS AND METHODS

Study population

We conducted a cross-sectional study between October 2001 and November 2002. Data were gathered from two Affiliations; Shinshu University (Japan) and Suez Canal University (Egypt) Hospitals. A total of 334 consecutive patients with chronic liver disease seen at outpatient liver clinics in the two settings (who met our inclusion/exclusion criteria) were included; of them: 110 patients were diagnosed as HCC with a mean age of 61±11 years and M:F (4:1). Sixty-five were Egyptians and 45 Japanese with viral-related liver disease accounting for 94% and 98% of them respectively. Non-HCC patients were 234 with a mean age of 56±13 years; M:F (7/3). One hundred and six were Egyptians and 128 Japanese with viral-related liver disease accounting for 91% and 84% of them respectively (Table 1).

Chronic liver disease and cirrhosis were identified and diagnosed according to liver biopsy findings, clinical and/or radiological evidence of portal hypertension. HCC was excluded by imaging studies (abdominal ultrasound (US), computed tomography (CT), magnetic resonance imaging (MRI) and/or hepatic angiography), one of which must have been performed at least 6 months following the measurement of AFP.

HCC was diagnosed when meeting our inclusion criteria of positive cytology and/or histology or by the presence of characteristic hepatic masses on liver CT, MRI and/or hepatic angiography (i.e., enlarging tumors and/or tumors with typical arterial vascularization).

We excluded patients with alcoholic and schistosomal liver diseases from our study populations. We had also excluded patients known from their medical history to have interstitial lung fibrosis or any other lung disease from our study population.

Tumor markers measurement

Serum KL-6 was measured by the sandwich enzyme immunoassay method using the KL-6 antibody (Ab) as both the capture and tracer Ab (14) according to the manufacturer's instructions (Eisai, Tokyo, Japan). KL-6 cut-off point was set at 500 U/L for this study. Assessment of alpha fetoprotein (AFP) and protein-induced vitamin K deficiency or absence (PIVKA-II) was performed using commercially available kits. Cut-off points were set at 10 ng/mL for AFP and 40 mAU/L for PIVKA-II.

Statistical analysis

Univariate statistical analysis was performed using Student's *t*-test for quantitative and χ^2 test with Yates' correction for qualitative data. Fisher's exact test was used

for comparison of small numbers; statistical significant level was set at $P<0.05$. Statistical analysis was performed using a computer software (SPSS, version 6.0).

RESULTS

Population background

A difference in mean age, prevalence of advanced Child class and HBV infection was observed between Egyptian and Japanese patients with HCC (Table 1). However, no difference in tumor characteristics was found between the two studied populations (Table 2).

KL-6 and other tumor markers in HCC

A significantly higher mean serum KL-6 (556±467) was found in HCC in comparison with non-HCC groups of patients with (391±176; $P<0.001$) and without (361±161; $P<0.001$) liver cirrhosis (LC). Serum KL-6 level did not correlate with either AFP (Figure 1) or PIVKA-II (Figure 1) serU/Levels. Using receiver operation characteristic (ROC) curve, the KL-6 level that gave the best sensitivity (61%) was found to be 334 U/L with a specificity of 50%, while PIVKA-II and AFP showed a sensitivity/specificity of (60/72)% and (80/78)% respectively. However, according to the manufacturer's instructions; a cut-off point of 500 U/L was used in this study that showed the highest specificity (80%) for KL-6 in comparison with the other two markers. Combining the values of KL-6; AFP and PIVKA-II resulted in improvement in the specificity of AFP for HCC diagnosis from 78% for AFP alone; 93% for AFP plus PIVKA-II to 99% for both plus KL-6 ($P<0.001$) (Table 3).

Table 2 Comparison of background tumor characteristics between Egyptian and Japanese HCC patients

Tumor characteristic	Egyptian (n = 65)	Japanese (n = 45)	P
Tumor multiplicity			
Solitary	25 (38)	22 (49)	>0.2
Multiple	40 (62)	23 (51)	0.06
Tumor size			
<3 cm	32 (49)	20 (44)	>0.2
3:< 5cm	15 (23)	14 (31)	>0.2
⩾5 cm	18 (28)	11 (25)	0.13
Metastases	01 (2)	>0.2	
Tumor grade[1]			
Well differentiated	5 (16)	2 (8)	>0.2
Poorly differentiated	5 (16)	4 (16)	>0.2

[1]Tumor grade is analyzed in 32 of the Egyptian and 22 of the Japanese groups who passed HCC resection operation during the study period.

Factors associated with positive KL-6 in the study population

Univariate analysis (Table 4) of possible factors that could be associated with elevated serum KL-6 in our study group showed that elevated AFP ($P<0.001$), Child's class C ($P = 0.002$), Egyptian race ($P = 0.003$) and HCC ($P = 0.008$) were significantly associated with positive serum KL-6. Also mean serum alkaline phosphatase level was significantly higher in KL-6 positive (564±475) in comparison with KL-6 negative (505±469) HCC patients ($P = 0.021$), but such a difference was not found among non-HCC corresponding group (Table 5). Mean serum bilirubin was found to be higher in KL-6 positive subgroups in both HCC and non-HCC ($P = 0.077$, 0.023) respectively, while mean serum albumin was significantly lower in both groups ($P = 0.029$, 0.041), respectively (Table 5).

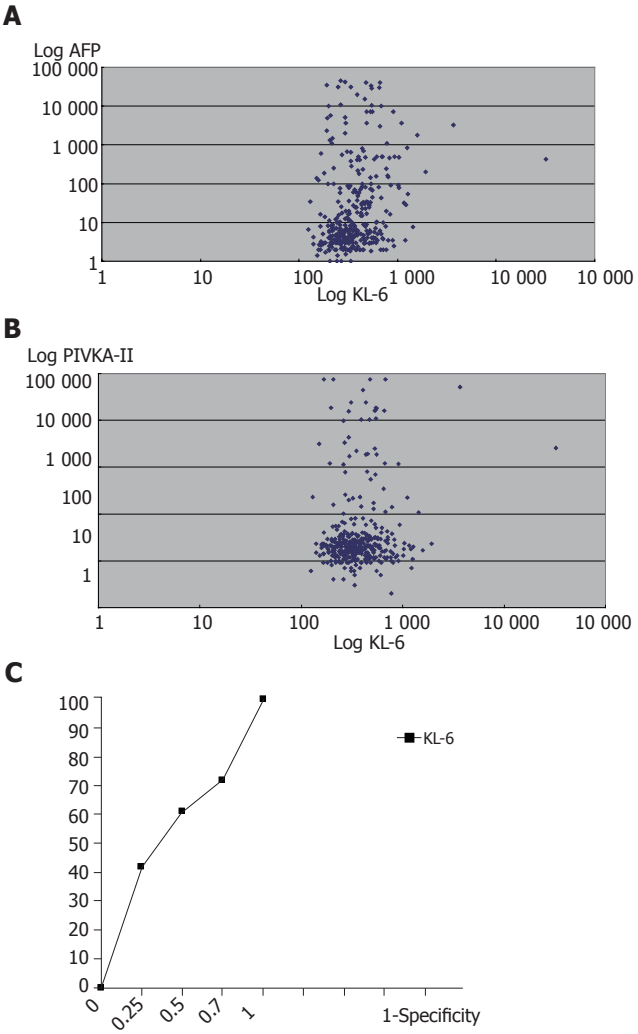

Figure 1 A: Correlation between KL-6 U/L and AFP ng/ml serU/Levels in the study population. $C = 0.04$, $P>0.1$. The Log values of both markers are shown; **B:** Correlation between KL-6 U/L and PIVKA-II mAU/L serU/Levels in the study population. $C = 0.03$, $P>0.5$. The Log values of both markers are shown; **C:** Receiver operating characteristic curves for KL-6 as predictors of HCC. The area under the ROC was found to be 0.574 (95%CI = 0.50–0.64). The best KL-6 sensitivity was obtained at a cut-off point = 334 U/L.

KL-6 in Egyptian vs Japanese

Mean KL-6 was significantly higher in Egyptians (576±522) in comparison with Japanese (510±300) HCC

Table 3 Comparison of the result of different tumor markers between HCC and non-HCC group

Tumor marker (cut-off point)	Sensitivity %	Specificity %
AFP (10 ng/mL)	86	78
PIVKA-II (35 mAU/L)	61	72
KL-6 (500 U/L)	34	80
AFP+PIVKA-II	86[1]	93
AFP+KL-6	87[2]	94
AFP+PIVKA-II+KL-6	87	99

[1]All PIVKA-II (+) HCC patients are AFP (+). [2]One KL-6 (+) HCC patient is AFP (–).

patients ($P = 0.041$) (Table 6). Although a significant difference in mean KL-6 level between HCC and non-HCC was observed in both Egyptian and Japanese patients with chronic liver disease ($P<0.001$ respectively), the difference was not statistically significant among Japanese patients with HCV-related disease (Table 6). No difference in mean KL-6 level was found between cirrhotic and non-cirrhotic in either HCC or non-HCC patients.

KL-6 and tumor characteristics

In the HCC groups of both Egyptian and Japanese patients; KL-6 showed no significant association with tumor site, echogenicity or multiplicity. However, a significantly lower mean KL-6 (Table 7) was noticed in larger size tumors of >5 cm (371±168 U/L) in comparison with tumors of less than or equal to 5 cm (537±323) ($P<0.05$ in the Japanese group).

DISCUSSION

KL-6 was studied as a tumor marker in different malignancies like breast, lung and pancreatic cancer and it was reported to be elevated in up to 50% of these malignancies[14]. Two previous studies by Moriyama *et al*.[19, 20] addressed KL-6 as a tumor marker for HCC in patients with HCV-related chronic liver disease, and his results showed that the estimated cumulative incidence of HCC development in HCV-related chronic liver disease patients was significantly greater in patients with positive KL-6[19] and suggested KL-6 to be used as a serological marker for HCC development in HCV-positive patients[20]. In our study, we included consecutive patients with chronic liver disease seen at outpatient settings in two different ethnic groups of possible different risk factors for HCC[22, 23] in order to have a wider spectrum of disease to judge KL-6 validity as a diagnostic test for HCC; however, one limitation was that most of the encountered patients in the two settings were actually with HCV-related disease with low proportion of HBV and non-viral-related disease. Our results showed a significantly higher mean KL-6 in HCC compared with non-HCC; either with or without LC; in addition no difference in mean KL-6 was found among HCC patients with and without LC; such findings together point to KL-6 association with HCC independent on the presence or absence of LC. A significantly higher mean KL-6 level was found in HBV-related in comparison with HCV-related HCC in both Egyptian and Japanese populations; a finding that deserves future study on a larger population of HBV-related disease. Our results also showed a significantly higher mean KL-6 level in HCC patients of Egyptian compared with Japanese race. The finding of a difference in the clinical background between both in terms of lower mean age and lower prevalence of HBV-related HCC could reflect a difference in the risk factors for HCC in both groups. Also, a higher prevalence of advanced Child class in the HCC Egyptian patients was observed that could stand behind the finding of higher mean KL-6 level in this group compared to their corresponding Japanese group. Although we excluded patients with overt schistosomal from this study, still some Egyptian patients had a past history of schistosomiasis with US evidence of hepatic periportal fibrosis (denoting a background of schistosomal liver disease) that could also explain the finding of higher mean KL-6 level in Egyptian HCC patients, if we consider the possibility that KL-6 could be a fibrosis marker too[21]. This topic is highly suggested for future study.

<3 cm	485±227		618±361	
3:<5 cm	643±685	>0.1	456±285	0.17
⩾5 cm	581±420	>0.1	371±168	0.04

[1]*P* value is shown for the difference group (<3 cm) and the other two groups.

We used a cut-off point of 500 U/L for KL-6 positivity in this study; however, applying the ROC analysis showed that a cut-off point of 334 U/L would give the best sensitivity in our study population of 60% compared with only 32% for a cut-off (500 U/L); however, the best specificity was obtained using the later. Moriyama *et al*. used a cut-off point of 300 U/L in his analysis of KL-6 in HCV-related disease[19,20]. KL-6 serU/Level did not correlate with either serum AFP or PIVKA-II levels, which points to its behavior independently from either of them and this may justify its clinical significance as an independent tumor marker for HCC diagnosis when considered with both AFP and PIVKA-II. Our results also supported this finding as AFP specificity for HCC diagnosis improved from 78% for AFP alone and 93% of both AFP and PIVKA-II to 99% when combined with KL-6. Univariate analysis showed that low serum albumin, hyperbilirubinemia and elevated ALP were significantly associated with positive KL-6 in HCC patients, while KL-6 showed no association with LC in turn, and this denotes a possible association between positive KL-6 and deterioration of hepatic condition in HCC patients independent from their cirrhotic status; a finding that might point to KL-6 as a predictor of tumor aggression and/or local or systemic metastasizing potential. A follow-up study is needed to confirm its exact role in this regard.

Abstract

AIM: To elucidate the molecular mechanisms of the inhibitory effects of IFN-α on tumor growth and metastasis in MHCC97 xenografts.

METHODS: Three thousand international units per milliliter of IFN-α-treated and -untreated MHCC97 cells were enrolled for gene expression analysis using cDNA microarray. The mRNA levels of several differentially expressed genes in cDNA microarray were further identified by Northern blot and RT-PCR.

RESULTS: A total of 190 differentially expressed genes including 151 IFN-α-repressed and 39 -stimulated genes or expressed sequence tags from 8 464 known human genes were found to be regulated by IFN-α in MHCC97. With a few exceptions, mRNA levels of the selected genes in RT-PCR and Northern blot were in good agreement with those in cDNA microarray.

CONCLUSION: IFN-α might exert its complicated anti-tumor effects on MHCC97 xenografts by regulating the expression of functional genes involved in cell metabolism, proliferation, morphogenesis, angiogenesis, and signaling.

Key words: Interferon α; cDNA microarray; Gene expression profile; HCC

INTRODUCTION

Human hepatocellular carcinoma (HCC) is one of the most prevalent malignancies in China. Patients with HCC often die of tumor metastasis and recurrence even after curative resection. Recently, a metastatic human HCC model in nude mice (LCI-D20) and a series of HCC cell lines (MHCC97, MHCC97-H, MHCC97-L) with different metastatic potentials derived from LCI-D20 have been established in our institute[1,2]. Using this model, IFN-α significantly inhibits tumor growth and metastasis of MHCC97 xenografts has been found[3-5]. However, the underlying molecular mechanisms are still unclear.

IFN-α is a multifunctional cytokine capable of interfering with viral infection, inhibiting cell proliferation, regulating cell differentiation, as well as modulating immune response[6-9]. It is well known that these pleiotropic effects of IFN-α are mediated primarily through the transcriptional regulation of many different functional genes. Thanks to the rapid progress in human genetic projects; many functional human genes and expressed sequence tags (ESTs) are identified and released, which make us possible to use cDNA microarray to survey IFN-α-modulated genes in MHCC97 cells. In this study, we identified 190 differentially expressed genes from 8 464 known human genes, which might mediate various biological functions of IFN-α. These data provide us useful clues for further studying the anti-tumor mechanisms of IFN-α and finding the IFN-α mimics for HCC therapy.

MATERIALS AND METHODS

Cell culture

MHCC97, a metastatic HCC cell line derived from LCI-D20 xenografts, was cultured in high glucose Dulbecco's modified Eagle's medium (Gibco-BRL, NY, USA) supplemented with 10% fetal calf serum (Hyclone, UT, USA), 100 U/mL penicillin and 100 μg/mL streptomycin in 20-cm^2 tissue culture flasks. Cells were grown at 37 °C in a humidified atmosphere of 50 mL/L CO_2 and passaged every 3 d.

cDNA microarray analysis

A total of 8 464 cDNAs of known human genes (United Gene Holding, Ltd, Shanghai) were amplified by polymerase chain reaction (PCR) using universal primers and spotted onto silylated slides (CEL Associates,

Houston, TX, USA) using a Cartesian PixSys 7500 motion control robot (Cartesian Tech, Irvine, CA, USA) fitted with ChipMaker micro-spotting technology (TeleChem, Sunnyvale, CA, USA). After being hydrated, dried, cross linked and washed, the microarray was ready for use. Total RNA was isolated from IFN-α-treated and untreated (3 000 IU/mL, 16 h) cells using TRIzol (Gibco-BRL). cDNA probes were prepared by reverse transcription and purified according to the methods described by Schena *et al*.[10]. Then equal amount of cDNA from IFN-α-untreated and treated MHCC97 cells was labeled with Cy3-dUTP and Cy5-dUTP, respectively. The mixed Cy3/Cy5 probes were purified and dissolved in 20 μL of hybridization solution (0.75 mol/L NaCl, 0.075 mol/L sodium citrate, 0.4% SDS, 50% formamide, 0.1% Ficoll, 0.1% polyvinylpyrrolidone and 0.1% BSA). Microarrays were pre-hybridized with 0.5 mg/mL salmon sperm DNA at 42 °C for 6 h. After being extensively washed, the denatured (95 °C, 5 min) fluorescent-labeled probe mixture was applied onto the pre-hybridized chips and further hybridized at 42 °C for 15-17 h under a cover glass. Subsequently, chips were sequentially washed for 10 min at 60 °C with 2×SSC+0.2% SDS, 0.1×SSC+0.2% SDS and 0.1×SSC solutions and dried at room temperature (1× SSC: 150 mmol/L NaCl, 15 mmol/L sodium citrate). Both Cy3 and Cy5 fluorescent signals of hybridized chips were scanned by ScanArray 4000 (GSI Lumonics, MA, USA) and analyzed using Genepix Pro 3.0 software (BioDiscovery Inc., CA, USA). To minimize artifacts arising from low expression, only genes whose Cy3 and Cy5 fluorescent intensities were both over 200 counts, or genes whose Cy3 or Cy5 fluorescent intensity was over 800 were selected for calculating the normalization cofactor (ln(Cy5/Cy3)). Genes were identified as differentially expressed, if the ratio of Cy5/(Cy3×normalization cofactor) (Cy5/Cy3*) was more than 2 or less than 0.5.

Reverse transcription and polymerase chain reaction

MHCC97 cells (106) cultured in 20-cm^2 flasks were treated with 3 000 IU/mL IFN-α (Roche, Shanghai) for 0 or 16 h, and total RNA was extracted (RNeasy Mini Kit, QIAGEN Inc., CA, USA). One microgram RNA was used to set-up reverse transcription reactions (Gibco-BRL, NY, USA). Nine differentially expressed genes identified by cDNA microarray were selected for analysis by semi-quantitative PCR. Appropriate primers were designed using Primer3 software (http://www-genome.wi.mit.edu). γ-Actin was used as an internal standard. PCR reaction conditions and primer sequences are summarized in Table 1.

Northern blot analysis

Total RNA of 3 000 IU/mL IFN-α-treated or untreated MHCC97 cells was isolated as described above. Thirty microgram was separated by 1% agarose formaldehyde gel electrophoresis and transferred to a nylon membrane (Millipore, MA, USA) in 10×SSC by capillary blotting. The membrane was hybridized with the appropriate cDNA probe prepared from the human library of cDNA clones (Biostar Genechip Inc., Shanghai) and labeled with [α-^{32}P]dCTP (Yahui Biomedical, Beijing) using random primer (Ambion Inc., Austin, TX, USA).

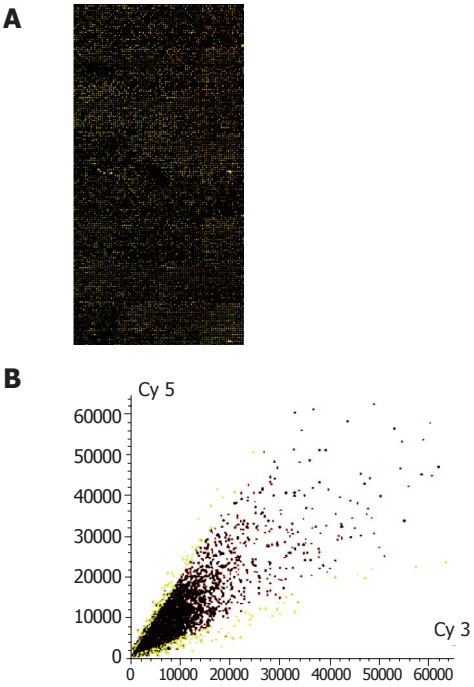

Figure 1 Representative hybrid result (**A**) and scatter plots (**B**) of cDNA microarray analysis in IFN-α treated MHCC97.

RESULTS

Gene expression profile identified by cDNA microarray

It is well known that the gene expression pattern of cells often varies with time and differentiation status and that cells derived from different individuals often have different genetic expression profiles. As a result, it is often difficult to extract useful information on the possible causes of phenotypic differences by comparing the genetic expression profiles of different cell lines. To minimize such complicated factors, we compared the gene expression profiles in 3 000 IU/mL IFN-α-treated and untreated (0 IU/mL) MHCC97 cells in two independent cDNA microarray analyses. We reasoned that such an internally consistent comparison might provide useful information on explaining the anti-tumor molecular mechanism of IFN-α in MHCC97 xenografts.

In 8 464 tested genes and ESTs, 190 genes were identified to be modulated by 3 000 IU/mL IFN-α treatment in MHCC97 cells. Among them the ex-pression of 151 genes was downregulated by IFN-α and the expression of 39 genes was upregulated by IFN-α. All differentially expressed genes are listed in Table 2 and the gene expression profiles obtained by cDNA microarray analysis are shown in Figure 1.

Nine differentially expressed genes evaluated by RT-PCR and Northern blot

To validate the results of cDNA microarray, we selected

Table 1 Primer sequence and condition for PCR analysis of selected genes

Category	Gene	Sense and antisense primers	Annealing (°C)	Cycles	Size (bp)
Cytoskeletal gene	Neutral calponin	5′-TGGCACCAGCTAGAAAACCT-3′; 5′-CAGGGACATGGAGGAGTTGT-3′	56	26	498

	ISG-56 ku	5′-AAAAGCCCACATTTGAGGTG-3′; 5′-GGCTGATATCTGGGTGCCTA-3′	54	30	451
MAPK pathway-related genes	ERK activator kinase (MEK2)	5′-CGAAAGGATCTCAGAGCTGG-3′; 5′-GTGCTTCTCTCGGAGGTACG-3′	56	26	349
	G3BP2	5′-GCAGAACCTGTTTCTCTGCC-3′; 5′-CACCACCACCTCTGGTTTCT-3′	56	30	475
	CHED	5′-TCCTTGGCGAACTCTTCACT-3′; 5′-TGCCATAAAGGGAGATCTGG-3′	56	30	336
cAMP/PI3 pathway-related gene	Adenylyl cyclase	5′-CCAGGAGCCTGAAGAATGAG-3′; 5′-GGCTTCTGAGCTCCAATCAC-3′	53	35	439
Housekeeping gene	γ-Actin	5′-ATGGAAGAAGAAATCGCCGC-3′; 5′-ACACGCAGCTCGTTGTAGAA-3′	55	25	287

nine genes whose expressions were clearly altered by IFN-α and evaluated their expressions by PCR and Northern blot. We enrolled IFN-α-regulated genes and found that the results were consistent with the previous reports[11,12].

For PCR analysis, we synthesized primers as indicated in Table 1 and performed semi-quantitative RT-PCR as outlined under "Materials and methods" after treatment of MHCC97 cells with 3 000 IU/mL IFN-α for 0 or 16 h. The transcription patterns of the same genes were also analyzed by Northern blot. Among the nine selected genes, seven downregulated genes were proved by cDNA microarray, six by RT-PCR and five by Northern blot analysis. Two stimulated genes, ISG-56 ku and 9-27 were proved by cDNA microarray, RT-PCR and Northern blot analysis. ERK activator kinase (MEK2), one repressed gene in cDNA microarray, was not changed in RT-PCR or Northern blot analysis. Thus, with a few exceptions, the results of RT-PCR and Northern blot were in good agreement with those of cDNA microarray analysis (Figure 2).

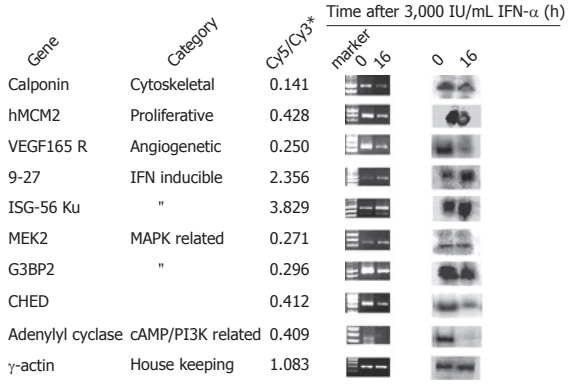

Figure 2 Confirmation of gene expression profiles in cDNA microarray analysis with RT-PCR and Northern blot.

DISCUSSION

cDNA microarray is a useful technique for rapid screening of gene expressions in cells, although the results need to be further confirmed by other molecular methods. Using this method, we found 211 hybrid dots, whose Cy5/Cy3* ratio was either more than 2 or less than 0.5 in IFN-α-treated MHCC97. Blasting the cDNA sequences in public database showed that these dots represented 190 different human genes or ESTs due to the redundant hybrids. Based on the results of RT-PCR and Northern blot, we believe that our cDNA microarray data are reliable. These differentially expressed genes might mediate the multiple biological functions of IFN-α directly or indirectly in MHCC97. We have artificially categorized these genes into nine functional clusters (Table 2).

IFN-α might interfere with cellular metabolisms by downregulating metabolic gene expression. In detail, IFN-α can inhibit glycolysis, glycogen degradation, gluconeogenesis as well as creatine or glucose transportation by repressing the expressions of liver-type phosphofructokinase (hPFKL), M2-type pyruvate kinase, brain glycogen phosphorylase, 2-oxoglutarate dehydrogenase, glucose transporter glycoprotein (SGLT) and cytosolic thyroid hormone-binding protein[13]. IFN-α can also inhibit lipolysis by reducing the expression of delta7-sterol reductase and pristanoyl-CoA oxidase, two key enzymes in lipid metabolism[14,15]. In addition, IFN-α reduces purine and pyridine biosynthesis by repressing the expression of GARs-AIRs-GART and serine hydroxymethyltransferase 2 (SHMT2). All these indicate that IFN-α-treated MHCC97 can result in lower ATP production and DNA synthesis, and slow down cell proliferation.

Many proliferation-, apoptosis- and cell cycle-regulating genes are modulated by IFN-α in MHCC97.

Table 2 Gene expression profile of MHCC97 cells induced by IFN-α

Category	GenBank ID	Gene description	Cy5/Cy3* (average)
2.1 Metabolism related genes	HUMCRTR	Creatine transporter	0.251
	HSGAGMR	GARs-AIRs-GART	0.289
	HUM2OGDH	2-Oxoglutarate dehydrogenase	0.298
	AF034544	Delta7-sterol reductase	0.318
	HUMTK	Thymidine kinase	0.333

Downregulating the expression of mutant p53, mitochondrial DNA, nuclear mitotic apparatus protein (NuMA), and RNA polymerase II 23 ku subunit (polR2) might cause cell cycle arrest[16,17]. Downregulating the expression of DNA ligase III, hRad1, minichromosome maintenance 2 (hMCM2) as well as UV-damaged DNA binding factor might hinder damaged DNA repairing[18,19]. Stimulating retinoid-IFN-induced mortality 19 (GRIM-19) expression might promote IFN-α-induced apoptosis[20].

Several genes functionally related to cell morphogenesis,

adhesion, and cytoskeleton remodeling are also modulated by IFN-α in MHCC97. For example, decreasing the expression of calponin, actin-related protein 2 (Arp2), fibulin 1D, beta-tublin and epidermal surface antigen (ESA), *etc.*, might damage mitotic spindle formation and might interfere with actin-based cell motility, migration, adhesion and morphogenesis[21-24]. Reducing the expression of prolyl 4-hydroxylase beta, a key enzyme in collagen biosynthesis and type IV collagenase, a tumor-derived extracellular matrix metalloproteases might block tumor invasion and metastasis. Although most genes in this category were first identified as IFN-α regulating genes, their roles in mediating IFN-α functions need to be further studied.

In this study, we found that many genes functionally related to signal transmitting were affected by IFN-α in MHCC97. By repressing the expressions of discoidin domain receptor, integrin-linked kinase, EPH-related tyrosine kinase (EPT2) and MEK2, *etc.*, IFN-α might block cellular signaling initiated by tyrosine-kinase receptors[25,26]. By modulating the expressions of Rab GDI, Ras-related GTP-binding proteins and farnesyl-protein transferase and nuclear transport factor (NTF2) and G3BP2, a Ras-GAP/RNA binding protein, IFN-α might interfere with GTP/GDP exchange and nuclear import, thus influencing the recycles and activities of ras and its homologs[27-29]. By attenuating the expressions of adenylyl cyclase (AC) and phosphatidylinositol 4,5-bisphosphate 5-phosphatase (PtdIns (4,5)P(2)5- phospharase), a catalyzer of phosphatidylinositol 4,5-bisphosphate and PRK1, IFN-α might decrease inositol polyphosphate levels in cytosol and might inhibit the serine/threonine-kinase activities through cAMP/ PI3P signal pathway[30,31]. All these changes might exert inhibitory effects of IFN-α on MAPK and PI3K signaling. In addition, other signaling pathways such as Ca(2+), NO and TGFβ/hMAD-dependent signaling pathways are suppressed by IFN-α as well[32,33]. Plausibly Jak/STATs pathway, the most important IFN-α signaling pathway, is confirmed not to be regulated in IFN-α-treated MHCC97. The deficient expression of p48 (ISGF3γ) in this cell line may be the possible mechanism for the non-response of IFN-α priming via Jak/STATs pathway (data not shown).

In this study, we found that many angiogenic-related genes were regulated by IFN-α. By attenuating the expressions of Golli-MBP[34], VEGF 165 receptor and aryl hydrocarbon receptor nuclear translocator (ARNT)[35] as well as Golgi membrane sialoglycoprotein MG 160, a bFGF binding protein and cysteine-rich FGF receptor (CFR-1)[36], IFN-α may destroy the balance between pro- and anti-angiogenic factors and exert its inhibitory effects on tumor angiogenesis.

It is well known that cells usually respond to various stimuli by rapidly shifting the functions of transcriptional factors. Using this strategy, IFN-α might impose its anti-proliferative functions and hormone response by fluctuating the expression of several transcriptional factors or their cofactors such as retinoblastoma binding protein2 (RBP2), interleukin enhancer binding factor 2, lost on transformation 1 (LOT1) and KRAB-zinc finger protein (SZF1)[37-40].

In addition, IFN-α might hinder with mRNA/rRNA spicing and maturation by downregulating RNA helicase (HRH1), U5 snRNP[41] and affect protein transportation, secretion and proteolysis by downregulating alpha SNAP, GPAA1, hSec10p, hsp40 and isopeptidase T, a putative molecular in ubiquitin–proteasome pathway[42-44]. Meanwhile IFN-α might evoke anti-viral or tumor immune response by upregulating 9-27, 56 ku protein and p44 expressions.

Except for functionally definite genes, many ESTs with unknown functions were identified as IFN-α-regulated genes in our study (Table 2). In conclusion, cDNA microarray is a useful, rapid method for screening transcriptome of cells and potentially paves a way for elucidating IFN-α effects on tumor growth and metastasis.

ACKNOWLEDGMENT

We thank Shanghai Biostar Genechip Inc. for cDNA microarray service.

Abstract

AIM: To detect the germline mutations of *hMLH1* and *hMSH2* based on mRNA sequencing to identify hereditary non-polyposis colorectal cancer (HNPCC) families.

METHODS: Total RNA was extracted from peripheral blood of 14 members from 12 different families fulfilling Amsterdam criteria II. mRNA of *hMLH1* and *hMSH2* was reversed with special primers and heat-resistant reverse transcriptase. cDNA was amplified with expand long template PCR and cDNA sequencing analysis was followed.

RESULT: Seven germline mutations were found in 6 families (6/12, 50%), in 4 *hMLH1* and 3 *hMSH2* mutations (4/12, 33.3%); (3/12, 25%). The mutation types involved 4 missense, 1 silent and 1 frame shift mutations as well as 1 mutation in the non-coding area. Four out of the seven mutations have not been reported previously. The 4 *hMLH1* mutations were distributed in exons 8, 12, 16, and 19. The 3 *hMSH2* mutations were distributed in exons 1 and 2. Six out of the 7 mutations were pathological, which were distributed in 5 HNPCC families.

CONCLUSION: Germline mutations of *hMLH1* and *hMSH2* can be found based on cDNA sequencing so as to identify HNPCC family, which is highly sensitive and has the advantages of cost and time saving.

Key words: *hMLH1*; *hMSH2*; Colorectal cancer; Hereditary non-polyposis; Reverse transcription; Germline mutation

INTRODUCTION

hMLH1 and *hMSH2* are the two most important genes for HNPCC, which is the most common hereditary colon syndrome accounting for 10% of all colorectal cancers. It is autosomally dominant with a penetrance rate of 80-90%. HNPCC occurrence is closely associated with deficiency or loss of function of mismatch repair (MMR) genes. Affected individuals have an approximately 70% lifetime risk of colon cancer with a mean onset age of 44 years and an approximately 40% lifetime risk of endometrial cancer in females. At least 5 MMR genes, *hMLH1, hMSH2, hMSH6, hPMS1,* and *hPMS2*, have been implicated in HNPCC[1,2]. Information of genetic linkage analysis shows that germline mutations of *hMLH1* and *hMSH2* account for nearly 90% of all germline mutations found in HNPCC[3]. Germline mutations in MMR genes predispose to colorectal and other HNPCC associated epithelial cancers. Identification of MMR gene germline mutations has direct clinical implications in counseling and management of HNPCC.

Methods such as microsatellite instability (MSI), immunohistochemistry (IHC)[4-6], and sequencing of genes are employed to screen HNPCC. The most specific method is to detect the germline mutations of MMR. Its cost and sensitivity limitations can be overcome at least in part by RNA-based analysis[7]. It is the first time in China that we identified HNPCC families by detecting germline mutations of *hMLH1* and *hMSH2* genes based on cDNA sequencing with special primers and heat-resistant reverse transcriptase.

MATERIALS AND METHODS

Subjects

Fourteen anticipants from 12 unrelated families fulfilling Amsterdam criteria II for HNPCC were studied. Personal and family cancer history was obtained from the patients and their relatives. Pathological diagnosis and death were confirmed by review of medical records, pathological reports or death certificates.

Samples

Three microliters of peripheral blood was taken from each participant. Total RNA was extracted using TRIzol (Sigma Company) according to the manufacturer's instructions.

RT-PCR

cDNA was synthesized with transcriptor reverse transcriptase (Roche Diagnostics) using 0.5 μg of total RNA and specific primers complementary to the 3' end of *hMLH1* (2484-TATGTTAAGACACATCTATTTATTTA-2459) and to the 3' end of *hMSH2* (3145-CCACCAAACTACA TGATTTTATTTATAAAATTC-3114). RT was performed at 60 °C for 60 min.

cDNA of *hMLH1* and *hMSH2* was amplified in two overlapping fragments using primers (Table 1) to generate products of ~2 000 bp. PCR was performed using expand long template PCR (Roche Diagnostics) at 94 °C for 5 min; then 10 cycles at 94 °C for 30 s, at 59 °C for 30 s, at 68 °C for 3 min; 32 cycles at 94 °C for 30 s, at 57 °C for 30 s, at 68 °C for 3 min with a final elongation at 68 °C for 7 min.

PCR products were size fractionated by agarose gel electrophoresis and analyzed by ethidium bromide staining.

Sequencing

Purified PCR fragments were sequenced directly using a DNA sequencing kit according to Applied Biosystems from USA with BigDye Terminators on an ABI3700 automated DNA sequencer.

cDNA of *hMLH1* (2 484 bp) was sequenced in six overlapping fragments and cDNA of *hMSH2* (3 145 bp) was sequenced in eight overlapping fragments using primers (Table 2).

RESULTS

The sizes of amplified *hMLH1* and *hMSH2* segments were respected (Figure 1). Seven germline mutations were found in 6 out of 12 families, 4 *hMLH1* and 3 *hMSH2* mutations (4/12, 33.3%); (3/12, 25%). The mutation types involved 4 missense, 1 silent and 1 frame shift mutations as well as 1 mutation in non-coding area, including *hMLH1* mutation in family H2 at 649 codon 217 exon 8: CGC→TGC; *hMLH1* mutation in family H31 at 1742 codon 581 exon 16: CCG→CTG; *hMLH1* missense mutation in family H114 at 1151 codon 384 exon 12: GTT→GAT; family H111 *hMLH1* non-coding area at 2438 exon 19: A→C; family H11 *hMSH2* at 14 codon 5: CCG→CAG; family H38 hMSH2 mutations at 295 and 296 codon 99 exon 2: 295: A→C, 296:del.G (Table 3, Figure 2).

DISCUSSION

Colorectal cancer (CRC) is one of the most common malignant tumors and its incidence is increasing gradually. According to the different molecular mechanism, CRC is divided into sporadic and genetic types. The latter type HNPCC is characterized by its early onset[8-10], location in the proximal colon and an increased risk of neoplasms in extracolonic organs including endometrium, stomach, urothelium, small intestine, ovary and multiple

metachronous CRCs[9,11-14]. Its prognosis is better than sporadic type of CRC[15]. HNPCC is closely associated with the deficiency or loss of MMR gene function. Identification of MMR gene germline mutations has direct clinical implications in counseling and management of HNPCC.

Methods are available for the identification of HNPCC. The most specific method is to detect the germline mutations of MMR genes. Up to now, the germline mutations are mainly detected by genomic DNA-based sequencing (gDNA). A lot of information shows that the germline mutations of MMR genes associated with HNPCC are mainly localized in exons[3,5,7,13]. The gDNA-based sequencing is invariably affected by introns. cDNA-based sequencing of MMR genes has been reported recently. The new technique utilizes specific primers and heat-resistant reverse trancriptase to specifically synthesize cDNA of MMR genes, then full-length cDNA is amplified in two over fragments using specific primers followed by sequencing analysis of cDNA. The technique can successfully avoid the influence of introns. Additionally, it is well known that RNA is easily decayed. If RNA samples are stored too long, reverse transcription with random primers and common reverse transcription enzyme often fails, while the new technique employs specific primers and heat-resistant reverse trancriptase, the limitations can be overcome at least in part, thus improving the specificity and efficiency. Anna *et al*.[7] compared the two techniques and found that cDNA-based sequencing not only has the advantage of specificity and efficiency, but also a lower cost, being 2.5-3 times less expensive than gDNA-based sequencing. We used 35 pair primers to amplify the two genes in the past, and only 4 pair primers were used in the present study, the procedure is greatly simplified.

We detected 7 germline mutations in 14 anticipants with HNPCC from 12 different families employing the new technique. The 3 mutations, at sites 1151, 14, and 217 in *hMLH1* reported, the first two have been verified to be pathological. Moreover, the mutation at 1151 in *hMLH1* has been found only in Japan and Korea, which is likely to be a hot mutation site in East Asia. The mutation at site 217 in *hMLH1* occurs at a less conserved region is in 80 healthy Japanese. Whether it is pathological or not needs further study. None of the 4 unreported mutations belongs to polymorphism[17]. The 6 pathological mutations (2 reported, 4 unreported) were distributed in 5 HNPCC families in our study.

Of course, all mutations cannot be detected by the improved technique. For example, mutations in the promoter and 3'-untranslated regions of *hMLH1* and *hMSH2* cannot be detected. Sequencing of individual exons of gDNA also has such limitations.

Up to now, there is no optimal method to screen HNPCC patients or their families. The new technique can be utilized to screen HNPCC patients and their families, which may achieve a better result.

Abstract

AIM: To observe the imbalance between T helper cell Th1 and Th2 cytokines in several chronic hepatitis disease at different stages of disease progression.

METHODS: We measured the cytokine levels of Th1 (IL-2 and IL-2R), Th2 (IL-10) and the pro-inflammatory cytokines (IL-6 and IL-6R and TNF and TNF-RI and II) by the ELISA technique in the sera of 33 hepatocellular carcinoma (HCC) patients and 20 chronic liver disease (CLD) patients. In addition, 20 asymptomatic hepatitis C virus carriers and 20 healthy subjects negative for hepatitis C virus(HCV) markers served as controls.

RESULTS: Anti-HCV antibodies were found to be positive in 94% of HCC cases and 75% of CLD cases. On the other hand, HCV viremia was detected using RT-PCR in 67% of HCC cases and 65% of CLD cases. HBsAg was positive in 9% of HCC cases and 30% of CLD cases. Also bilharzial-Ab was positive in 55% of HCC cases, 65% of CLD cases and in 70% of asymptomatic carriers (ASC). HCC patients had significantly higher values of IL-2R, TNF-RII (P<0.001), and TNF-RI (P>0.05), but lower TNFα (P<0.001) and IL-6 (P = 0.032) in comparison to ASC. But, in comparison to non-cancer controls, HCC patients had higher values of IL-2R, IL-6R, TNF-RI and TNF-RII, but lower TNF-α (P<0.001). CLD patients had higher IL-2R, TNF-RI, and TNF-RII (P<0.001) than ASC. But, in comparison to non-cancer controls, CLD patients had higher values of IL-2R, TNF-RI and TNF-RII, but lower TNF-α (P<0.001). IL-10 was higher (though not significantly) in HCC and CLD patients than in symptomatic carriers and non-cancer controls.

CONCLUSION: Liver disease progression from CLD to HCC due to HCV genotype-4 infection is associated with an imbalance between Th1 and Th2 cytokines. IL-2R, TNF-RI, and TNF-RII could be used as potential markers.

INTRODUCTION

Hepatitis C virus(HCV) is a common cause of hepatocellular injury that is associated with complex and vigorous immunologic mechanisms. Both humoral and cell-mediated immune responses participate in the host defense against HCV infection, but it is increasingly recognized that cellmediated response to the cytokine system plays a role in the im-munopathogenesis of chronic hepatitis C[1].

Cytokines constitute a complex network of molecules involved in the regulation of the inflammatory response and the homeostasis of organ functions. Moreover, cytokines coordinate physiologic and pathologic processes going on in the liver, such as liver growth and regeneration, inflammatory processes including viral liver disease, liver fibrosis and cirrhosis. Liver growth and regeneration are regulated by several cytokines. The cell-mediated immune response plays a central role in hepatocellular necrosis and in the immunopathogenic mechanisms involved in viral clearance and persistence in liver disease of viral etiology[2].

T lymphocytes and immunoregulatory cytokines are of critical importance in the host defense against HCV infection. T-helper type 1 (Th1) cytokines (interleukin-2 [IL-2], interferon-γ [IFN-γ]) are required for host anti-viral responses, while T-helper type 2 (Th2) cytokines (IL-4, IL-10) can inhibit the development of these effectors[3]. It has been demonstrated that pro-inflammatory IL-6 is able

to influence hepatocarcinoma progression in patients with liver cancer[4]. Tumor necrosis factor (TNF) plays a role in the pathogenesis of chronic hepatitis C[5]. Also, chronic HCV infection is associated with an increase in the levels of soluble TNF receptors I and II[6].

Screening high-risk populations with ultrasonography and serum αFP levels produces diagnosis of only 40-60% of patients with hepatocellular carcinoma (HCC) at a stage where the tumor can be resected or treated with curative intent[7].

In this study, we aimed to characterize serum cytokine levels of IL-2 and its receptor (IL-2R), IL-6 and its receptor (IL-6R), IL-10, TNF-α and its soluble receptors (TNF-RI and TNF-RII) by enzyme immunosorbent assay in HCC patients, chronic liver disease (CLD) patients, and HCV asymptomatic carriers (ASC), to figure out the possible imbalance between Th1 and Th2-like cytokines and their possible relation to hepatocarcinogenesis, as well as to evaluate the clinical significance of these cytokines in different stages of HCV infection, and their possible use as markers of disease progression, since there are no reliable markers for disease progression from CLD to HCC.

PATIENTS AND METHODS

Patients and controls

This study was conducted on 33 histologically proven HCC and 20 CLD patients (i.e., chronic active hepatitis with or without cirrhosis). All patients were presented before treatment to the specialized liver clinic of the National Cancer Institute (NCI), Cairo University, between April 2000 and June 2001. The study also included 40 control subjects: 20 asymptomatic carriers of HCV infection (ASC) as positive controls (positive for both HCV-AB and HCV RT-PCR), and 20 subjects without infection with HCV (NC) as negative controls (negative for HCV by both anti-HCV-Ab and HCV RT-PCR). The criteria for inclusion in the study groups were as follows: (a) ASC group: persistently normal alanine aminotransferase (ALT) values for 6 mo and no detectable liver changes by sonography except for a bright fatty liver, which is common in the Egyptian population. (b) CLD group: (1) persistent increase of the ALT values more than three times the normal value for atleast 6 mo; (2) exclusion of other causes of CLD such as alcoholism or hepatotoxic drugs; (3) histopathological examination of core needle biopsies. Accordingly, patients were classified into 8 mild, 7 moderate, and 5 severe cases of CLD. (c) HCC group: HCC neoplastic cells were identified histopathologically in H&E-stained sections of a core needle biopsy. Cases were classified into G1 (8 cases), G2 (22 cases) and G3 (3 cases). A detailed history and physical examination of the patients were carried out with special emphasis on history of bilharzias, prior parenteral therapy, infective hepatitis and jaundice or other signs of liver cell failure. Complete clinical examination, which includes the manifestations of hepatitis and liver cell failure such as jaundice, hepatomegaly, tenderness in the right hypochondrium, ascites, spleenomegaly, lower limb edema as well as abdominal ultrasonography was also done side by side with routine laboratory investigations including complete blood picture, liver and kidney function tests.

ELISA and HA assays

Sera collected from 5 mL of coagulated blood was aliquoted and stored at -80 ℃ until use. All the sera of patients and controls were tested for HCV antibody and HBsAg by the third-generation ELISA using kits from Innogenetics (Belgium) and the Equipar (Saronno, Italy). They were also tested for antibodies of Schistosomal infestation by quantitative indirect hemagglutination kits from Fumouze Laboratories (Paris, France). All tests were done according to the manufacturer's instructions.

RT-PCR of HCV

Nucleic acid extraction was done by QIAGEN viral RNA Mini-extraction kit (QIAGEN) using 140 μL of patient serum according to the manufacturer's procedure.

RT and PCR were done as previously described by Zekri *et al.*[8]. After completion of the amplification reaction, 10 μL of each PCR reaction product was analyzed by electrophoresis through an agarose 1.2% gel stained by ethidium bromide in Tris-acetate-EDTA buffer (pH 8.0) and DNA was transferred from the gel onto a nitrocellulose filter with alkaline buffer (4 N NaOH). The transferred DNA was cross-linked by incubation for 2-3 h at 80 ℃ and the blot was then hybridized with an internal probe[8].

HCV genotyping

The line immuno-probe assay was used to determine the HCV genotype as described previously[9] using INNO-LiPA II and III provided by Innogenetics (Belgium).

ELISA for cytokine assay

The following cytokines were assayed for all study groups using quantitative ELISA plate method: IL-2 (Quantikine, R&D Systems, Inc., Minneapolis, USA), soluble IL-2 receptor (sIL-2R) (Diaclone Research, France), IL-10 (Quantikine R&D Systems, Inc., Minneapolis, USA), IL-6 (Accucyte, Cytimmune Sciences Inc., MD, USA), soluble IL-6 receptor (sIL-6R) (Diaclone Research, France), tumor necrosis factor alpha (TNF-α) (Accucyte, Cytimmune Sciences Inc., MD, USA), as well as their soluble receptors (sTNF-RI, sTNF-RII; Immunotech, France). We considered the cut-off values for the studied cytokines as mean+2SD of the negative controls.

Histological studies of liver

Liver core needle biopsies (atleast 10 mm long) from CAH and HCC patients who participated in the study were examined by two independent pathologists. Biopsy specimens were assessed for fibrosis (score 0-4) and activity (score 0-18) according to the scoring system of

Knodell. Chronic hepatitis C was defined as mild, if the total score was 6, moderate, if the score was between 6 and 9, and severe, if the score was 9.

Statistical analysis

SPSS package (version 10) was used. Mean and standard deviation were estimates of quantitative data. Non-parametric *t* test (Mann-Whitney test) or non-parametric ANOVA (Kruskal-Wallis test) was used to compare means of more than two independent groups. Fisher's exact and chi-square tests were used to validate the hypothesis of proportional independency. Correlation analysis was used to detect the association between quantitative data.

RESULTS

The clinical characteristics of the studied groups are shown in Table 1. HCC patients had significantly higher cirrhosis, irregular surface of liver, jaundice, serum AST and HCV-Ab positivity than in CLD cases (0.05, 0.007, 0.002, 0.006, and 0.05 respectively) and only HCC patients had significantly lower HBsAg than CLD patients. All the studied cases showed HCV genotype-4 by INNO-LiPA.

No significant difference was found in the history of bilharziasis, prior to the parenteral anti-bilharzial therapy, smoking, diabetes and hypertension in relation to the presence of HCV-Ab was found in HCC and CLD patients. HCV viremia by RT-PCR was positive in 22 of 31 (71%) HCV-Ab positive HCC cases, and in 11 of 15 (73%) HCV-Ab positive CLD cases.

Scatter diagram representing the values of IL-2, IL-2R, IL-6, IL-6R, IL-10, TNF-α and their soluble receptors TNF-RI and TNF-RII in HCC, CLD cases, ASC and normal controls around the cut-off value are shown in Figures 1A-G.

Concentrations of IL-2R, IL-6R and IL-10 were higher in HCC patients than in other groups (16.7±5.4 ng/mL, 56.5±17.97 ng/mL, 9±26.07 pg/mL respectively). On the other hand, the mean concentrations of TNF-RI and TNF-RII were higher (1.87±1.5 and 9.160±0.4 ng/mL) in CLD patients than in other groups. Schistosomal-Ab and TNF-α were higher (1205±120 and 811±5.8 ng/mL) in asymptomatic HCV carriers than in other groups. IL-6R was significantly higher in HCC, CLD and ASC than NC group and there is a consistent increase in the IL-10 level with the disease progression from NC to HCC (Table 2).

In HCC group, positive HCV-RT-PCR cases had higher values of IL-2R, IL-6, IL-10 and TNF-RII (P = 0.689, P = 0.925, P = 0.636 and P = 0.05 respectively) than non-viremic cases, whereas positive HCV-RT-PCR in CLD cases had higher values of IL-6R, IL-10 and TNF-α (P = 0.28, P = 0.08 and P = 0.966) (results not shown).

No significant difference was noticed in any of the clinical characteristics of the patients with cytokine values above the cut-off, when compared to those below the cut-off in both HCC and CLD patients (results not shown). Scatter diagram representing the values of IL-1, IL-2R, IL-6, IL-6R, IL-10, TNF-RI and TNF-RII in HCC, CLD cases, ASC and non-cancer controls (NC) around the cut-off value are shown in Figures 1A-G. Mean serum cytokine levels in the different study groups are shown in Table 2. Regarding IL-2, no difference in its level was observed among the four groups. However, HCC patients had significantly higher values of IL-2R, TNFRII (P<0.001), and TNF RI (P>0.05), but lower TNF-α (P<0.001) and IL-6 (P = 0.032) in comparison to ASC.

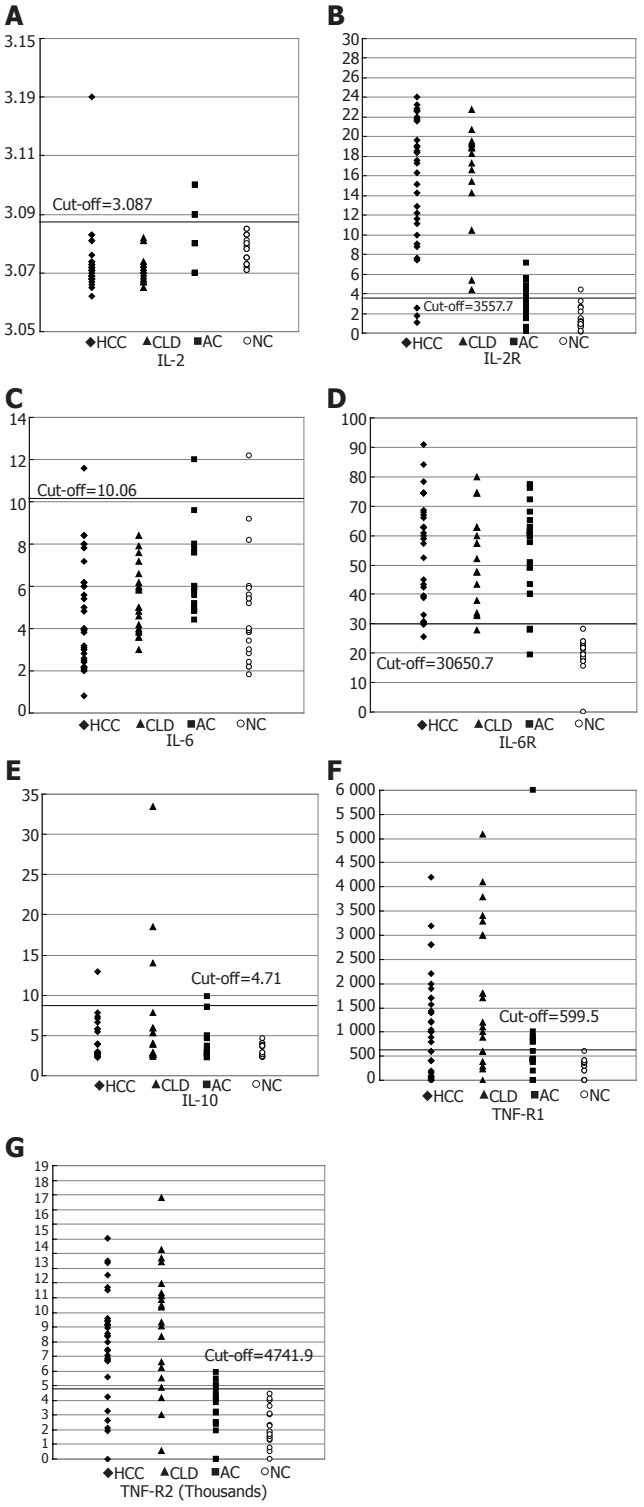

Figure 1 Scatter diagram represents the distribution value of (**A**) IL-2, (**B**) IL-2R (**C**) IL-6, (**D**) IL-6R, (**E**) IL-10, (**F**) TNF-R1, (**G**) TNF-R2 in HCC, CLD, ASC and normal controls around the cut-off value.

[1]Cut-off=mean±2 SD of non-cancer controls. P<0.05 difference is statistically significant.

But, in comparison to non-cancer controls, HCC patients had higher values of IL-2R, IL-6R, TNF-RI and TNF-RII, but less TNF-α (P<0.001). CLD patients had higher IL-2R, TNF-RI and TNF-RII (P<0.001) than in ASC. But, in comparison to non-cancer controls, CLD patients had higher IL-2R, TNF-RI and TNF-RII, but lower TNF-α (P<0.001). IL-10 was higher (though not significantly) in HCC and CLD patients than in symptomatic carriers and non-cancer controls. No significant difference was noticed in any of the clinical characteristics of patients with cytokines values above the cut-off, when compared with those below the cut-off in both HCC and CLD patients.

The most sensitive cytokines as markers for disease progression in HCV-infected patients were IL-2R (91% of HCC and 80% of CLD patients had values above the cut-off), IL-6R (88%, 95%, and 85% of HCC, CLD and ASC respectively, had values above the cut-off) and also TNF-RII (81% of HCC and 85% of CLD cases had values above the cut-off).

DISCUSSION

It has been reported that hepatotropic viruses HBV, HDV, HCV are associated with HCC, and more than 80% of HCCs that occur worldwide are thought to be associated with chronic viral hepatitis[10]. In our series, the prevalence of anti-HCV antibodies by the third-generation ELISA was 93.9% in HCC patients. HCV-AB

was positive in 86.5% of 37 HCC patients in our previous study[11]. However, this ratio is higher than those reported by other researchers[12,13]. The present study showed that the prevalence of anti-HCV antibodies was 75% in CLD patients, which is also higher than those reported by other researchers[14,15].

The HCV viremia in our HCV-serpositive HCC cases was also higher than those reported by other researchers[11,16,17]. This discrepancy might be explained by the fluctuations of the amount of the viruses in the serum[18]; or the discrepancy of RT-PCR methods used by the different series[8].

In our study, HBsAg was found in 9% of HCC cases, which is similar to that in our previous studies[11,12]. HBsAg was found in 30% of our CLD cases, which is higher than that reported by Angelico *et al*.[14]. In the present study, history of bilharziasis and prior anti-bilharzial parenteral therapy was found in 51.6% and 41.9% of HCC patients and in 73.3% and 60% of CLD patients respectively, indicating that history of parenteral anti-schistosomal therapy is a major risk factor for transmitting HCV infection.

Anti-bilharzial antibodies were found in 55% of HCC patients in our study, which is higher than that reported in our previous studies[11]. This high incidence could be attributed to the fact that most of our HCC patients (66.7%) came from rural areas. Rural populations in both Egypt and other African areas have a higher incidence of viral hepatitis. In the rural areas, many individuals may become infected due to tattooing[19].

A characteristic feature of HCV infection is a high frequency of persistence and progression to CLD. Persistent infection upsets the balance between immunostimulatory and inhibitory cytokines, which can prolong inflammation and lead to necrosis, fibrosis, and CLD[1]. Elevated concentrations of cytokines also represent a characteristic feature of CLD, regardless of underlying etiology, which may represent a consequence of liver dysfunction instead of inflammatory disorder[20].

Missale *et al*.[2] and Cacciarelli *et al*.[3] found that serum IL-2 is significantly elevated in HCV chronically HCV-infected patients. However, Simsek and Kadayifci[21] found that serum IL-2 has no significant change in the same group of patients. In contrast, our study showed no significant change in the levels of IL-2 among the different groups. The high level of sIL-2R might explain the apparently normal level of IL-2 in our patients as low IL-2 level could therefore be due to soluble receptor binding to IL-2. This theory is also supported by Sismek and Kadayifci[21]. On the other hand, Izzo *et al*.[22] found that serum levels of sIL-2R correlate with the histological severity of liver damage in patients with chronic HCV infection and may be used as a marker in patients at high risk of getting HCC and the highest levels of soluble IL-2R occur in patients with HCC[23]. We could not, however, correlate serum levels of sIL-2R with the different clinical and biochemical findings in HCC in this study.

Thus, sIL-2R may play a role in the pathogenesis of chronic active hepatitis and HCC, and could be considered as a good marker for disease progress in chronic HCV-infected patients. IL-2R was above normal in 91% of HCC and in 80% of CLD cases in our study.

Interleukin-6, a multifunctional cytokine produced by a variety of cells, plays a central role in regulating the immune system, hematopoiesis, and acute phase reaction. It interacts with a receptor complex consisting of a specific ligand-binding protein (IL-6R, gp80) and a signal transduction protein (gp130)[24,25]. Serum IL-6 levels are higher in patients with chronic HCV infection in comparison to healthy adults[26,27]. In contrast, our results showed that IL-6 was slightly higher only in asymptomatic HCV carriers than in non-cancer controls, but apparently normal in both HCC and CLD patients, which is in accordance with that reported by Tovey *et al*.[28]. Altered IL-6 gene expression is a characteristic feature of advanced stage of severe liver disease. McGuinness *et al*.[29] also found that IL-6 mRNA is down-regulated in chronic HCV-infected patients.

On the other hand, Steffen *et al*.[30] revealed that IL-6 is inversely correlated with sIL-6R, as IL-6 may play a role in the decrease of sIL-6R either by the direct inhibitory effect on the expression of the IL-6R gene or by the formation of IL-6R/sIL-6R complexes followed by their internalization in target cells. This might partially explain the apparently normal levels of IL-6 in our HCC and CLD patients by the increase in their sIL-6R levels.

The pro-inflammatory cytokine tumor necrosis factor-α plays an important role in the pathophysiology of liver disease. Specific antagonists of this cytokine have been found in recent years. TNF soluble receptors p55 and p57 derived from the cell surface are naturally occurring substances that inhibit the biological effects of tumor necrosis factor.

The striking elevation of pro-inflammatory cytokine TNF-α in asymptomatic HCV carriers may reflect both insufficiency of HCV elimination and a failure to control the cytokine cascade. Our result is opposite to those reported by Goyal A[20] and Toyoda *et al*.[31]. This could be attributed also to the difference in the epitopes of the ELISA system used by the different groups or to the difference in genotypes. All our cases showed HCV genotype-4.

The promoter in the IL-6 gene has been shown to contain regulatory regions to which DNA-binding proteins can bind. These DNA-binding proteins, induced by IL-1 and TNF-α, stimulate transcription of the IL-6 gene. Thus, as IL-1 and TNF-α levels increase, production of IL-6 also increases[32]. Our result is in accordance with the above findings, and the decrease in TNF-α is associated with a decrease in IL-6 in HCC and CLD cases.

In our study, HCC cases had significantly higher values of TNF-RII and TNF-RII ($P<0.001$) than ASC and NC subjects. Thus, the rise in concentrations of TNF receptors I and II in our patients suggests that HCV-related liver disease involves immunological mechanisms including activation of the TNF system and may reflect the degree of inflammation and development of HCC. These results are in accordance with other studies[33,34].

Tai *et al*.[5] also showed that sTNF-RI levels correlate with liver inflammation in all patients, whereas this correlation cannot be found with sTNF-RII, IL-2, IL-10 and TNF-α.

Accordingly, we can use TNF-RII as a marker in HCV-infected cases at high risk of getting CLD and HCC.

Delpuech *et al*. [35] showed that even if the infection of H9 T cell line with HCV does not result in any viral progeny, HCV induces the activation of IL-10 secretion, which supports the role of IL-10 in HCV pathogenesis. Cacciarelli *et al*.[3] and Kakumu *et al*.[33] found that serum IL-10 levels are significantly higher in all CLD groups than in controls, indicating that IL-10 reflects the degree of inflammation in the liver and may be related to the development of HCC. In our series, IL-10 levels were increased (though not significantly) in HCC, CLD in comparison to non-cancer controls. The positive HCV-viremic CLD cases also had higher values of IL-10 ($P = 0.08$) than non-viremic cases. In addition to the production at the site of inflammatory changes with activated infiltrating mononuclear cells in the liver, the high serum IL-10 levels in patients with HCC presumably also result from the secretion of IL-10 by tumor cells. Its secretion by human hepatocellular tumors has been observed previously[36]. Thus, a high IL-10 level is suggested to contribute to a relative state of immuno-suppression, and in patients with HCC, may help the tumor cells escape host immune surveillance and potentiate tumor cells to metastasize[37].

It has been postulated that an imbalance between Th1 and Th2 cytokine production is implicated in disease progression or inability to clear infections. It was reported that HCV-infected patients who develop chronicity have a predominant Th2 response, but a weak Th1 response, suggesting that this immune response imbalance can result from HCV interaction with dendritic cell functions[38]. These results agree with ours and support the notion that Th-lymphocyte polarization may play an important pathophysiologic role in influencing the outcome of HCV infection. All these immunological findings are mostly due to HCV infection rather than schistosomal infection, because patients with no schistosomal antibody had the same elevation of the same cytokines, late Schistosoma mansoni cases showed a suppressed cell-mediated immunity and a significant depletion of T-helper/inducer subset[39].

In conclusion, the most sensitive cytokines as markers for disease progression in HCV-infected patients are IL-2R, IL-6R and TNF-RII. Accordingly, we may use serum IL-2R, IL-6R, TNF-RII as markers in HCV-infected cases at high risk of getting CLD and HCC. Thus, disease progression due to HCV infection is associated with decrease of circulating Th1 cytokines (IL-2) and increase of Th2 cytokine (IL-10). Persistent infection upsets the balance between immunostimulatory and inhibitory cytokines, which can prolong inflammation and lead to necrosis, fibrosis, and CLD.

Abstract

AIM: Toll-like receptor 4 (TLR4) has been shown to be important for bacterial infection, especially to lipopolysaccharide signaling. Its possible role in HBV infection is studied in the present study.

MATERIALS AND METHODS: pHBV3.6 plasmid, containing full-length HBV genome was used in the murine model of acute HBV expression by hydrodynamics *in vivo* transfection. TLR4 normal or mutant mouse strain was compared to investigate the possible role of TLR4 in acute HBV expression.

RESULTS: After pHBV3.6 injection, the infiltrating leukocytes expressed TLR4 were observed nearby the HBsAg-expressing hepatocytes. The HBV antigenemia as well as the replication and transcription were higher in TLR4-mutant C3H/HeJ mice than in normal C3H/HeN mice. The HBV-specific immune responses were impaired in the liver or spleen of the C3H/HeJ mice. Their inducible nitric oxide synthase (iNOS) expression on the hepatic infiltrating cells was also impaired. When adoptively transferring splenocytes from C3H/HeN mice to C3H/HeJ mice, the HBV replication was inhibited to the level as that of C3H/HeN.

CONCLUSION: These results suggest that TLR4 plays an anti-HBV role *in vivo* through the induction of iNOS expression and HBV-specific immune responses after HBV expression.

INTRODUCTION

Hepatitis B virus (HBV) is an enveloped, double-strand DNA virus, and its replication is through an RNA intermediate that requires reverse transcriptase activity[1]. HBV infection in human beings can cause chronic hepatitis and is associated with liver cirrhosis and hepatocellular carcinoma[2,3]. One-third of the global population has been infected with HBV and about 350 million people are chronic carriers of HBV[4]. HBV is non-cytopathic to hepatocytes and the hepatitis it causes is thought to be mediated by immune mechanism. However, the innate immune response to HBV infection is not fully understood.

Toll receptors are type I membrane proteins that was first identified in Drosophila and play a key role in antifungal immunity of Drosophila[5]. The mammalian homologs of Drosophila Toll protein are called Toll-like receptors (TLRs), and there are 10 human (TLR1 to TLR10) and murine TLRs (TLR 1 to TLR9 and TLR11)[5,6]. TLRs play a key role in host defense against microbial infection by regulating both innate and acquired immunity[7,8]. For example, TLR4 is the receptor of Gram-negative bacterial lipopolysaccharide (LPS). After binding, the MyD88, interleukin-1 receptor-associated kinase, and tumor necrosis factor receptor associated factor 6 are activated, and then through MAP kinases and NF-κB transcription factors[6,9] to turn on the genes expression, which were involved in the inflammatory responses[10]. TLR4 also plays a role in viral infections. Respiratory syncytial virus (RSV) persists longer in the lung of TLR4-deficient mice than normal mice, and RSV fusion protein can activate the human monocytes through TLR4[11].

Hydrodynamics-based *in vivo* transfection has been

recently described. With this procedure, naked DNA can be introduced and expressed significantly in liver[12,13]. This property allows investigators to develop hepatitis virus infection model in mouse[14]. Recently, a murine acute HBV expression model was generated by hydrodynamics-based injection of plasmid containing full-length HBV genome by our group[15] or others[16]. After hydrodynamic injection of pHBV3.6, including full-length HBV genome, the HBV transcript and replicative intermediate were induced in the liver whereas the HBV-antigens, HBV-DNA, and HBV-specific antibody were detected in the sera[15].

We are interested in the role of TLR4 during HBV infection. Using the murine model of acute HBV expression in this study, we reported that HBV expression-induced TLR4 expression has anti-HBV activity by upregulating the iNOS expression and HBV-specific immune response to help clearing the virus.

MATERIALS AND METHODS

Mice

Breeder mice of C3H/HeN and C3H/HeJ strain were purchased from The Jackson Laboratory (Bar Harbor, ME, USA) or Charles River Japan, Inc. (Atsugi, Japan). They were fed standard laboratory chow and water *ad libitum* in the animal facility. The animals were raised and cared for according to the guidelines set up by the National Science Council of the Republic of China. Eight- to twelve-week-old male mice were used in all experiments.

Plasmids

pHBV3.6 containing all HBV open-reading frames was provided by Dr LP Ting (Department of Microbiology and Immunology, National Yang-Ming University), p(3A)SAg that encodes HBsAg was provided by Dr CC Lu (Department of Pathology, National Cheng Kung University) and pHBV^PSX that encodes HBcAg was provided by Dr SJ Lo (Department of Microbiology and Immunology, National Yang-Ming University). pEGFP-N1 was obtained from Clontech (Palo Alto, CA, USA). All plasmids were prepared with Hi-speed Plasmid Midi Kit (Qiagen, Hilden, Germany).

Cells and transfection

The C3H/He bladder cancer cell line, MBT-2, was kindly provided by Dr MD Lai (Department of Biochemistry, National Cheng Kung University). Cells were maintained in Dulbecco's modified Eagle medium (Gibco BRL, Grand Island, NY, USA) and 10% fetal bovine serum (HyClone, Logan, UT, USA) at 37 ℃ under 50 mL/L CO_2. The cells were plated at a density of 3×10^5 cells/well in six well-culture plate. One day later, cells were transfected with 1 μg of p(3A)SAg and pHBV^PSX using Lipofectamine 2000 (Invitrogen, Carlsbad, CA, USA) according to the manufacturer's protocol. The medium was replaced with a fresh medium 8 h after transfection, and cells were used for T cell stimulation at 36 h after transfection.

Hydrodynamics-based in vivo transfection

Ten micrograms of plasmid, dissolved in Ringer's solution (NaCl 0.154 mol/L, KCl 5.63 mmol/L, $CaCl_2$ 2.25 mmol/L), were injected in the mouse tail vein, within 5 to 7 s, at a 12% of mouse bodyweight (around 3.0 mL) following the hydrodynamics-based transfection protocol described previously[15].

Immunohistochemical analysis of HBsAg, TLR4, and iNOS expression

Mouse liver tissues were embedded in OCT compound (Miles Inc., Elkhart, IN, USA) and frozen in liquid nitrogen. Four micrometer cryosections were made using cryostats (Leica CM 1800, Nussloch, Germany). For TLR4 and HBsAg double staining, sections were fixed by 3.7% formaldehyde/PBS and then firstly stained with sheep-anti-HBsAg antibody (Serotec, Oxford, UK) and FITC-conjugated donkey-anti-sheep antibody (Jackson Laboratories, West Grove, PA, USA). After washing with PBS, the sections were further stained with rat-anti-mouse TLR4 antibody (Santa Cruz Biotechnology, Inc., Santa Cruz, CA, USA) and Rhodamine-conjugated donkey-anti-rat antibody (Jackson Laboratories, West Grove, PA, USA). The nucleuses were stained by Hoecsht 33258. For HBsAg and iNOS staining, the sections were fixed by cold acetone and endogenous peroxidase was inhibited by 3% H_2O_2/PBS. HBsAg and iNOS were detected with sheep polyclonal anti-HBs (Serotec, Oxford, UK) and rabbit polyclonal anti-iNOS antibodies (Chemicon, Temecula, CA, USA), respectively. Secondary antibody used was either biotinylated anti-sheep or anti-rabbit, and then incubated with avidin-peroxidase complex (Vector Laboratories, Burlingame, CA, USA). Peroxidase stain of red color was developed by aminoethyl carbazole substrate (Zymed Laboratories, San Francisco, CA, USA) and counterstained with Mayer's hematoxylin (Merck, Darmstadt, Germany).

Northern and Southern blot hybridization of HBV transcription and replication

Total RNA was purified from mouse liver by TRI Reagent (Molecular Research Center, Inc, Cincinnati, OH, USA). The cytoplasmic DNA of mouse liver was purified as described previously by Guidotti *et al*.[17]. Thirty micrograms of total RNA or cytoplasmic DNA isolated from 30 mg of liver tissue were run on agarose gel electrophoresis, transferred to a nylon membrane and hybridized with biotin labeled HBV specific DNA probe, which was prepared by PCR amplication with the primers as: HBV1806: 5'-CCGGAAAGCTTGAGCT CTTCAAAAAGTATGGTGCTGG-3' ; HBV1821: 5' -CCGGAAAGCTTCTTTTTCACCTCTGCCTAATCA-3', at 45 ℃ overnight. To verify the transfection efficiency, we injected pEGFP-N1 with pHBV3.6 simultaneously and detected by a specific biotin labeled DNA probe. The hybridized bands were detected by Detector AP Chemiluminescent Blotting Kit (KPL, Inc., Gaithersburg, MD, USA) and visualized by X-ray films.

HBV DNA detection in mouse sera

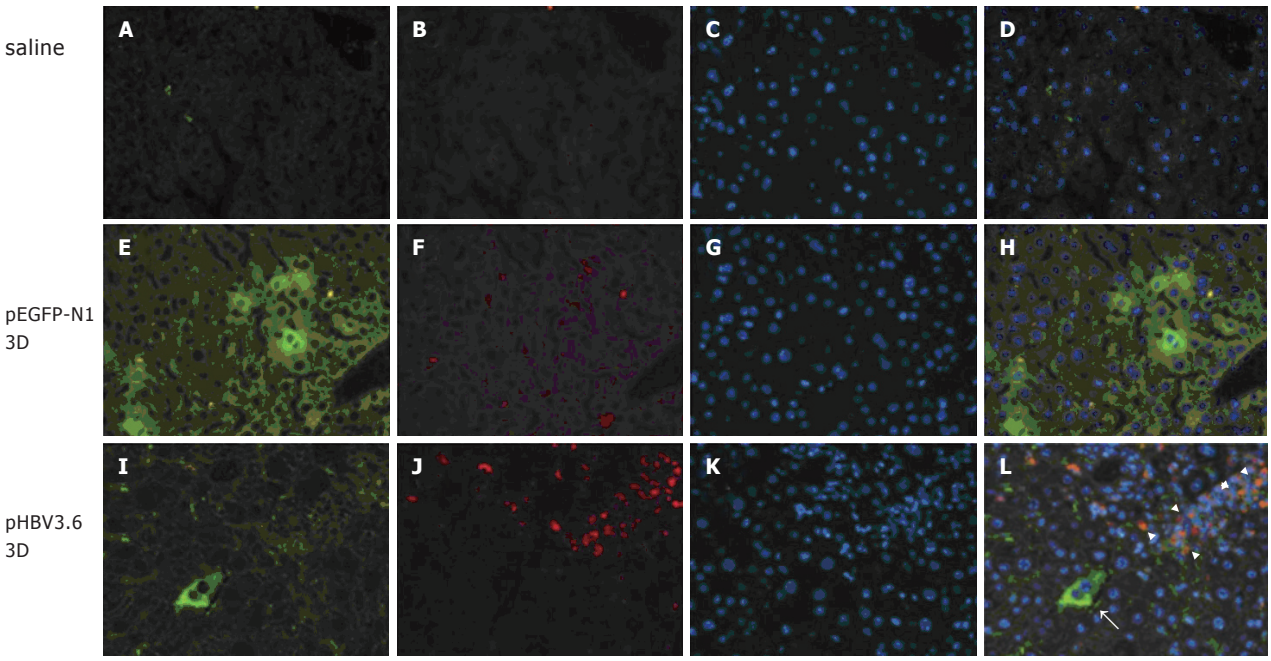

Figure 1 TLR4 expression in the liver of C3H/HeN mice after hydro-dynamic injection of pHBV3.6. Groups of four C3H/HeN mice were injected intravenously with 10 μg of plasmid by hydrodynamics-based transfection. The liver tissues were collected at day 3 post injection and 4-μm cryosections were made, stained with anti-HBsAg-FITC and anti-TLR4-PE antibody. The green represents EGFP-positive (**E**) or HBsAg-positive cells (**I**) and the red represents TLR4-positive cells (**B, F, J**). The blue represents counter staining by Hoechst 33258 dye (**C, G, K**). **A-D:** naïve; **E-H:** pEGFP-N1; **I–L:** pHBV3.6. The arrows indicate the HBsAg positive hepatocytes and the arrowheads indicate the TLR4 positive immune cells (original magnification ×200)

Two hundred microliters of mouse serum was treated with 20 U DNase I for at least 12 h to remove retaining plasmid. After DNase I treatment, the serum DNA was purified by Viral DNA/RNA Isolation Kit (Maxim Biotech, INC., San Francisco, CA, USA). Five microliters of isolated DNA solution was used to detect the HBV DNA by PCR analysis. The preS2 region of surface antigen gene was amplified and visualized on an agarose gel as described previously[18].

Detection of HBsAg and HBeAg in mouse sera

The level of HBsAg and HBeAg were determined using enzyme-linked immunosorbent assay (ELISA) kits (General Biological Corp., Taiwan, ROC) following the manufacturer's protocol.

ELISA for detecting cytokines

The intrahepatic lymphocytes (IHLs) were isolated as described previously[15] with further removing the adhering cells. The IHLs or splenocytes were co-cultured with mitomycin C-treated (100 μg/mL at 37 ℃ for 90 min) MBT-2[19] or p(3A)SAg and pHBV^PSX transfected, MBT-2 (MBT-2-SC) at a ratio of 10:1 for 48 h The co-cultured supernatants were harvested and assayed by sandwich ELISA for mouse IFN-γ, TNF-α or IL-12 (R&D Systems, Minneapolis, MN, USA).

RESULTS

Infiltrating cells in the liver expressed TLR4 after transfection of HBV gene

To investigate the association of TLR4 and HBV expression, the plasmid pHBV3.6, containing the full-length HBV genome was administrated to C3H/HeN mice by hydrodynamics *in vivo* transfection. As shown in Figure 1, the TLR4 expression could be detected on infiltrating leukocytes at day 3 post-injection (Figures 1I-L). But it was not detected in the liver of naïve C3H/HeN mice (Figures 1A-D) or pEGFP-N1 injected mice (Figures 1E-H). These results indicate that TLR4 expressed on leukocytes might involve the acute HBV expression.

HBV antigenemia and replication was higher in C3H/HeJ than in C3H/HeN

In C3H/HeJ mice, a missense mutation in the cytoplasmic domain of TLR4 impaired its ability to respond to lipopolysaccharide (LPS)[20]. To further investigate the role of TLR4 in HBV expression, we compared the response in C3H/HeN (TLR4 normal) and C3H/HeJ (TLR4 mutation) after the pHBV3.6 *in vivo* transfection. As shown in Figure 2, the serum HBsAg (Figure 2A) or HBeAg (Figure 2B) level was higher in C3H/HeJ than in C3H/HeN mice. By Northern and Southern blot analyses, the specific HBV transcripts or HBV replication fragments were also higher in the liver of C3H/HeJ than C3H/HeN mice under similar transfection efficiency that was verified by co-injection of pEGFP-N1 (Figure 2C). Using viral DNA isolation and PCR analysis, the serum HBV-DNA showed higher level in C3H/HeJ than in C3H/HeN mice (Figure 2D). These results suggest that TLR4 is involved

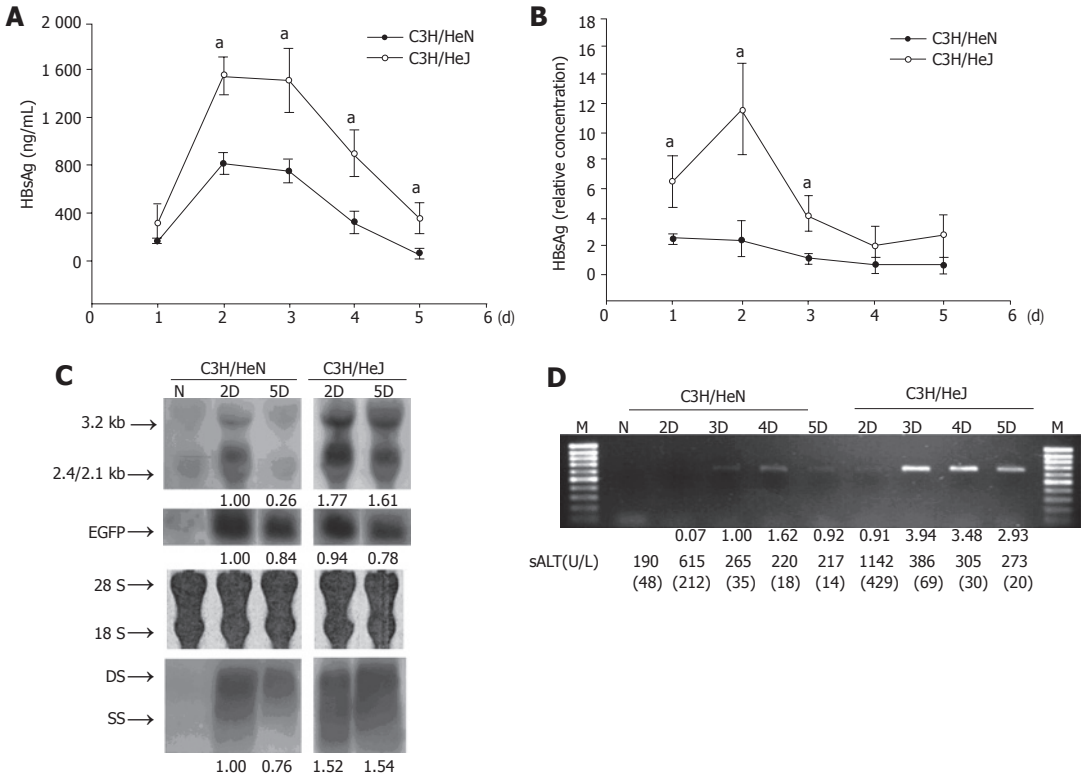

Figure 2 HBV antigenemia and replication in TLR4-mutant C3H/HeJ mice or normal C3H/HeN mice. Groups of four C3H/HeN or C3H/HeJ mice were injected intravenously with 10 μg of pHBV3.6 and 10 μg of pEGFP-N1 that was used as control of transfection efficiency by hydrodynamics-based transfection. The HBsAg (**A**) or HBeAg (**B**) in the serum was detected by ELISA kits as described in Materials and methods. [a]*P*<0.05. in host responses to HBV replication and a mutation in C3H/HeJ impaired its ability to clear the HBV virus.

HBV-specific immune responses were defective in TLR4 mutant C3H/HeJ mice after hydrodynamic injection of pHBV3.6

To investigate the effect of TLR4 on immune responses to HBV, intrahepatic lymphocytes (IHLs) or splenocytes from pHBV3.6-injected C3H/HeN or C3H/HeJ mice were isolated and stimulated with HBsAg- and HBcAg-expressing syngenic MBT-2 cells. The IFN-γ and TNF-α production of IHLs from C3H/HeN mice was significantly increased at 48 h after HBsAg and HBcAg stimulation. But this was not observed in IHLs from C3H/HeJ mice (Figures 3A and B). The IFN-γ and IL-12 production of splenocytes of C3H/HeN mice was also significantly increased in C3H/HeN mice, but not in C3H/HeJ mice (Figures 3C and D). These data suggest that TLR4 mutation in C3H/HeJ affects the HBV specific immune responses (IFN-γ and TNF-α production in liver or IFN-γ and IL-12 production in spleen).

Induction of iNOS was also defective in TLR4 mutant C3H/HeJ mice after hydrodynamic injection of pHBV3.6

It was reported that the activation of TLR4 signaling can induce the iNOS expression[21], and we also reported that iNOS plays an anti-HBV role in acute HBV expression[15]. Therefore, the iNOS expressed was compared in wild type and TLR4 mutant mice after pHBV3.6 transfection. The HBsAg-expressing hepatocytes were equivalent among C3H/HeN and C3H/HeJ mice after pHBV3.6 injection, indicating the transfection efficiency was similar in both strains of mice. But iNOS stainings were detected on the infiltrating leukocytes nearby the HBsAg-expressing hepatocytes in the liver of pHBV3.6-injected C3H/HeN (Figures 4C and D) whereas the expression of iNOS on infiltrating leukocytes was impaired in the liver of C3H/HeJ mice (Figures 4G and H). These data suggested that the mutation of TLR4 influences the induction of iNOS expression during acute HBV expression and may further affect the clearance of HBV.

HBV replication was reduced in C3H/HeJ mice after adoptive transfer of splenocytes from C3H/HeN mice

To further confirm, if TLR4-expressing immune cells provide the protection role to HBV expression, the splenocytes from C3H/HeN mice were injected into C3H/HeJ mice intravenously at the day before pHBV3.6 injection. The HBsAg antigenemia was higher in C3H/HeJ than in C3H/HeN mice, but the adoptive transfer of C3H/HeN splenocytes into the C3H/HeJ mice reduced the serum HBsAg to the level similar to that in C3H/HeN mice (Figure 5A). The HBV transcription or replication in liver (Figure 5B) or HBV-DNA in sera (Figure 5C) was also reduced as well under similar transfection efficiency as verified by co-injection of pEGFP-N1. But when adoptive transfer of splenocytes from C3H/HeJ mice to C3H/HeN mice was carried out, there was no effect to HBsAg in sera (Figure 5A), HBV replication in liver (Figure 5B), or HBV-DNA in sera (Figure 5C). These results indicate that the TLR4 enhances the immune functions to help clear the HBV replication.

DISCUSSION

In this study, we investigated the role of TLR4 in a murine acute HBV expression model. The HBV antigenemia, serum HBV-DNA, as well as HBV transcription and replication in liver were higher in TLR4 mutant C3H/HeJ than TLR4 normal C3H/HeN. This is probably caused by the impaired induction of iNOS and HBV specific immune response because of TLR4 mutation in C3H/

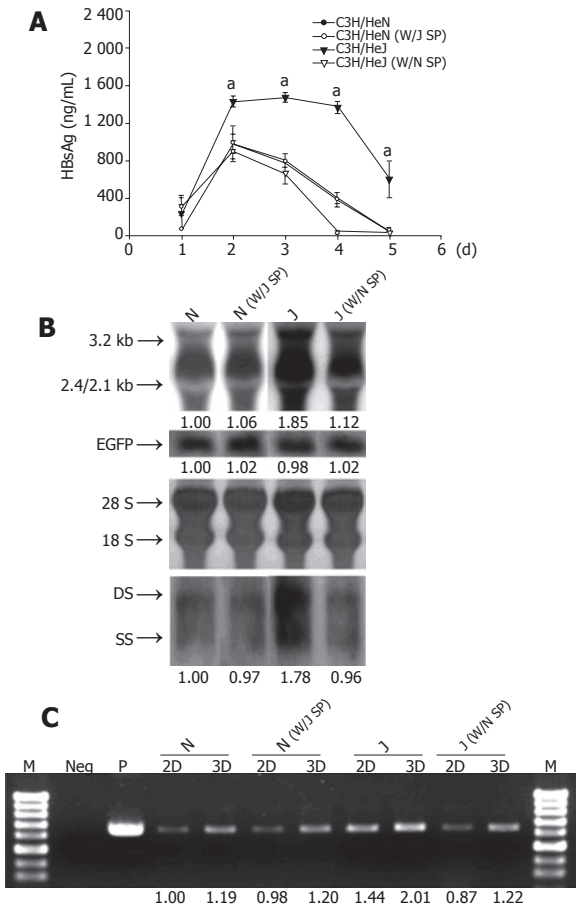

Figure 5 HBV replication was reduced in C3H/HeJ mice after adoptive transfer of splenocytes from C3H/HeN mice. 5×10^6 splenocytes from C3H/HeN or C3H/HeJ mice were injected into C3H/HeJ or C3H/HeN mice intravenously at the day before pHBV3.6 injection, respectively. (**A**) The HBsAg in sera was detected as indicated day by ELISA. $^aP<0.05$. (**B**) The total RNA or cytoplasmic DNA of liver was isolated at day 3 and was further analyzed for HBV transcription or replication by Northern or Southern blot. The transfection efficiency was verified by co-injection of pEGFP-N1 and EGFP RNA confirmation. The number below each land of Northern or Southern blot was represented as the relative fold of expression comparing to C3H/HeN mice. N, C3H/HeN; J, C3H/HeJ; SP, splenocytes. (**C**) The HBV-DNA in sera was isolated as on the indicated day and detected by PCR method. The number below each land was represented as the relative fold of expression comparing to day 2 result of C3H/HeN mice. M, 100-bp DNA ladder; Neg, no template control; P, pHBV3.6 5 ng; N, C3H/HeN; J, C3H/HeJ; SP, splenocytes.

HeJ mice, and suggests that TLR4 plays an antiviral role in HBV replication. Recently, Isogawa *et al*. reported that TLR signaling which includes TLR4 could inhibit HBV replication in transgenic mice model and the mechanism might be through the induction of type I interferon[22]. Our finding of iNOS and HBV specific immune response has increased further understanding on anti-HBV response in addition to the induction of type I interferon.

The TLRs are pattern-recognition receptors that have an important role in mammalian immunity[7,8]. At least 10 TLRs are expressed on a variety of cell types including immune cells, endothelial cells[23], cardiac myocytes[24], and intestinal epithelial cells[25]. Most TLR ligands are conserved pathogen-associated molecular patterns of microbes and the TLR signals serve as a sensor to the presence of infection[13]. TLR4 is the first identified mammalian TLR that expresses predominantly on macrophages and dendritic cells (DCs)[5]. A point mutation ($His^{712}\rightarrow Pro^{712}$) in the Toll/interleukine-1 receptor domain of TLR4 gene causes the C3H/HeJ mice to become defective after LPS challenge[20,26]. TLR4 has been shown to initiate a response to the fusion protein of RSV[11]. Prolonged RSV infection was found in TLR4-deficient mice because of the impaired recruitment of natural killer cells and $CD14^+$ cells in the lung tissue as well as the impaired IL-12 production[27]. Two vaccinia virus ORFs, A46R, and A52R, have been shown to share amino acid sequence similarity to TIR domain, and these two proteins can partially or potentially inhibit the IL-1 and TLR4 mediated NF- κ B activation[28]. These reports indicate that TLR4 also has anti-virus activity in addition to its anti-bacterial function.

In our study, the IHLs nearby the HBsAg-positive hepatocytes (which represented HBV-replicating hepatocytes) expressed TLR4 post pHBV3.6 hydrodynamic transfection (Figure 1). The HBV replication was higher in TLR4 mutant C3H/HeJ than C3H/HeN mice (Figure 2). This is probably caused by the impaired specific anti-HBV immunity in liver or spleen (Figure 3). When adoptively transferring splenocytes from TLR4 normal C3H/HeN mice to TLR4 mutant C3H/HeJ mice, the anti-HBV responses could be upregulated (Figure 5). These results indicate that anti-HBV specific immune responses may be initiated by TLR4 activation. Activation of DCs by LPS through TLR4 has been found to induce IL-12 production and elicit the Th1 responses against intracellular pathogens[29]. In our study, the IL-12 production in splenocytes after HBsAg or HBcAg stimulation (Figure 3D) and IFN-γ production in IHLs (Figure 3A) was also impaired in the C3H/HeJ mice. These results correlated with the impaired function of TLR4 in the C3H/HeJ mice.

TLR4 can signal to induce iNOS expression. After TLR4 agonist stimulation, iNOS gene could be induced through MyD88-dependent (NF-κB) or -independent (IFN-β and STAT-1) pathway in murine macrophage cell line[21]. We have also reported the role of iNOS in anti-HBV response[15]. The iNOS induction in the infiltrating immune cells was impaired in C3H/HeJ mice (Figure 4). Therefore, the iNOS may also involve in the TLR4-mediated anti-HBV responses. In conclusion, the present study reports that TLR4 plays an anti-HBV role in acute HBV expression through induction of iNOS expression and specific anti-HBV immune responses.

Abstract

AIM: To explore the effect of He Jie Tang (decoction for medication) on serum levels of T lymphocyte subsets, NK cell activity and cytokines in chronic hepatitis B patients.

METHODS: Eighty-five patients with chronic hepatitis B were divided randomly into two groups. Fifty patients in group I were treated with He Jie Tang (HJT) and 35 patients in group II were treated with combined medication. The levels of T-lymphocyte subsets (CD_3^+, CD_4^+, CD_8^+), NK cell activity, cytokines (TNF-α, IL-8, sIL-2R) were observed before and after the treatment. Another 20 normal persons served as group 3.

RESULTS: The level of CD_4^+ cells and NK cell activity were lower, whereas the level of CD_8^+ cells in patients was higher than that in normal persons (t = 2.685, 3.172, and 2.754 respectively; P<0.01). The levels of TNF-α, IL-8, and sIL-2R in chronic hepatitis B patients were higher than those in normal persons (t = 3.526, 3.170, and 2.876 respectively; P<0.01). After 6 months of treatment, ALT, AST, and TB levels in the two groups were obviously decreased (t = 3.421, 3.106, and 2.857 respectively; P<0.01). The level of CD_4^+ cells and NK cell activity were increased whereas the level of CD_8^+ cells decreased (t = 2.179, 2.423, and 2.677 respectively; P<0.05) in group I. The levels of TNF-α, IL-8, and sIL-2R in group I were decreased significantly after the treatment (t = 2.611, 2.275, and 2.480 respectively; P<0.05) but had no significant difference in group II after the treatment (t = 1.906, 1.833, and 2.029 respectively; P>0.05). The total effective rate had no significant difference between the two groups (χ^2 = 2.882, P>0.05) but the markedly effective rate was significantly different between the two groups (χ^2 = 5.340, P<0.05).

CONCLUSION: HJT is effective in treating chronic hepatitis B. HJT seems to exert its effect by improving the cellular immune function and decreasing inflammatory cytokines in chronic hepatitis B patients. The function of HJT in protecting liver function in the process of eliminating virus needs to be further studied.

INTRODUCTION

Chronic hepatitis B virus (HBV) infection is a serious clinical problem worldwide and may lead to end-stage liver disease, cirrhosis, and hepatocellular carcinoma (HCC), *etc.*[1-3]. The pathogenesis of hepatitis B is very complex and has not been clarified. Generally, HBV itself does not directly damages hepatocytes, but results in dysfunction of cell-mediated immunity[3-5]. Peripheral blood mononuclear cells (PBMCs), which are aggregated immunologically competent cells, such as T lymphocytes, natural, and lymphokine-activated killer cells, likely play an important role in anti-HBV infection.

Some agents such as interferon (INF) and lamivudine have been proved to be effective for chronic hepatitis B, but their efficacy is limited to a small percentage of highly selected patients[6-13]. The management of chronic hepatitis B remains a clinical challenge.

Traditional Chinese medicine (TCM) has a long history in treating hepatitis, and has been proven to have good curative effects and fewer side effects in treating acute and chronic liver diseases. HJT is a recipe for chronic hepatitis B, which can improve liver function and immunity of chronic hepatitis B patients as the seroconversion rate of HBeAg[14]. In order to analyze the immunoregulatory mechanisms of HJT, we treated chronic hepatitis B patients with HJT from June 1999 to March 2003 and

observed the clinical effect of HJT on T lymphocyte subset level, NK cell activity as well as TNF-α, IL-8, and sIL-2R level.

MATERIALS AND METHODS

Patients

A total of 85 patients with chronic hepatitis B were enrolled in this study and randomly divided into two groups. There were 27 males and 23 females aged 18-60 years (mean 36.9±9.5 years) in group I. There were 19 males and 16 females aged 18-60 years (mean 38.5±9.1 years) in group II. The difference in clinical data between the two groups was insignificant. Twenty age-matched healthy donors from the Blood Center of our hospital were assigned as group III. This prospective study was approved by the local ethics committee and written consent was obtained from the participants.

Diagnostic criteria

Patients with a history of hepatitis B or HBsAg carriers for at least 6 mo, who still had symptoms and signs of hepatitis as well as abnormal liver function and positive HBsAg, HBeAg and HBV-DNA, were diagnosed as chronic hepatitis B in the present study.

Criteria for enrollment

Patients, aged 18-60 years with their serum alanine aminotransferase (ALT) level being 80-240 μ/L and who had positive serum HBeAg and HBV-DNA, were enrolled. The diagnosis of hepatitis B was made in accordance with the standards for chronic viral hepatitis issued in the Fifth National Conference on Infectious Diseases and Parasitosis (Beijing, China, 1995).

Criteria for exclusion

Patients aged over 60 years or less than 18 years, patients in pregnancy or in breast feeding period; patients who had hepatitis C or other hepatic viral infection, autoimmune hepatitis and drug-induced hepatitis or alcoholic hepatitis; patients with severe complications of the cardiovascular, renal or hematopoietic system and patients with mental diseases, were excluded.

Group I was treated with HJT that consisted of 10 g Radix Bupleuri, 12 g Radix Scutellariae, 9 g Rhizoma Pinelliae, 30 g Radix Codonopsis Pilosulae, 6 g Radix Glycyrrhizae Praeparata, 9 g Fructus Ziziphi Jujubae, 30 g Rhizoma Polygoni Cuspidati, 8 g Radix Morindae Officinalis, 30 g Herba Hedyotis Diffusae. One dose was taken per day for 6 mo. Group II was treated with oxymatrine (200 mg, t.i.d.), compound vitamin B (2 tablets, t.i.d.), vitamin C (100 mg, t.i.d.), vitamin E (50 mg, t.i.d.), and ester capsule (2 tablets, t.i.d.) for 6 mo.

Patients who had normal serum ALT and sero-conversion of HBeAg and HBV DNA (quantitative PCR) after treatment were defined as responders while those with negative results as non-responders.

Recording and observation of symptoms and signs

The symptoms and signs of patients were recorded in detail using the "Clinical Observation Table" once a month before and during the treatment.

Etiological markers of hepatitis B

HBV-M and anti-HAV, anti-HCV, anti-HDV, and anti-EBV marks were detected by enzyme-linked immunosorbent assay (ELISA). HBV-DNA was detected by quantitative polymerized chain reaction (PCR).

Liver function

The patients had liver function examination every month during the treatment, including contents of serum proteins, total bilirubin (TB) and activities of ALT and AST (aspartate aminotransferase).

T-lymphocyte subsets and NK cell activity

T-lymphocyte subsets were detected by the single clone antibody APAAP method, NK cell activity was assayed by MTT colorimetry.

Detection of cytokines

The levels of TNF-α, sIL-2R, and IL-8 were detected by double antibody sandwich ELISA.

Statistical analysis

All statistical analyses were performed by χ^2 test and Wilcoxon rank sum test using SPSS software. $P<0.05$ was considered statistically significant.

RESULTS

Standard for efficacy evaluation

The clinical efficacy of treatment was evaluated according to the following standards. Markedly effective: chief symptoms including right upper abdomen pain, poor appetite, and abdominal distention disappeared; HBeAg and HBV-DNA turned negative; serum levels of ALT, AST, and TBIL restored to normal. Effective: chief symptoms were alleviated or improved; the level of HBV-DNA decreased; HBeAg did not turn negative; serum levels of ALT, AST, and TBIL decreased by >50% of the original levels. Ineffective: the chief symptoms or the serum levels of ALT, AST, and TBIL or HBeAg and HBV-DNA did not show any improvement.

Clinical efficacy of treatment

In group I, treatment was markedly effective in 7 cases, effective in 41 and ineffective in 2, the total effective rate being 96.0%. In group II, treatment was markedly effective in 0 cases, effective in 30, and ineffective in 5, the total effective rate being 85.7%. The difference in total effective rate was insignificant between the two groups ($P>0.05$) and the markedly effective rate was significantly different between the two groups ($P<0.05$).

Levels of ALT, AST, TB, and HBV-DNA before and after the treatment

After 6 mo of treatment, the levels of ALT, AST, and TB in two groups were obviously decreased ($P<0.01$). HBV-DNA level in group I was obviously decreased ($P<0.05$). HBV-DNA and HBeAg turned negative in seven patients and HBeAg turned negative in two patients but HBV-DNA did not turn negative. HBeAg turned negative in two patients of group II but HBV-DNA did not turn negative (Table 1).

T lymphocyte subsets before and after the treatment

The level of CD_4^+ cells was lower whereas the level of CD_8^+ cells (groups I and II) was higher in patients than in normal persons (group III) ($P<0.01$). There was no significant difference between the levels of CD_3^+ cells in patients and normal persons ($P>0.05$). After 6 mo of treatment, the level of CD_4^+ cells increased, whereas the level of CD_8^+ cells decreased ($P<0.05$) in group I. However, the levels of CD_4^+ and CD_8^+ cells had no significant difference in group II ($P>0.05$, Table 2).

Serum levels of TNF-α, sIL-2R, and IL-8 as well as NK activity before and after the treatment

The NK cell activity was lower whereas the levels of TNF-α, sIL-2R, and IL-8 was higher in patients (groups I and II) than in normal persons (group III) ($P<0.01$). After 6 mo of treatment, NK cell activity was significantly increased, whereas the levels of TNF-α, sIL-2R, and IL-8 decreased ($P<0.05$) in group I. However, there was no significant difference in group II ($P>0.05$, Table 3).

T lymphocyte subsets and NK activity of responders and non-responders of group I before and after the treatment

The levels of CD_3^+, CD_4^+, and CD_8^+ cells and NK cell activity in the two groups had no significant difference before treatment ($P>0.05$). After 6 mo of treatment, the level of CD_4^+ cells and NK cell activity increased, whereas the level of CD_8^+ cells decreased in responders ($P<0.05$). NK cell activity and the level of CD_4^+ and CD_8^+ cells in the non-responders had no significant difference after treatment ($P>0.05$, Table 4).

DISCUSSION

Though the pathogenesis of chronic hepatitis B remains unclear, a great many studies have shown that chronic hepatitis B patients are usually accompanied with disorder of immune function and hepatocyte damage is mainly caused by immunological injury[15–19]. Alterations of T

lymphocyte subsets and NK cells are important reasons for the disorder of immune function due to HBV infection, TNF-α, IL-8, and sIL-2R are important cytokines associated with liver damage. Therefore, the importance of T lymphocytes and NK cells as well as cytokines in the occurrence of chronic HBV infection has received more and more attention.

CD_3^+, CD_4^+, and CD_8^+ cells are major function subgroups of T cells. An antiviral cellular immune response of CD_4^+ and CD_8^+ is the important mechanism of hepatocyte injury induced by HBV, the specific response of CD_4^+ and CD_8^+ to the virus antigen is closely related with the elimination of the virus[6,20,21]. NK cells play a critical role in host innate defense against viruses and are partly responsible for liver injury in the process of erasing viruses[22-28]. Recent studies found that NK cells are potent activators of dendritic cells (DCs), which have an impact on the magnitude and direction of DC activation of T cells under the conditions of chronic viral infection, activated NK cells can release cytokines and prevent virus from reproducing[23,29]. Therefore, T-lymphocyte subsets and NK activity can be considered as an appropriate response of immune system to inhibit viral replication and HBV eradication. In the present study, we discovered that in the outbreak period of chronic hepatitis B, NK activity and level of CD_4^+ cells were lower, whereas the level of CD_8^+ cells was higher in patients than in normal persons, suggesting that disorders of cellular immune function and pathologic damages occur in chronic hepatitis B patients.

The serum NK activity and CD_4^+ cell level in non-responders were lower than those in normal persons, whereas the level of CD_8^+ cells in non-responders was higher than that of normal persons. After treatment, the NK activity and CD_4^+ cell level were increased in seven patients with the conversion of HBV-DNA and HBeAg and the liver function resumed to normal. The results suggest that T-lymphocyte subsets and NK activity are depressed rather than activated in viral hepatitis B, but levels of T lymphocyte subsets and NK activity are closely related with different courses of hepatitis B. At the same time, levels of T lymphocyte subsets and NK activity in some patients were still low in palliative period, indicating that the chance of recrudescence might increase. T lymphocyte subsets and NK cells play a critical role in response to HBV infection and their level and mutual relation can be used to identify the cellular immune level in patients with chronic hepatitis B[11,38].

TNF-α plays an indispensable role in liver injury mediated by specific immune response to HBV infection[30]. Pretreatment with anti-TNF-α mAb in animal model strongly blocks Th1 cell-induced hepatocyte necrosis and apoptosis[32]. However, it was reported that TNF-α exerts its antiviral effects without destruction of hepatocytes[33]. IL-8 is a chemotactic factor of neutrophils and T cells and plays a role in hepatic injury in patients with chronic viral hepatitis. Remarkable increase of IL-8 leads to accumulation of cytotoxic T lymphocytes, which get direct and immediate access to the target hepatocytes and the resident intrahepatic macrophages, subsequently causing the damage of hepatocytes[34-36]. Release of sIL-2R from activated T lymphocytes may occur as a result of proteolysis of mIL-2R or as a result of alternative mRNA process. High level of sIL-2R in chronic HBV infection appears directly related to the activity of liver diseases; therefore, serum sIL-2R levels can be used to indicate the degree of liver damage in patients with chronic HBV infection[31,37,38].

In the present study, we discovered that in the outbreak period of chronic hepatitis B, the levels of IL-8, TNF-α, and sIL-2R were higher in patients than in normal persons during and after HJT treatment, significantly increased suggesting that cytokines and immunocytes may play a role in the pathogenesis of chronic hepatitis B.

HJT is a recipe for treating hepatitis in which cold and warm drugs are used to eliminate evils and restore healthy energy. Former research indicates that HJT can protect the liver from injury[20,21]. We discovered that HJT could improve liver function and NK activity, regulate T cellular immune function in chronic hepatitis B patients. The results suggest that HJT exerts its effect by improving the cellular immune function and decreasing inflammatory cytokines in chronic hepatitis B patients.

Abstract

AIM: To assess the frequency of herpes simplex virus type I in upper gastrointestinal tract ulcers and normal mucosa with the modern and better assays and also with a larger number of well characterized patients and controls and its relationship to *Helicobacter pylori*(H *pylori)*.

METHODS: Biopsy specimens from 90 patients (34 with gastric ulcer of the prepyloric area and 56 with duodenal ulcer) were evaluated. Biopsies from 50 patients with endoscopically healthy mucosa were considered as the control group. The method used to identify herpes simplex virus-1 (HSV-1) was polymerase chain reaction. *H pylori* was detected by the CLO-test and by histological method.

RESULTS: Herpes simplex virus-1 was detected in 28 of 90 patients with peptic ulcer (31%) [11 of 34 patients with gastric ulcer (32.4%) and 17 of 56 with duodenal ulcer (30.4%)] exclusively close to the ulcerous lesion. All control group samples were negative for HSV-1. The likelihood of *H pylori* negativity among peptic ulcer patients was significantly higher in HSV-1 positive cases than in HSV-1 negative cases (P = 0.009). Gastric ulcer patients with HSV-1 positivity were strongly associated with an increased possibility of *Helicobacter pylori* negativity compared to duodenal ulcer patients (P = 0.010).

CONCLUSION: HSV-1 is frequent in upper gastrointestinal tract ulcers but not in normal gastric and duodenal mucosa. There is an inverse association between HSV-1 and *H pylori* infection.

Key words: HSV-1; Herpes simplex virus type 1; Peptic ulcer; Duodenal ulcer; Gastric ulcer; PCR; Polymerase chain reaction; *H pylori*; Non-steroidal anti-inflammatory drugs

INTRODUCTION

During the last two decades, a significant progress has been made in the role of *Helicobacter pylori*(*H pylori*) in the pathogenesis of peptic ulcers, while the invention of new powerful antisecretory drugs has changed dramatically the treatment of the disease. However, the exact etiopathogenesis of peptic ulcer disease is still under investigation.

The significant role of gastric acidity and inflammation of mucosa due to *H pylori* cannot be disputed, but a multifactorial etiology for peptic ulcer disease seems to be emerging[1-3].

The idea of a possible correlation between HSV-1 and peptic ulcers has appeared almost 40 years before[4,5], due to many common characteristics observed in the clinical picture and the natural history of both diseases[4-7].

A possible involvement of HSV-1 in peptic ulcer disease was reported from several investigators, but a firm conclusion has not yet been reached. The vast majority of these studies are based on the detection of antibodies against the virus in the serum and the duodenal juice of patients with peptic ulcer[8-12], a finding also common in the apparent healthy population. There are only two studies that report the presence of HSV-1 in tissue samples obtained from gastric and duodenal ulcers, using polymerase chain reaction (PCR) methods, but the number of the examined populations is small[13,14]. On the other hand, in the studies reported above, a possible correlation between HSV-1 and *H pylori* has been investigated in the

pathogenesis of peptic ulcer disease.

DNA of HSV-1 has been detected also in human vagal[15] and celiac ganglia[16], which provide the nerve network to gastric tissue. Theoretically, since vagotomy is used to treat peptic ulcer disease, the same treatment may interrupt the migration of activated HSV-1 from ganglia to gastric mucosa, thus preventing the recurrence of ulcer.

The purpose of this study was to investigate the possible relationship between HSV-1 and peptic ulcer and whether viral infection of ulcer patients is related to the presence of *H pylori* infection.

MATERIALS AND METHODS

Patients and biopsies

All patients who underwent esophagogastroduodenoscopy at our institution from September 1999 to September 2002 were recruited. The first group included 56 patients (31 men and 25 women) with active duodenal ulcer (average 53.5±15 years, range from 19 to 83 years). The second group included 34 patients (22 men and 12 women) with active ulcer of the prepyloric area of the stomach (mean of 61.5±16.2 years, range from 22 to 89 years) and the third group that formed the control group, consisted of 50 patients (28 men and 22 women) with no evidence of pathologic findings (mean of 54.8±16.7 years, range from 21 to 86 years).

Tissue samples were taken from all 90 patients with peptic ulcer for the detection of HSV-1 in duplicate, from the following areas: the base and the rim of the ulcer; the adjacent area of the ulcer at a distance of 3 cm (minimal and maximal distance from the crater 3 and 5 cm respectively). For this reason, in the duodenal ulcer group a second duodenal biopsy was obtained; an endoscopically normal area of the stomach (the corpus in gastric ulcer cases and the antrum in duodenal ulcer cases).

Two samples were also taken from endoscopically healthy areas of the antrum and corpus of the stomach in all 50 controls.

Two samples from the antrum and two from the corpus of the stomach were taken for the detection of *H pylori* using the rapid urease test (CLO-test) and routine histology.

Finally, specimens from the gastric ulcers were examined histopathologically to exclude malignancy.

Risk factors probably involved in the pathogenesis of peptic ulcer, such as non-steroidal anti-inflammatory drugs (NSAIDs), smoking, alcohol, history of herpes labialis, family history of peptic ulcer, and ulcer site, were recorded and analyzed.

DNA extraction

Genomic DNA was extracted using the QIAamp DNA mini kit, following the protocol supplied for purification from fresh tissues. DNA was finally dissolved in 50–100 μL of TE buffer depending on the size of DNA pellets and stored at -20 °C until amplification.

Primer design

For the nested PCR assay, oligonucleotides deduced from the published sequence of the RL2 gene-coding region from HSV-1 were used[17]. For the control DNA assay, oligonucleotides for b-actin gene were used. The primer sequences and characteristics are shown in Table 1.

Table 1 Characteristics and nucleotide base sequences of primers used for nested PCR and control assays

Gene target	GenBank accession number	Product size (bp)	Sequences[1]	T_m (°C)
HSV-1: RL2	X14112	450	Outer sense agcagcgactctgaggcggagaccg	69.1
			Outer antisense tgcgggtctgggggtcgttcacga	71.4
		110	Inner sense cccggcagttgcgggggcgc	73.4
			Inner antisense aaggtgtcgcagcggcaggtg	60.8

			Reverse ctcttccagccttccttc	52.7

T_m, melting temperature. [1]Sequences shown are in the 5′ to 3′ direction.

Nested PCR amplification and detection assay of HSV-1

B-actin PCR generating a 200-bp product was performed to determine the DNA integrity of the samples. For the quality control PCR assay, the following program was used 1 cycle at 94 °C for 2 min; 35 cycles at 94 °C for 30 s, at 58 °C for 30 s, at 72 °C for 30 s; and a final cycle at 72 °C for 7 min.

PCR detection of HSV-1 was carried out in a 50 μL reaction mixture containing 25 μL of Taq PCR master mix solution (Qiagen), 13 μL of double-distilled DNase-free water, 1 μmol/L concentration of each primer and 10 μL of the extracted sample. PCR was performed on a PE 9 600 thermocycler (Perkin-Elmer Cetus, Branchburd, NJ, USA). The cycling conditions were at 94 °C for 1 min, 5 cycles at 94 °C for 5 s and at 72 °C for 4 min; 5 cycles at 94 °C for 5 s and at 70 °C for 4 min; 30 cycles at 94 °C for 5 s and at 68 °C for 4 min. After the final cycle, tubes were incubated for an additional 10 min at 72 °C. Nested PCR amplification was done with a 0.5 μL aliquot from the first run, 25 μL of Taq PCR master mix solution, 18 μL of double-distilled DNase-free water and 1 μmol/L concentration of each inner primer under the following cycling conditions: at 94 °C for 2 min; 35 cycles at 90 °C for 30 s, at 68 °C for 30 s, at 72 °C for 30 s and a final extension at

72 °C for 10 min. Each amplification run contained one negative and one positive control. The negative control consisted of blank reagent and water. For the positive control, HSV-1 genomic DNA provided by Sigma was used. Consistent PCR analyses were repeated twice or more.

The PCR products were analyzed by 2% agarose gel electrophoresis in 0.5×Tris–borate EDTA buffer along with ethidium bromide. A molecular weight marker (Φ× 174/Hae III, Sigma) was also run simultaneously to identify the molecular size of the PCR products. The DNA bands were visualized by UV transillumination and analyzed using a gel-documentation system. None of the PU and the control samples were negative in the b-actin test ultimately leaving 90 PU and 50 controls that were subjected to HSV-1 PCR analysis.

Helicobacter pylori testing

For the detection of *H pylori*, a CLO-test was used with high sensitivity and specificity (Kimberly-Clark CLO test, Ballard Medical products, Draper, UT 84020, USA)[18,19].

An experienced pathologist also assessed the histological sections with Giemsa stain[20].

Statistical analysis

All associations between parameters of interest were examined either by Fisher's exact test or Pearson's *chi square* test with continuity correction.

Multivariate analysis was performed using the stepwise logistic regression model to assess the contribution of the common risk factors to peptic ulcer development and *H pylori* detection.

$P<0.05$ was considered statistically significant.

RESULTS

Polymerase chain reaction

The genome of HSV-1 was present in 28 of the 90 patients with peptic ulcer (31.1%), contrary to the control group in which no positive detections were found (0%, $P<0.0005$, Figures 1-3). There was an equal prevalence in the two subgroups of patients, 17 of 56 patients with duodenal ulcer (30.4%) and 11 of 34 with gastric ulcer (32.4%) were tested positive ($P = 0.843$). In all HSV-1 positive cases, the viral genome was detected from the tissue samples obtained from the crater of the ulcer as from the samples obtained from the rim, while all samples from adjacent and distant areas were negative.

CLO test

All the *H pylori* positive subjects by CLO test from both groups were also positive for the bacteria with histology.

The incidence of *H pylori* was significantly higher in peptic ulcer patients (76/90, 84.4%) than in controls (30/50, 60%) ($P = 0.002$). A statistically significant difference was also found between patients with duodenal ulcer and those with gastric ulcer ($P = 0.036$). Negative *H pylori* was more frequently observed in patients with gastric ulcer (26.5%) than in patients with duodenal ulcer (8.9%, Table 2).

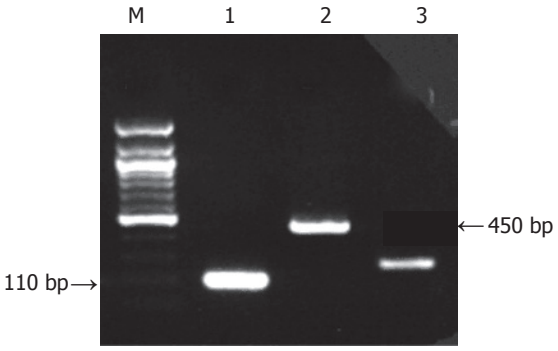

Figure 1 Nested PCR with HSV-1 outer and inner primers (450- and 110-bp amplicons: arrows) on 2% agarose gel, by ethidium bromide staining. Lane M: DNA molecular weight marker Φ×174/*Hae* III, lane 1: HSV-1 positive control (second run of nested PCR), lane 2: HSV-1 positive control (first run of nested PCR), lane 3: b-actin quality control PCR peptic ulcer sample.

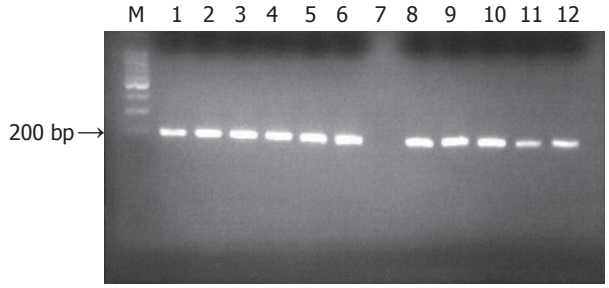

Figure 2 PCR quality assay control. Lane M: DNA molecular weight marker Φ ×174/Hae III, lanes 1-6: positive b-actin peptic ulcer samples; lane 7: negative control (without template); lanes 8-12: positive b-actin peptic ulcer samples.

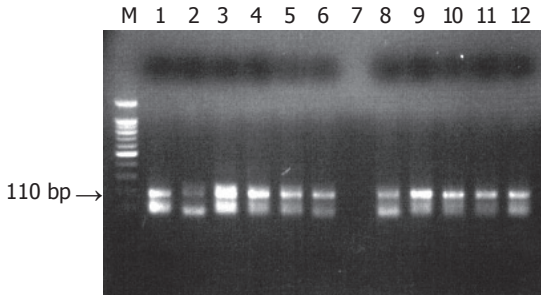

Figure 3 Nested PCR amplification of HSV-1 in samples of patients with peptic ulcer. Lane M: DNA molecular weight marker Φ×174/Hae III, lane 1: HSV-1 positive control (HSV-1 genomic DNA by Sigma), lanes 2-6: positive samples from patients with peptic ulcer, lane 7: negative control (without template), lanes 8-11: positive samples from patients with peptic ulcer, lane 12: HSV-1 positive control.

PCR and CLO test were significantly associated with respect to *H pylori* detection in all 90 peptic ulcer patients. Negative *H pylori* was more frequently detected in positive PCR samples (32.1%) than in negative PCR samples (8.1%) ($P = 0.009$) (Table 2). In the group of duodenal ulcer patients, *H pylori* negativity was more frequently observed in positive PCR samples (11.8%), than in negative PCR samples (7.7%). However, this difference was not

HSV-1 (+)/gastric ulcer, patients with gastric ulcer positive for HSV-1; HSV-1 (–)/gastric ulcer, patients with gastric ulcer negative for HSV-1; HSV-1 (+)/duodenal ulcer, patients with duodenal ulcer positive for HSV-1; HSV-1 (–)/duodenal ulcer, patients with duodenal ulcer negative for HSV-1; CI, confidence interval.

Table 3 Association between *H pylori* and HSV-1 in relation with the site of peptic ulcer

	H pylori (+), %	*H pylori* (-)	*P*-value	Odds ratio (95% CI)
HSV-1(+)/ gastric ulcer	4/11 (36.4)	5/11	0.010	13.13 (1.92–89.5)
HSV-1(–)/ duodenal ulcer	15/17 (88.2)	2/17		

HSV-1 (+), patients positive for HSV-1; CI, confidence interval.

statistically significant ($P = 0.634$) (Table 2) whereas it was statistically significant in the subgroup of gastric ulcer patients ($P = 0.002$). In the gastric ulcer subgroup, *H pylori,* negative cases were observed in 63.6% of positive PCR samples and in 8.7% of negative PCR samples (Table 2). Finally, the likelihood of negative *H pylori* in HSV-1 positive samples in the group of gastric ulcer patients was significantly higher than that in the group of duodenal ulcer patients ($P = 0.010$) (Table 3).

Statistical analysis of other parameters

We also studied some of the common risk factors for the development of peptic ulcer disease. No statistically significant difference was found between patients and controls regarding family history of upper gastrointestinal ulcer, history of *Herpes labialis*, alcohol consumption, and use of NSAIDs (Table 4).

As expected, tobacco smoking was the only statistically significant risk factor for the development of peptic ulcers between patients and control population ($P = 0.019$). Smokers were associated with a 2.57-fold increase risk of peptic ulcer development.

The performed multivariate analysis also confirmed that *H pylori* and tobacco smoking (OR: 3.320 and 2.619 respectively) were more likely to induce peptic ulcer (Table 5).

Table 4 Risk factors and peptic ulcer disease

DISCUSSION

Despite the progress during the last 20 years in the understanding of the pathogenesis of peptic ulcer disease, it is clear that gastroduodenal ulcer is the result of a multifactorial process.

H pylori infection and NSAIDs have been recognized as the two most important causes of peptic ulcer disease. The proportion of peptic ulcers not associated with *H pylori* infection or the use of NSAIDs is increasing. Yet several studies have shown that 4.1-44% of peptic ulcers are not related to either of the two factors[21-25].

The possible involvement of HSV-1 in the process is a field of interest for several investigators, but a firm conclusion has not been reached. The presence of viral DNA in tissue samples obtained from the ulcer site is 9.5-18%[13,14]. The possible explanation for this finding is that the HSV-1 expression is prompted either by the ulcer injury or by immune cells[14,16] or HSV-1 itself might cause the ulcerative lesion by directly infecting the mucosal cells[13] or finally that HSV-1 expression is induced by the ulcer treatment[26-28].

In the present study, in a substantially larger number of patients than in the studies reported above (90 *vs* 22 and 21 respectively), the positivity for HSV-1 DNA was expressed using PCR in a greater percentage of samples (31% *vs* 9.5% and 18% respectively).

It should be noted that viral DNA was detected only in the tissue samples obtained from the base and the rim of the lesions, whereas all the other examined samples obtained from the adjacent ulcer areas and endoscopically healthy mucosa from the patients and the control group were negative for the viral genome.

This finding can be explained as follows. The HSV-1 may have initially entered the vagus ganglia through the oral pharynx or other peripheral connecting sites. Upon activation, the virus would travel down the vagal nerve to the potential site of peptic ulcer lesion. HSV-1 itself might cause ulcerative lesion in selected cases of a subset of peptic ulcer diseases by directly infecting the mucosal cells in the stomach and duodenum following virus release from neuroendocrine cells or vagal nerve terminals or both. Alternatively, peptic ulcer might activate latent HSV-1 in vagal ganglia, making replication of HSV-1, a contributing but not an initiating factor of ulcer[13].

The detection percentage of positive HSV-1 was similar between the group of patients with gastric and the group of patients with duodenal ulcer (32.4% and 30.4% respectively), in contrast to previous studies, where the viral DNA is demonstrated only in tissue samples from gastric ulcers[13,14]. The exact cellular localization of HSV-1 DNA could not be identified.

On the other hand, investigating a possible association between *H pylori* and HSV-1 in pathogenesis of a subset of gastroduodenal ulcers, our data suggest that the PCR HSV-1 positivity is associated with a 5.4-fold increase in negative *H pylori* detection. Moreover, the patients with ulcer lesions infected with HSV-1 presented a similar prevalence of *H pylori* infection as the control group, which was significantly lower than that in the HSV-1 negative ulcer cases ($P = 0.09$). This finding requires further investigation.

Possible interpretations for the increased HSV-1 DNA positive detection rate in *H pylori* negative ulcers include the following. *H pylori* negativity is influenced by the viral expression, HSV-1 negativity influences *H pylori* infection and the virus independently causes some gastroduodenal ulcers.

According to our results, in the subgroup of patients with duodenal ulcers, the risk of *H pylori* infection was independent from HSV-1 DNA expression ($P = 0.634$). On the other hand, in the subgroup of patients with gastric ulcer disease, the possibility of *H pylori* negativity was 18.5-fold higher ($P = 0.002$). These data are in accordance with those reported by Lohr *et al*.[13].

Additionally, according to our results, there was not any correlation between peptic ulcer disease and age, sex, ulcer site, family history of gastroduodenal ulcers, history of *H. labialis*, alcohol consumption and NSAIDs use. On the contrary, statistically significant difference ($P = 0.019$) was observed between patients with peptic ulcers and controls, as far as smoking was concerned.

Our results indicate an involvement of HSV-1 in the pathogenesis of peptic ulcer disease. Although an opportunistic infection with the virus in the ulcer site cannot be excluded, the inverse relationship between HSV-1 detection and *H pylori* infection indicates a possible implication of this virus in the formation of the ulcer crater, at least in a subgroup of patients. Furthermore, experimental data support this[13,15,16,30,31]. The exact localization of the virus in ulcer tissue cells should be precisely determined in order to clarify whether the lesion is caused by HSV-1 or the virus opportunistically is established, especially in immunocompromised patients[32].

Abstract

AIM: To evaluate endoscopic mucosal resection (EMR) in patients with high-grade dysplasia (HGD) and/or intramucosal cancer (IMC) in Barrett's esophagus (BE).

METHODS: Between June 2000 and December 2003, 39 consecutive patients with HGD (35) and/or IMC (4) underwent EMR. BE >30 mm was present in 27 patients. In three patients with short segment BE (25.0%), HGD was detected in a normal appearing BE. Lesions had a mean diameter of 14.8±10.3 mm. Mucosal resection was carried out using the cap method.

RESULTS: The average size of resections was 19.7±9.4×14.6±8.2 mm. Histopathologic assessment post-resection revealed 5 low-grade dysplasia (LGD) (12.8%), 27 HGD (69.2%), 2 IMC (5.1%), and 5 SMC (-12.8%). EMR changed the pre-treatment diagnosis in 10 patients (25.6%). Three patients with SMC underwent surgery. Histology of the surgical specimen revealed 1 T0N0 and 2 T1N0 lesions. The remaining two patients were cancer free at 32.5 and 45.6 mo, respectively. A metachronous lesion was detected after 25 mo in one patient with HGD. Intra-procedural bleeding, controlled at endoscopy, occurred in four patients (10.3%). After a median follow-up of 34.9 mo, all patients remained in remission.

CONCLUSION: In the medium term, EMR is effective and safe to treat HGD and/or IMC within BE and is a valuable staging method. It could become an alternative to surgery.

Key words: Endoscopic mucosal resection; Barrett's esophagus; High-grade dysplasia; Intramucosal cancer

INTRODUCTION

The incidence of adenocarcinoma (AC) of the esophagus has increased in the last three decades in the Western world[1-3]. Most esophageal adenocarcinomas arise in a precursor lesion, Barrett's esophagus (BE). The esophageal cancer risk in BE patients is about 1 cancer per 200 patient-years, or 0.5% per year[4,5]. The prognosis is poor for the typical patient who presents with invasive cancer, with a 5-year survival rate of under 10%[6].

Dysplasia arising in BE is a marker of progression toward invasive cancer. High-grade dysplasia (HGD) is an uncommon but a serious problem. In 16-60% of patients found to have HGD, invasive cancer was diagnosed in the next 5-7 years[6,7], although spontaneous regression of HGD can also occur[8]. Following surgical esophagectomy for HGD, 10-50% of cases had previously undetected foci of invasive cancer found in the resected specimen[9,10].

When HGD is detected, the three options that are available are: endoscopic surveillance, esophagectomy, and endotherapy.

Surveillance in patients with HGD is controversial. The uncertainty of natural history of HGD and its slow progression rate, could justify a contemplative attitude. Schnell *et al.* evaluated the long-term outcome of 75 patients with HGD who were enrolled in an endoscopic

surveillance program. After a mean follow-up of 7 years, AC occurred in 12 (16%) patients[7].

Esophagectomy has been the standard treatment of HGD and early cancer in BE. However esophagectomy is associated with surgical morbidity of 20-50% and mortality of about 3%, even at high-volume centers. In patients older than 70 years, mortality was 11%[11,12]. A less invasive treatment would be desirable. A newer alternative to esophagectomy is endoscopic mucosal resection (EMR). Improved diagnosis of early malignancy in BE, including endoscopic ultrasound (EUS), may change the therapeutic approach. The superficial lesions of HGD and intramucosal cancer (IMC), with minimal risk of lymph node metastasis, can be removed by EMR. This procedure allows adequate histologic assessment and definitive treatment.

The use of EMR to treat HGD and IMC in BE is increasing, but the number of published series remains less. Our aim was to evaluate EMR in the treatment of HGD and IMC in Barrett's patients in terms of complications and recurrence rate.

PATIENTS AND METHODS

Patients

Between June 2000 and December 2003, 39 consecutive patients (mean age 62.8±11.4 years) with histologically confirmed HGD (35) or IMC (4) in BE underwent EMR in three Departments of Gastroenterology acting as regional referral centers. All patients were previously identified by endoscopic examination performed in our centers or referred from other hospitals. In this case, the original histologic slides were re-evaluated by two expert pathologists (G.L., V.V.) on BE before EMR.

This study was approved by our institutional review board. All patients gave written informed consent to endoscopic therapy. Patients were evaluated and treated using the same protocol by one of the authors representing each of the three institutions.

At endoscopy, superficial lesions were defined using the following classification: slightly elevated (0-IIa), flat (0-IIb), and slightly depressed (0-IIc)[13]. Endoscopy was performed with standard diagnostic videoendoscopes (GIF-Q145, Olympus Optical Co. Ltd., Tokyo, Japan). Patients with ulcerated lesions seen on endoscopy were excluded.

Before EMR, EUS with mechanical rotating transducer, using the water-filling method (GF-UMQ130, 7.5-20 MHz, Olympus Optical Co. Ltd.), was routinely performed to assess lesion depth and mediastinal lymph node status. All patients had a CT scan of the thorax. Only lesions confined to the mucosal layer with no apparent lymph node metastases were considered for EMR.

Deep sedation with propofol was used. EMR was performed using a plastic cap (MH-594, Olympus Optical Co. Ltd, Tokyo, Japan) preloaded on the tip of a standard diagnostic forward-viewing endoscope. The cap had an outer diameter of 13 mm and a length of 15 mm. Inside the distal end of the cap was a gutter, which positions the opened polypectomy snare. A 2-mm segment of the gutter was removed with a scalpel before placement on the endoscope tip. This modification was then aligned with the operative channel to avoid interference by the injection needle or other devices (hemoclips, biopsy forceps). Submucosal injection of epinephrine solution (1:60.000-1:100.000) to create a fluid cushion was performed using variceal injection needles (VIN-23, Wilson Cook Medical Inc; Variject Contrast Injection Needle, Boston Scientific) in all patients. Injected volume ranged between 8 and 30 mL, depending on the lesion diameter. Methylene blue was added to the solution for visual enhancement of the fluid cushion in contrast to the lesion. The cap was next applied against the lesion, which was aspirated into it. A monofilament polypectomy snare (SD-221U-25, Olympus Optical Co. Ltd, Tokyo, Japan) was then firmly secured around the tissue and resection was performed. Resection was performed by endocut mode only, using the ERBE-ICC 200 cautery device (ERBE Elektromedizin GmbH, Tubingen, Germany). The output setting predefined by the manufacturer was adopted: cut 120 W, coagulation 60 W. To minimize interobserver variability among the three endoscopists performing EMR, the diameter of the lesion and the resected areas were estimated by placing an open polypectomy snare around the lesion. In patients with lesions ⩽12 mm wide "en-bloc" resection was performed. For larger lesions, piecemeal resection was completed by applying the cap close to the previously resected area. Specimens were aspirated into the cap and all materials were retrieved for histopathologic assessment. To complete EMR, multiple withdrawals and re-intubations were needed. No overtube was used.

Intra-procedural bleeding (during the EMR) was controlled by epinephrine-saline injections (1:10.000) and, when required, by placing hemoclips (HX-600-090L; rotatable clip fixing device HX-6UR-1, Olympus Optical Co., Ltd).

All patients were hospitalized for 48 h. They were kept fasting for 24 h, then a soft diet was advised for the next two weeks. After EMR, an intravenous PPI (omeprazole, 40 mg/d) was administered for 24 h, followed by a maintenance oral dose of 40 mg/d.

Surveillance

Following EMR, patients were contacted by phone weekly in the first fifteen days, then monthly, to monitor for symptoms such as dysphagia. Endoscopy was repeated at 3, 6, and 12 mo and then yearly, with multiple biopsies from the EMR site, and four-quadrant biopsies from the residual BE.

Complete remission was defined, when well demarcated areas of squamous re-epithelialization without mucosal irregularities, were observed. A lesion was considered metachronous, when diagnosed more than 12 mo from the EMR, irrespective of its location.

Histology

Following the WHO guidelines, we defined HGD by cytologic and architectural changes confined to the

mucosa. IMC was defined by cytologic and architectural changes confined to the lamina propria. Invasive cancers were considered to be those infiltrating the submucosa (SMC)[14,15].

Statistical analysis

Statistical data were expressed as mean±SD. The Kruskal-Wallis test was used to compare histologic severity with lesion size. A P value of 0.05 or less was considered statistically significant.

RESULTS

EMR was performed in 39 patients, 34 males and 5 females. Their mean age was 62.8±11.4 years. Thirty-six patients had type 0-IIa mucosal abnormalities and three had HGD detected by random biopsies in a normal appearing BE.

Mean Barrett's length was 4.3±2.5 cm. Long segment BE (LSBE, ⩾3 cm) was present in 27 patients. The three patients with non-visible lesions had short segment BE (SSBE). These patients underwent EMR with the aim of completely removing the metaplastic epithelium.

Lesions had a mean diameter of 14.8±10.3 mm. Histologic severity did not correlate with lesion size. The average size of reconstructed resected specimens was 19.7±9.4×14.6±8.2 mm. In all patients the EMR was completed in one session. "En-bloc" resection was performed in 19 cases with lesions of ⩽12 mm. The size of the first resected specimen by EMR-C method ranged between 8 and 12 mm.

Following EMR, the pre-treatment histology was re-classified in 10/39 patients (25.6%). Among the 35 initially diagnosed as HGD, five were found to have only LGD, but three had SMC. Of the four patients initially diagnosed as IMC, two were re-classified as SMC. EUS did not help to identify submucosal infiltration.

Table 1 shows the characteristics of patients and lesions according to the histology found in the EMR resection specimens.

Table 1 Characteristics of patients and lesions according to histology of mucosa resected at EMR (mean±SD)

	LGD	HGD	IMC	SMC (no surgery)
Age (yr)	60.6±8.8	61.76±11.8	56±4.2	73.6±8.3
BE length (cm)	6.6±4.1	3.6±1.8	3.7±1.8	5.8±3.1
Size of lesion (mm)	22.5±8.7	13±10.2	16±5.7	17.6±11.9
Metachronous lesion (%)				
No	5 (100)	24 (88.9)	2 (100)	2 (100)
Yes	-	1 (3.7)	-	-
No follow-up endoscopy (%)	-	2 (7.4)	-	-
Total	5	27	2	2

LGD: low-grade dysplasia; HGD: high-grade dysplasia; IMC: intramucosal cancer; SMC: submucosal cancer; BE: Barrett's esophagus.

Cancers

The five patients with SMC had a mean age of 73.6± 8.3 years. The mean BE length was 5.8±3.1 cm, and lesion size ranged from 5 to 30 mm. The lesions were type IIa (superficial elevated). Histologic assessment detected tiny areas of low-grade differentiation, and in two of them, lymphatic permeation. Three (7.7% of all patients) underwent esophagectomy and the histopathologic assessment showed one T0N0 and two T1N0. The remaining two patients were considered unfit for surgery due to advanced age (81 and 84 years) and/or comorbidities (cardiovascular disease). They were included in the surveillance program.

Complications

Intra-procedural bleeding occurred in four patients (10.3%), and was controlled with epinephrine injections in two, and with epinephrine plus clipping in the other two. Delayed bleeding was not seen. No patient needed blood transfusion. No perforations occurred. Retrosternal pain was present in one patient. An esophageal stenosis developed 8 mo later in a patient with LSBE (7 cm). He had a 30 mm HGD lesion and the diameter of the EMR area was 40 mm. He was successfully treated by a single bougienage.

Surveillance

Follow-up endoscopy was performed in 32 of the 34 patients without invasive cancer (94.1%), two patients declining repeat examination. The follow-up ranged from 16.3 to 72.1 mo (median 34.9 mo). In one patient (3.1%), with an original lesion of 20 mm (HGD), a metachronous lesion was detected after 25 mo. It was easily removed by EMR, and the histology showed HGD. One of the two patients with SMC, who did not undergo surgery died of cardiovascular disease 45.6 mo later, and the other was alive and cancer free at a 32.5 mo surveillance.

EUS was repeated at 3 and 6 mo after EMR. CT of the thorax and upper abdomen were also performed after 6 mo, and then after 1 year to evaluate the lymph node status and the presence of metastases. Figures 1A and 1B show endoscopic appearance of a SSBE with HGD before and three months after EMR.

DISCUSSION

The use of EMR for EC in the digestive tract was described by Inoue *et al*.[16]. We employed EMR to remove 39 focal esophageal HGD and IMC lesions of 3-30 mm size in BE, with few complications. Most lesions were flat mucosal abnormalities. Systematic biopsies were taken from the remainder of the BE to exclude non-visible multifocal lesions.

The data reported in the present study represent the first experience of EMR in BE, in Italy. Three major referral centers joined in the effort of evaluating the clinical outcome of EMR. In a period of three years a relatively small number of patients has been included in our study, especially when compared with the series

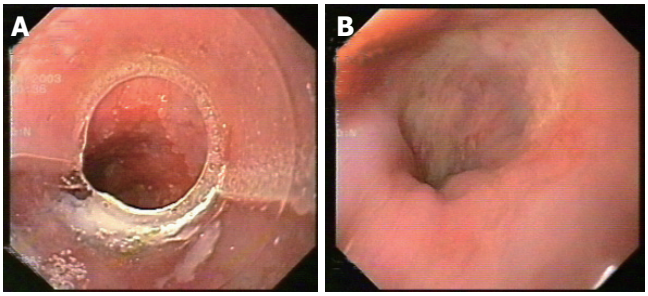

Figure 1 Endoscopic appearance of SSBE with HGD before (**A**) and 3 mo after EMR (**B**).

reported by German authors[17]. This difference is attributable to the still limited number of patients with early neoplastic lesions in BE, detected in endoscopic centers. Furthermore, as surgery is still the gold standard treatment for HGD and IM, the majority of these patients is referred for esophagectomy.

EMR could become a management option for HGD, and also for IMC, where the risk of lymph node involvement is from 0% to 4%[18,19]. Unfortunately, in cases with SMC, the incidence of regional lymph-node metastasis is 15-50%[20-22]. Current data support surgical resection in the setting of submucosal infiltration by AC, unless comorbidity or advanced patient age precluded it.

Table 2 displays data from selected studies on EMR in BE since 2000. Most published studies report EMR of endoscopically visible areas of HGD. Some of these studies differ in methodology and it is difficult to compare them. However, our results are in accordance with the data reported by other authors. EMR provides greater diagnostic precision than endoscopic biopsy, despite endoscopy with biopsies and standard EUS before EMR in all patients. In five of 39 cases, undetected SMC was found on histological examination of the resected specimen. Reclassification of the histology after EMR occurred in 26% of our patients. Other authors have reported reclassification in 0% to 75% of cases after EMR (Table 2). Causes may include biopsy sampling error and observer interpretation variability.

Bleeding is the most frequent adverse event with EMR, reported in a median 10% of patients. Intra-procedural bleeding also occurred in 10% of our patients and was managed endoscopically without transfusion. Esophageal stenosis is a late complication of EMR, reported in 0-30% of cases (Table 3). In our study, one patient (2.5%) developed stenosis. Larger EMR resections may increase the risk; in a study of 137 patients, stenosis was seen only when EMR involved more than two-thirds of the esophageal circumference[23]. However, in one report of circumferential EMR, only two of 12 patients developed stenosis[24]. The perforation risk is generally less than 1%. No perforations occurred in our series. Overall, complications seem fewer for EMR than for surgical resection. In one study, complications occurred in 48% of esophagectomies *vs* 16% for EMR combined with photodynamic therapy (PDT)[25].

A recent controlled study of 100 mucosectomies compared the cap method and a ligation method for suction EMR. The diameter of the removed specimen, the diameter of the resected area, and the complication rate showed no significant differences between the two groups, and no severe complications occurred[26].

There is limited information on the long-term effectiveness of EMR. May *et al.* followed 70 patients with HGD or early AC for a mean of 34 mo after EMR. Ten percent had minor complications. During follow-up, 21/70 patients were found to have locally recurrent or metachronous disease, treated endoscopically with success in all but one case. The only death from Barrett's AC was in a patient who had surgery for SMC[17]. In our series, follow-up for a median 35 mo was available in 94.1% of patients. One of the 39 patients (2.6%) had a metachronous lesion after 25 mo, successfully treated with another EMR. According to other authors, malignant transformation of HGD is about 34% in 6-54 mo[27], corresponding to our follow-up period. In this time range we did not find invasive AC. In our two patients with SMC who did not undergo surgery, no histologic evidence of disease was detected.

Pts: patients; EMR: endoscopic mucosal resection; EUS: endoscopic ultrasonography; HGD: high-grade dysplasia; IMC: intramucosal carcinoma; BE: Barrett's esophagus; LGD: low-grade dysplasia; AC: invasive adenocarcinoma; Bl: bleeding; EMR-C: EMR with cap; PDT: photodynamic therapy; Nos: not otherwise specified; VLD: variceal ligator device; EC: early cancer; [1]persistence of HGD.

We used EMR to remove focal lesions, but did not attempt to resect long circumferential segments of Barrett mucosa. This might seem a logical extension of the use of EMR. Removing both focal lesions and also the remainder of the BE might give greater assurance that no neoplasia or columnar mucosa remained than with PDT or thermal methods, as well as providing complete histological assessment of the mucosa. Potential risks and technical difficulties have so far limited the use of circumferential EMR, but this has now been tried. Experimentally, we assessed the feasibility of 3 cm circumferential EMR in a porcine model using EMRC. One out of four pigs developed a severe stenosis[28]. This work was advanced by Rajan *et al*. who performed more extensive EMR without complications[29]. In the clinical setting, Satodate *et al*. resected an entire 5 cm circumferential BE, together with 2 cm of gastric mucosa. The patient had early multifocal AC, with one small area of submucosal invasion. EMR was performed using the cap method in a single session, 30 separate pieces of the mucosa being removed. Following dilatations for esophageal stenosis, at 10 mo he was asymptomatic and endoscopy showed no stenosis, no recurrent cancer, and no remaining BE[30]. Seewald *et al*. performed circumferential EMR in 12 patients with HGD and IMC. Seven had no visible lesions. A monofilament polypectomy snare without a cap was used. In each case, the entire BE (median length 5 cm) was completely removed in 1-5 sessions, with a median number of 5 snare resections per endoscopic session. Four patients had minor bleeding, and two required esophageal dilations[24].

Recent advances in techniques as chromoendoscopy with methylene-blue and high-magnification endoscopy may help in identifying non-visible dysplastic lesions and in recognizing their width in Barrett's esophagus. Chromoendoscopy with methylene-blue may be useful to detect dysplastic mucosal areas. In fact, about 90% of these areas are unstained[31]. High-magnification endoscopy allows the identification of specific pit-patterns of the esophageal epithelium. Dysplasia seems to distort this pattern[32]. In our three patients with non-visible lesion in SSBE, we did not use these techniques because we performed EMR with the aim to completely remove the metaplastic epithelium.

Our study confirms that EMR is a feasible, low risk procedure to treat focal HGD and IMC within BE. Given encouraging short and medium-term results, endoscopic therapy is more often being considered as primary treatment[17]. However, controlled studies comparing EMR and esophagectomy are not available. Further experience is needed to determine the place of total removal of Barrett' s mucosa by a more extensive EMR.

Abstract

AIM: To investigate the association between cytokine gene polymorphism and disease status in chronic hepatitis C genotype 3 by liver biopsy, ALT, HCV RNA levels and response to treatment.

METHODS: Patients with chronic hepatitis C genotype 3 were analyzed for single nucleotide polymorphisms of interleukin (IL)-10, IL-1 beta, interferon-gamma (IFN-γ), tumor necrosis factor-alpha (TNF-α) and transforming growth factor-beta (TGF-β) by polymerase chain reaction using sequence-specific oligonucleotide primers. Liver biopsies were assessed by modified histological activity index (HAI) scoring system using a scale of 0–18 for grading the necro-inflammatory activity and 0–6 for staging the fibrosis. HCV RNA levels were determined by bDNA assay. The patients were treated with interferon alpha and ribavirin for 6 mo. Sustained virological response was assessed 6 mo after the completion of the treatment.

RESULTS: Out of the 40 patients analyzed, 26 were males. Mean age was 40.5±12.5 years (range 18–65 years). The frequencies of different dimorphic polymorphisms based on single nucleotide substitution were as follows: IL-10-1082 G/A 85%, A/A 12.5%, G/G 2.5%; IL-10-819 A/C 87.5%, C/C 10%, A/A 2.5%; IL-10-592 C/A 72.5%, C/C 27.5%; IL-1 C 90%, U 10%; IFN-874 T/A 50%, T/T 27.5%, A/A 22.5%; TNF-308 A/G 95%, G/G 5%; TGF-10 T/C 52.5%, C/C 35%, T/T 12.5%. The mean grades of necro-inflammatory activity of different genotypes of IL-10 at promoter site -1082 were A/A = 3.6, A/G = 5.0, and G/G = 10.0 and the difference was significant (P = 0.029). The difference in the stage of disease at a scale of 0–6 was A/A 0.8, A/G 2.3, and G/G 4.0 (P = 0.079). The difference in the HAI seemed to be related to the presence of allele -1082G. For IL-10 -819 genotypes, mean scores of fibrosis were A/A = 6.0, A/C = 2.2, and C/C = 1.0 (P = 0.020) though the inflammatory activity was not much different. No significant differences in HAI were noted among polymorphisms of other cytokines. Moreover, ALT and HCV RNA levels were not significantly different among different cytokine polymorphisms. There was a significant correlation of HAI and HCV RNA levels with the duration of disease. TGFβ -10 genotype CC patients had a better end of treatment response than those with other genotypes (P = 0.020). Sustained virological response to the treatment was not influenced by the cytokine polymorphism. No effect of other factors like viral load, degree of fibrosis, gender, steatosis, was observed on sustained virological response in this population infected with genotype 3.

CONCLUSION: There is no significant correlation between cytokine polymorphisms and HAI except for the polymorphisms of anti-inflammatory cytokine IL-10, which may influence hepatic inflammatory activity and fibrosis in patients with chronic hepatitis C genotype 3. Sustained virological response in this genotype does not seem to be influenced by cytokine gene polymorphisms.

INTRODUCTION

HCV infection is a leading cause of chronic liver disease worldwide. The infection leads to viral persistence and chronic disease in a very high proportion of cases. Pathogenesis of liver injury is not fully understood. There is a complex relationship between HCV and its host. Liver lesions could be the result of immune

responses or cytopathic action of the virus. Cytotoxic T cells and cytokines produced by both CD4+ (T helper) and cytotoxic T cells may be responsible for much of the damage that occurs in the livers of infected patients[1].

Two distinct patterns of cytokine production may occur[2]. Type 1 responses are characterized by production of interleukin-2 (IL-2), tumor necrosis factor-alpha (TNF-α) and interferon-gamma (IFN-γ), which are prime and maintain antigen-specific cellular immunity[3,4] and are important in defense against viruses. Type 2 responses are characterized by IL-4, IL-5, and IL-10, which promote humoral immune responses. An imbalance in helper T-cell type 1 (Th1) and type 2 (Th2) cytokines is suggested to play an important role in the pathogenesis of chronic hepatitis C. The progressive liver injury seen in chronic HCV infection is associated with the upregulation of intrahepatic Th1-like cytokines. Intrahepatic IFN-γ and IL-2 mRNA expression is upregulated in chronic hepatitis C, while the expression of IL-10, a Th2-like cytokine, is downregulated[5] .

Intrahepatic CD4+ T cells play a pathogenetic role in the hepatic injury of HCV infection[6]. Vigorous HCV-specific CD4+ Th1 response, particularly against the nonstructural proteins of the virus, may be associated with viral clearance and protection from disease progression[7]. Patients without viremia after HCV infection frequently have strong Th lymphocyte responses of the Th1 type to multiple HCV antigens many years after the onset of infection, whereas antibody responses are less marked. These results suggest that control of HCV replication may depend on effective Th lymphocyte activation[8,9]. There is also an enhanced Th2 response during chronic HCV infection, which may partly be responsible for the persistence of HCV infection.

In addition to the altered intrahepatic cytokine expression, there might be a significant correlation between circulating cytokines and degree of inflammation in the liver. One study has shown such a correlation between baseline TNF levels and histologic grading score of hepatitis[10]. The maximal capacity of cytokine production varies between individuals and may correlate with polymorphism in cytokine gene promoters. The objectives of our study were to analyze the role of allelic or genotype variations of IL-10, IL-1 beta, IFN-γ, TNF-α and TGF-β and its association with hepatocellular injury as suggested by liver biopsy and ALT and treatment outcome. We selected genotype 3 for this study which is the main genotype in our country.

MATERIALS AND METHODS

Out of the 40 patients analyzed, 26 were males. Mean age was 40.5±12.5 years (range 18-65 years). The participants did not receive interferon therapy and had neither co-infection with human immunodeficiency virus and hepatitis B virus nor other associated forms of chronic liver disease.

Quantitative serum HCV RNA was determined by bDNA assay (Bayer, USA) according to the manufacturer's instructions. The minimum quantification limit of the assay was 3 000 HCV RNA copies/mL serum. HCV genotyping was performed using PCR and reverse hybridization assay (Innogenetics, Belgium). All patients included in this study were of HCV genotype 3. For cytokine gene polymorphism, DNA was extracted by proteinase K digestion from peripheral mononuclear cells, followed by phenol chloroform extraction and ethanol precipitation. After amplification polymorphisms in IL-10 (592, 819, 1082), IL-1β (-511), IFNγ (874), TNFα (308) and TGF (codon25) were examined as described previously[11-13]. The number in parenthesis indicates the location of the polymorphism on the DNA sequence. Briefly, single nucleotide polymorphisms (SNPs) were determined using sequence specific oligonucleotide primers. Each PCR reaction consisted of 1× PCR buffer, 0.2 mmol dNTPs. Concentration of $MgCl_2$ varied with the type of SNP examined, 50 ng of each polymorphism specific primer, 1 U of *Taq* polymerase in a final volume of 10 μL. To monitor PCR inhibition, growth hormone gene was simultaneously amplified as an internal control. Thermal cycling was performed in a Perkin-Elmer 9700 thermal cycler. Following PCR amplification, amplicons were stained with ethidium bromide and visualized on a UV transilluminator. The size of product generated in each PCR assay was ascertained and scored as positive/negative for the presence/absence of a particular polymorphism. The PCR product obtained with IL-1β-511 specific primers was digested with the restriction enzyme *Ava*II. The digested product was then visualized for the presence of restriction fragments.

Liver biopsy specimens were analyzed by a single pathologist, who was unaware of the patient's identity, treatment regimen, response, or timing of the biopsy relative to the treatment. Liver biopsies were assessed by modified histological activity index (HAI) scoring system[14] using a scale of 0-18 for grading and 0-6 for staging. Degree of steatosis was scored at a scale of 0-3. Presence or absence of lymph follicles was also documented.

Duration of disease was determined by calculating time interval from the exposure to a possible risk factor. Patients were treated with standard doses of interferon alpha (3 mega units subcutaneous, thrice a week) and ribavirin (800-1 200 mg/d) for 6 mo and followed up for another 6 mo. HCV RNA was repeated 6 mo after the treatment to document sustained response.

Statistical analysis

Statistical analysis was performed by two-tailed tests. *P* values were calculated by one-way analysis of variance (ANOVA), Pearson's χ^2 and Spearman's rho correlation tests. $P<0.05$ was considered statistically significant.

RESULTS

The frequencies of different dimorphic polymorphisms based on single nucleotide substitution were as follows:

IL10-1082 G/A 85%, A/A 12.5%, G/G 2.5%; IL10-819 A/C 87.5%, C/C 10%, A/A 2.5%; IL10-592 C/A 72.5%, C/C 27.5%; IL-1 C 90%, U 10%; IFN-874 T/A 50%, T/T 27.5%, A/A 22.5%; TNF-308 A/G 95%, G/G 5%; TGF-10 T/C 52.5%, C/C 35%, T/T 12.5%. The mean grades of necro-inflammatory activity at a scale of 0-18 for different genotypes of IL10 at promoter site -1082 were A/A = 3.6, A/G = 5.0, and G/G = 10.0 and the difference was significant (P = 0.029). The difference in the stage of disease at a scale of 0-6 was A/A 0.8, A/G 2.3, and G/G 4.0 (P = 0.079). This difference in the HAI seemed to be related to the presence of allele -1082G. For IL 10 -819 genotypes the mean scores of fibrosis were A/A = 6.0, A/C = 2.2, and C/C = 1.0 (P = 0.020) though the inflammatory activity was not much different.

No significant differences in the degree of necro-inflammatory activity and fibrosis were noted among the polymorphisms of other cytokines (Table 1). Moreover, ALT and HCV RNA levels were not significantly different among different cytokine polymorphisms. There was a significant correlation of duration of disease with grade and stage of disease and HCV RNA levels (P = 0.017, 0.018, and 0.015 respectively with Spearman's rho test).

Out of the 40 patients, 34 remained under the follow-up. These patients completed the 6-mo treatment with interferon and ribavirin. HCV RNA was repeated 6 mo after the treatment to document the sustained response and the effect of cytokine gene polymorphism. TGFβ -10 genotype CC patients had a better end of treatment response than those with other genotypes (P = 0.020), though there was no difference in the sustained virological response. No effect of other factors like viral load, degree of fibrosis, gender, steatosis, was observed on the sustained virological response in this population infected with genotype 3.

DISCUSSION

Approximately 80-90% of patients acutely infected with hepatitis C virus develop persistent infection, about one-half of them have elevated transaminases indicative of ongoing liver inflammation[15]. In the context of an inflammatory response against the virus, variable cytokine response of the host may be responsible for the variable liver damage. Moreover, the cause of viral persistence during HCV infection may be the development of a weak antiviral immune response to the viral antigens, with corresponding inability to eradicate infected cells or insensitivity of the virus to such cytokines or insufficient production of cytokines[16]. Thus, the continuing inflammation results in liver damage in the absence of complete virologic recovery[17].

Studies have shown that active liver injury in chronic hepatitis C patients is associated with increased circulating Th1 cytokine IL-2 but not with Th2 cytokine IL-10[18]. It has also been shown by some workers that serum alanine transaminase and the hepatic fibrosis levels are related directly to the frequencies of peripheral memory effector CD8(+) T cells producing IFN-γ (Tc1), but inversely to the frequencies of those producing both IL-4 and IL-10 (Tc2)[19]. Moreover, most liver-infiltrating T cells in chronic hepatitis C are type 1 cells. Studies to date in liver tissue showed that intrahepatic mRNA for type 1-like cytokines, such as IL-1β, IL-2, IL-6, IL-8, TNF-α, and IFN-γ were upregulated in chronic HCV infection[20]. The level of expression of type 1 cytokines, such as IL-2 and IFN-γ, is correlated with the degree of histologic injury as well as the likelihood of non-responsiveness to IFN-α therapy[21]. The presence of an ongoing cellular immune response probably also contributes to the process of hepatic fibrosis. Kupffer cells can be activated by the production of cytokines such as TNF-α, which in turn produce TGF-β[22].

Serum levels of different cytokines may not give the true picture of what is going on in the liver. For example, the mean IL2Rs and IFN serum levels are much higher in patients with anti-HCV than in the control group,

Table 1 Statistical significance of effects of cytokine gene polymorphisms on different parameters

Cytokine gene polymorphism	ALT (upper limit normal)	HCV RNA level	Grade of inflammation (0-18)	Stage of fibrosis (0-6)	Steatosis (0-3)	Lymph follicles	End of treatment response	Sustained response
IL 10 -1082 (GA, AA, GG)	0.636	0.241	0.029	0.079	0.267	0.848	0.078	0.331
IL 10 -819 (AC, CC, AA)	0.794	0.781	0.412	0.020	0.57	0.295	0.063	0.331
IL 10 -592 (CA, CC)	0.582	0.198	0.243	0.281	0.551	0.626	0.416	0.283
IFNγ -874 (AA, TT, TA)	0.389	0.848	0.919	0.921	0.955	0.382	0.21	0.933
TNFα -308 (AG, GG)	0.952	0.436	0.777	0.307	0.32	0.85	0.674	0.451
TGFβ -10 (CC, TC, TT)	0.734	0.72	0.386	0.959	0.232	0.643	0.026	0.206
IL 1 (C/U)	0.144	0.591	0.964	0.826	0.326	0.836	1.00	1.00

P values were calculated by ANOVA and Pearson' s χ^2 test. Statistically significant values. IL: interleukin; IFNγ: interferon gamma; TNFα: tumor necrosis factor alpha; TGFβ: transforming growth factor beta.

whereas the mean IL4 and IL6 levels are lower in patients infected with HCV[23]. Another study shows the higher levels of serum IL-1β, IL-4 and IL-6 (0.221, 0.104 and 1.393 pg/mL) in all HCV patients than in healthy adults (0.188, 0.025 and 0.600 pg/mL)[24].

Sustained response to interferon and ribavirin, defined as undetectable HCV RNA at 6 mo after discontinuation of therapy, is achievable in 30-60% of treated patients[25,26]. Predictors of response include viral factors such as viral genotypes, viral load and early disappearance of HCV RNA after initiation of therapy, while the host factors include gender, age and degree of fibrosis[25-27]. In recent years, increasing attention has been drawn to the role of host variation in cytokine levels in inflammatory and immune responses. Polymorphisms in genes encoding immunoregulatory proteins, proinflammatory cytokines, and fibrogenic factors may affect the production of these factors and influence disease progression in patients with chronic liver disease due to alcohol, primary biliary cirrhosis, or hepatitis C[28].

There might be an association of cytokine gene polymorphism and susceptibility to hepatitis C infection. Hohler *et al*.[29] have reported such an association with the polymorphism at the TNFα promoter. The TNF promoter variants TNF2 (-238A) and TNF3 (-308A) confer a 3.2-fold and 5.1-fold risk of cirrhosis respectively (P = 0.03 for both). Reciprocal effects have been observed with several TNF alleles and haplotypes defined by the -238 G/A and -308 G/A dimorphic sequences, thus polymorphisms in the TNF alpha promoter appear to be associated with the variability in the histological severity of chronic hepatitis C infection[30]. In our study done on hepatitis C genotype 3 patients, no such effect of TNFα -308 variability was observed.

Interleukin (IL)-10 is a cytokine that downregulates the proinflammatory response and has a modulatory effect on hepatic fibrogenesis and is a potent anti-inflammatory Th2 cytokine that downregulates the expression of major histocompatibility complex (MHC) class I and class II molecules, as well as the production of Th1 cytokines[31-36]. IL-10 levels differ widely between individuals, possibly because of polymorphisms in the promoter region of the IL-10 gene[37,38]. Specifically, three SNPs in the promoter (at positions -1082, -819, and -592 relative to the transcription start site) form three SNP combinations (ATA, ACC, GCC), which are associated with differential IL-10 expression[38-40]. It is reasonable to assume that hepatitis C patients who produce high levels of IL-10 have less hepatocellular injury and less ability to control infection and patients with low secretion of IL-10 have a better ability to eliminate the hepatitis infection. Perhaps low IL-10 production can skew the immune system into the Th1 type of response, facilitating the clearance of viral load. -1082A allele is associated with reduced IL-10 production *in vitro*[39]. In our study, individuals who were homozygous for IL-10 AA at position -1082 had a lower HAI.

It has been shown that hepatitis C patients, genotyped as high IL-10 producers, have a poor response to IFN-α therapy[40]. Such polymorphisms may also predict the sustained viral response to antiviral therapy[41]. These patients may benefit from additional treatment strategies designed to enhance T-helper type 1 (Th1) response. In one study, the interleukin-10 -1082 G/G genotype was identified more frequently in patients than in controls (P = 0.048). The patients exhibiting transforming growth factor-beta 1+29 (codon 10) C/C genotype variables were less likely to respond to treatment than patients with the T/T or T/C genotypes[42]. Liver transplant recipients, who are genotyped as having a low production profile of IL-10, are more prone to rejection and less likely to have hepatitis C recurrence[43]. The IL-1beta-31 genotype T/T or the IL-1beta-511/-31 haplotype C/T is associated with the presence of HCC in Japanese patients with chronic HCV infection[44].

However, not all the studies favor such effect of polymorphisms. Three members of the interleukin-1 gene family (IL-1A, IL-1B and IL-1RN), three polymorphic sites in the interleukin-10 gene promoter (-1082, -819, -592) and two in the TNF-α promoter (-308, -238) were studied in two independent DNA banks, each with appropriate controls. Standard PCR-based genotyping techniques were used. No significant difference in the distribution of any of the polymorphisms has been found in either study set[45].

We, in this study, determined SNP at position -1082, -819 and -592 in case of IL-10, -874 for IFN-γ, -308 for TNF-α, -10 for TGF-β and IL-1 C/ U and analyzed the frequency of their distribution and correlation with the ALT and HCV RNA levels, HAI and response to treatment. In our series, we selected genotype 3 patients because this is the main genotype in our region and not enough data are available on the influence of host cytokine gene polymorphisms of this viral genotype. Another reason of selecting a single genotype was to make the group uniform as different genotypes have different response rates to antiviral therapy and influence of cytokines may also be different. We could not find any significant difference in the cytokine genotype profile while analyzing different variables except for some influence of polymorphisms of IL-10 on liver histology. These polymorphisms did not modulate the response to interferon plus ribavirin therapy. This may be due to the small sample size or the fact that viral genotype 3 is easy to treat genotype in any case.

Abstract

AIM: To evaluate the role of reactive oxygen species in the pathogenesis of acute ethanol-induced gastric mucosal lesions and the effect of *Nigella sativa* L oil (NS) and its constituent thymoquinone (TQ) in an experimental model.

METHODS: Male Wistar albino rats were assigned into 4 groups. Control group was given physiologic saline orally (10 mL/kg body weight) as the vehicle (gavage); ethanol group was administrated 1 mL (per rat) absolute alcohol by gavage; the third and fourth groups were given NS (10 mL/kg body weight) and TQ (10 mg/kg body weight p.o) respectively 1 h prior to alcohol intake. One hour after ethanol administration, stomach tissues were excised for macroscopic examination and biochemical analysis.

RESULTS: NS and TQ could protect gastric mucosa against the injurious effect of absolute alcohol and promote ulcer healing as evidenced from the ulcer index (UI) values. NS prevented alcohol-induced increase in thiobarbituric acid-reactive substances (TBARS), an index of lipid peroxidation. NS also increased gastric glutathione content (GSH), enzymatic activities of gastric superoxide dismutase (SOD) and glutathione-S-transferase (GST). Likewise, TQ protected against the ulcerating effect of alcohol and mitigated most of the biochemical adverse effects induced by alcohol in gastric mucosa, but to a lesser extent than NS. Neither NS nor TQ affected catalase activity in gastric tissue.

CONCLUSION: Both NS and TQ, particularly NS can partly protect gastric mucosa from acute alcohol-induced mucosal injury, and these gastroprotective effects might be induced, at least partly by their radical scavenging activity.

Key words: *Nigella sativa*; Thymoquinone; Ulcer; Antioxidant; Rat

INTRODUCTION

Intragastric application of absolute ethanol has long been used as a reproducible method to induce gastric lesions in experimental animals[1]. Gastric lesion is accompanied with the formation of free radicals (FRs) and reactive oxygen species (ROS)[2-4]. These radicals in particular seem to play an important role in ulcerative and erosive lesions of the gastrointestinal tract[5], as they attack and damage many biological molecules. Therefore, treatment with antioxidants and FR scavengers can decrease ethanol-induced gastric mucosal damage[6,7].

The black seed, *Nigella sativa* L (NS), a member of the family of ranunculaceae, contains more than 30% of fixed oil and 0.4-0.45 % wt/wt of volatile oil. The volatile oil contains 18.4-24% thymoquinone (TQ) and 46% many monoterpenes such as *p*-cymene and α-piene[8]. Recently, clinical and animal studies have shown that extract of the black seeds have many therapeutic effects such as immunomodilative[9], antibacterial[10], hypotensive[11], hepatoprotective[12] and antidiabetic effects[13]. Ohkawa *et al*.[14] also reported that NS oil and its derivative TQ inhibit eicosanoid generation in leukocytes and membrane lipid peroxidation. However, the gastroprotective effect of this plant and its major constituent against ethanol-induced gastric mucosal injury remains unclear.

In the present investigation, we studied the influence of NS on gastric mucosal lesions and the redox state induced by ethanol and to compare its actions with those of its constituent TQ.

MATERIALS AND METHODS

Plant materials and extraction procedure

The NS seeds were purchased from a local herb store, Van, Turkey. Voucher specimens were kept at the Department of Biochemistry, Yuzuncuyil University, Van, Turkey, for the future reference. The seeds of NS were powdered in a mixer, placed in a distillation flask and the volatile oil with 0.2% yield was collected by steam distillation. TQ 2-isopropyl-5-methyl-1,4-benzoquinone, was purchased from Sigma (St. Louis, MO, USA).

Treatment of rats

Forty male Wistar albino rats, weighing 200-250 g (aged 4 mo), were supplied by The Center of Medical Investigations of Yuzuncu Yil University. The animals were fed with a standard rat chaw (Murat Food Factory, Ankara, Turkey) and allowed to drink water *ad libitum*, but they were deprived of food 12 h before the experiment. The animals were housed in a single temperature controlled (20-25 °C) cage in dark/light cycle. All procedures were performed in sterilized conditions. All animals received human care according to the criteria outlined in the "Guide for the Care and Use of Laboratory Animals" prepared by the National Academy of Sciences and published by the National Institutes of Health.

Rats were assigned into 4 groups (each containing 10 animals). Control group was given physiologic saline orally (10 mL/kg body weight) as the vehicle (gavage), ethanol group was administrated 1 mL (per rat) absolute alcohol by gavage. The third and fourth groups were given NS (10 mL/kg body weight) and TQ (10 mg /kg body weight p.o) respectively 1 h prior to alcohol intake. One hour after ethanol administration, the animals were euthanized by cervical dislocation. The stomach was excised, cut along the greater curvature, and gently rinsed in tap water. The stomach was stretched on a piece of cork with mucosal surface up, and then examined in a standard position for macroscopic examination. Scoring of ulcer was performed with the help of magnifying glass. Lesion size (mm) was determined by measuring each lesion and its greatest diameter was recorded in the case of petechial lesions. Four such lesions were considered to be the equivalent of an 1 mm ulcer. The sum of the total severity scores in each group of rats divided by the number of animals, was expressed as the mean ulcer index (UI).

Biochemical analysis

Stomachs were cut into small pieces and homogenized in 0.15 mol/L ice-cold KCl using Heidolf Diax 900, type 595 (Germany) to give 20% homogenates. The homogenates were then made into aliquots and used for the assessment of antioxidant parameters.

MDA levels were determined as previously described[15]. Less than 0.2 mL of 10% (w/v) tissue homogenate, 0.2 mL of 8.1% sodium dodecyl sulfate (SDS), 1.5 mL of 20% acetic acid solution adjusted to pH 3.5 with NaOH, and 1.5 mL of 0.8% aqueous solution thiobarbituric acid (TBA) were added into the sample. The mixture was made up to 4.0 mL with distilled water, and heated at 95 ^{0}C for 60 min. After cooling, 1.0 mL of distilled water and 5.0 mL of the mixture of *n*-buthanol and pyridine (15:1, v/v) were added and shaken vigorously. After centrifugation at 4 000 r/min for 10 min, the organic layer was taken and its absorbance at 532 nm was measured. Total TBA-reactive materials were expressed as MDA, using a molar extinction coefficient for MDA of 1.56×10^5 cm/mol/L. MDA level was expressed as nmol/g.

Reduced glutathione (GSH) was determined according to the method described by Sun[16]. The GSH concentration (μmol/g) was computed from a standard curve constructed using different concentrations of standard GSH.

Stomach homogenate (20%) was centrifuged at 10 000 *g* for 10 min for 30 min at 4 ^{0}C (Beckman XL-70, USA). Following centrifugation, the supernatant (cytosolic fraction) was carefully removed from the pellet and used directly for assay of the enzymatic activities of SOD, GST and CAT.

SOD activity was detected according to Sun and Habig[17]. One SOD unit was defined as the enzyme amount causing 50% inhibition in the $NBTH_2$ reduction rate. SOD activity was also expressed as U/mg protein of stomach tissue sediment.

Gastric GST activity was determined according to the method of Clairborne *et al*.[18]. In brief, the GST activity toward 1-chloro-2,4-dinitrobenzene in the presence of glutathione as a co-substrate was measured specrophotometrically at 25 °C. The enzyme activity was determined by monitoring the changes in the absorbance at 340 nm for 4 min at 1-min intervals. The enzymatic activity was expressed as nmol min/g tissue.

CAT activity was determined according to the method of Lowry[19]. In short, the supernatant (50 μL) was added to a quartz cuvette containing 2.95 mL of 19 mmol/L H_2O_2 solution prepared in potassium phosphate buffer (0.1mol/L, pH 7.4). The change in absorbance was monitored at 240 nm over a 5-min period using a spectrophotometer (Shimadzu UV-1201, Japan). Commercially available CAT was used as the standard. CAT activity was expressed as U/g tissue.

The amount of protein was determined by the Lowry method[20].

Statistical analysis

The data were expressed as mean±SD and analyzed by repeated measures of variance (ANOVA). Tukey test was used to test for differences among means for which ANOVA indicated a significant ($P<0.05$) F ratio.

RESULTS

Oral administration of absolute ethanol produced multiple mucosal lesions in the rat stomach. Pretreatment with NS and TQ inhibited the ethanol-induced gastric mucosal injury in rats. Pretreatment with single oral dose of NS significantly reduced the ulcer index compared to alcohol

($P<0.01$). TQ also significantly inhibited ethanol-induced gastric lesions ($P<0.05$). Ulcer index (UI) is shown in Figure 1.

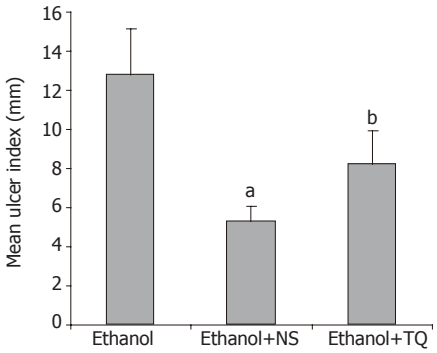

Figure 1 Mean UI in ethanol, ethanol + NS and ethanol + TQ treated rats. $^{b}P<0.01$, $^{a}P<0.05$ *vs* ethanol group

Administration of ethanol increased the MDA level in rat gastric tissue. In contrast, pretreatment with NS significantly decreased the MDA levels as compared to ethanol. TQ also significantly decreased the gastric MDA content, but to a lesser extent than NS. GSH activity decreased in the gastric tissue after ethanol administration, but pretreatment with NS or TQ increased the GSH activity gastric tissue compared to ethanol (Table 1). Prior administration of NS to rats markedly increased the gastric activity of SOD. Likewise, TQ increased the enzymatic activity of SOD compared to alcohol (Table 1). Pretreatment with either NS or TQ increased the enzyme activity of gastric GST. Neither NS nor TQ had any effect on the CAT activity of gastric mucosa (Table 1).

DISCUSSION

ROS are continuously produced during normal physiologic events, and removed by antioxidant defence mechanisim[21]. In pathological conditions, ROS are over produced and result in lipid peroxidation and oxidative damage. The imbalance between ROS and antioxidant defence mechanisms leads to oxidative modification in the cellular membrane or intracellular molecules[22]. Recent studies showed that ROS are one of the important factors in the pathogenesis of ethanol-induced mucosal damage[7,23,24]. Some ROS scavengers or inhibitors such as melatonin have protective effects on indomethacin- or ethanol-induced acute gastric injury in rats[25,26]. The cytoprotective role of antioxidants in the prevention and healing of gastric lesions has been widely investigated in a number of studies[24,27].

In the present study, administration of absolute alcohol by gastric gavage induced marked damage to the gastric mucosa that was obvious by macroscopic examination. The lesions were elongated hemorrhage and confined to the glandular portion with the highest subjective ulcer-scoring rate.

It was reported that alcohol causes severe oxidative stress in gastric tissue manifested as stimulated lipid peroxidation by increasing MDA content and decreasing of gastric GSH content[3,24,27].

The gastric activities of SOD and GST notably decreased following alcohol intake. The CAT activity, however, was unchanged. These results are in line with previous reports that demonstrated marked alterations in the enzymatic antioxidants following acute administration of alcohol to rats[3,28]. Depletion of non-protein sulfhydryl concentrations[1], modulation of nitric oxide sytem[29], reduction of mucosal blood flow[30], and autonomic nervous system regulation[31], are involved in the development of gastric lesions. One of the major mechanisms underlying the induction of gastric erosions by absolute alcohol is the oxidative damage with its dual events of lipid peroxidation and oxygen reactive species generation. Actually, oxygen-derived radicals have been implicated in the pathogenesis of gastric tissue damage and ulcerogenesis[6,32,33].

Pretreatment with a single oral dose of NS could partly reduce the ulcer index and promote healing of gastric lesions induced by acute intake of alcohol in rats. NS significantly decreased the gastric MDA content while it increased the gastric level of GSH compared to alcohol. The gastric activities of both SOD and GST were markedly elevated following administration of NS, whereas the CAT activity was not altered. Likewise, prior administration of TQ to animals could protect gastric mucosa and ameliorate most of the biochemical adverse effects induced by alcohol application, but to a lesser extent than NS.

These findings are in good agreement with a recent study by El-Denshary *et al.*[34]. The anti-ulcerogenic effects of NS can be attributed to the improvement of

Table 1 Effects of alcohol intake alone and following administration of either NS or TQ on the contents of MDA and GSH and activities of SOD, GSH and CAT in rat gastric tissue (means ± SD)

Parameters	Control	Ethanol	Eth + NS	Eth + TQ
MDA (nmol/g proteine)	136.33 ± 11.42	329.43 ± 19.80[a]	112 ± 17.16[c]	201.15 ± 29.11[c]
GSH (μmol/g proteine)	0.84 ± 0.04	0.44 ± 0.03[a]	0.54 ± 0.05[c]	0.42 ± 0.02
SOD (U/g proteine)	47.39 ± 5.74	17.75 ± 3.02[a]	56.88 ± 4.09[c]	51.08 ± 3.17[c]
GST (nmol/min/g proteine)	4.39 ± 0.29	1.81 ± 0.32[a]	4.02 ± 0.31[c]	4.07 ± 0.28[c]
CAT (U/g proteine)	56.45 ± 3.30	59.5 ± 7.99	55.63 ± 6.52	54.18 ± 10.19

$^{a}P<0.05$ *vs* control group. $^{c}P<0.05$ *vs* alcohol group.

the antioxidant status of animals due to an increase in mucin content of the gastric mucosa[34], or the presence of FR scavenging substances such as TQ[35]. It was also reported that NS given to sensitized quinea pigs, inhibits FR generation, and increases serum levels of SOD and glutathione[14]. NS could protect the gastric mucosa by increasing the bioavailability of arachidonic acid, resulting in biosynthesis of the cytoprotective prostaglandins in the stomach[36]. NS has also been reported to produce a marked inhibition on the release of leukotrienes, which cause mucosal tissue injury and hypoxemia[37]. Therefore, it may alter the delicate balance between prostaglandins and leukotrienes in the gastric mucosa favoring cytoprotection. TQ is the main active component of NS, and is able to inhibit lipid peroxidation[14]. Moreover, its ability to preserve the cell membrane integrity can be proven by the restoration.

In conclusion, pretreatment with NS and TQ, particularly NS can partly protect the gastric mucosa against the injurious effects of absolute ethanol and promote ulcer healing. NS or TQ can also mitigate most of the biochemical adverse effects induced by alcohol instillation in gastric tissue. Further studies are required to clarify the anti- ulcer and antioxidant action of NS or TQ.

Abstract

AIM: To investigate the prevalence of giardiasis in patients with dyspeptic symptoms.

METHODS: Clinical records of consecutive patients who attended Gastroenterology Department at Aga Khan University Hospital from January 2000 to June 2003 and had esophagogastroduodenoscopy (EGD) with duodenal biopsies and international classification of diseases 9th revision with clinical modifications (ICD-9-CM) coded with giardiasis were studied.

RESULTS: Two hundred and twenty patients fulfilled the above criteria. There were 44% (96/220) patients who were giardiasis positive, 72% (69/96) of them were males and 28% (27/96) of them were females. There were 65% (81/124) males and 35% (43/124) females who were giardiasis negative. The mean age of patients with giardiasis was 28±17 years, while that of giardiasis negative patients was 40±18 years (P<0.001). In patients with giardiasis, abdominal pain was present in 71% (68/96) of patients (P = 0.02) and diarrhea in 29% (28/96) (P = 0.005); duodenitis in 25% (24/96) on EGD (P = 0.006) and in 68% (65/96) on histopathology (P = 0.002).

CONCLUSION: Giardiasis occurs significantly in young people with abdominal pain, while endoscopic duodenitis is seen in only 25% of giardiasis positive cases, which supports routine duodenal biopsy.

Key words: Abdominal pain; Giardiasis; Stool examination; EGD; Duodenal biopsy

INTRODUCTION

Giardia lamblia is the most common protozoan isolated from the gastrointestinal tract[1]. Worldwide incidence is believed to range from 20% to 60%[2]. The incidence rate is 2-7% in industrialized nations[3]. Patients with giardiasis typically present with diarrhea, vague abdominal discomfort, nausea and distention together with mild weight loss and lassitude. The absence of these symptoms may result in a low clinical index of suspicion for the diagnosis. Giardiasis is diagnosed by signs and symptoms, as well as the presence of giardia cysts and trophozoites in the stool. Stool examination can be unreliable, as organisms may be excreted at irregular intervals which can produce a false negative test result[4]. There is no gold standard for the diagnosis of giardiasis. The initial method of diagnosis is by demonstration of the trophozoite or cysts of *G lamblia* in the stool by microscopy or stool antigen detection by ELISA. Other methods of diagnosis include examination of duodenal contents by aspiration or biopsy with endoscopy. A definitive diagnosis may require repeated stool examinations, fecal immunoassays, or even sampling of the upper intestinal contents. Two stool examinations can detect 80-90% of infections, while three samples detect >90%[5]. About 20% of infestations are symptomatic, and do not continue for more than 3 mo along with the passage of cysts[2]. Difficulties are often encountered in finding the underlying cause of recurrent abdominal pain. Giardiasis is considered as an infrequent cause of dyspepsia[6], but this might not be true in a third world country. Prevalence of giardiasis is the highest in areas of poor sanitation and drinking water treatment. It is transmitted by eating and drinking contaminated food and water or fecal-oral contact. In immunocompetent patient, small bowel biopsy may show normal histology or villous architecture, but increased intraepithelial lymphocytes and plasma cells in the lamina propria or villous atrophy and inflammatory cells[7]. Giardia trophozoites can be found on the surface or penetrating the epithelium down to the lamina propria[7]. The aim of this study was to investigate the prevalence of giardiasis in patients with dyspeptic symptoms.

MATERIALS AND METHODS

Patients

We carried out a retrospective analysis of medical records of all the patients who attended endoscopy unit of gastrointestinal section at the Aga Khan University Hospital from January 2000 to June 2003 consecutively for dyspeptic symptoms. They had an esophagogastrodu odenoscopy (EGD) with duodenal biopsies after routine examination including stool examination. The giardiasis negative group consisted of the patients who had a stool examination and an EGD with duodenal biopsy and were not diagnosed as giardiasis. The giardiasis positive group consisted of the patients who had positive EGD with duodenal biopsy and stool examination for giardia cysts or trophozoites. Clinical symptoms at the time of presentation, diagnosis, drug treatment dosage and duration, past history of giardiasis, neutrophil and lymphocyte counts from complete blood picture, random blood glucose and stool examination were noted. Patients with diagnosis of celiac disease were excluded from the analysis.

Stool examination

Stool parasitological analysis of samples collected from spontaneous bowel movement was performed. Samples were collected in a sterile container and transported soon after to the laboratory for examination. Microscopically each stool specimen was examined in a fresh normal saline smear and Lugol's iodine preparation.

Esophagogastroduodenoscopy

All endoscopic examinations were performed by staff-members of our hospital's gastroenterology section, using an Olympus video scope GIF xQ 140. Duodenitis was diagnosed when scattered. Reddened raised non-eroded mucosal patches were endoscopically identified in the duodenal bulb and descending duodenum.

Histopathology

Hematoxylin and eosin (HE) staining of duodenal biopsy was used for pathological confirmation of giardia trophozoites. Most organisms were tangentially cut and many were seen as small sickle-shaped objects near the epithelial surface.

Statistical analysis

The SPSS (Release 11.5.0, standard version, copyright © SPSS; 1989-02) was used for data analysis. Descriptive analysis was done for demographic and clinical features. Results were presented as mean±SD for continuous variables, and number (percentage) for categorical variables. Univariate analysis was performed by using the independent sample *t*-test for continuous variables and Pearson's chi-square test for categorical variables to assess the demographic and clinical parameters associated with giardiasis. Odds ratio (OR) estimates with their 95% confidence interval (CIs) and *P* values were calculated (Table 1). $P \leqslant 0.05$ was considered statistically significant. All *P* values were two sided.

RESULTS

Patients

Two hundred and twenty patients fulfilled the criteria. There were 44% (96/220) patients who were giardiasis positive and 56% (124/220) were giardiasis negative. In patients with giardiasis, 72% (69/96) were males and 28% (27/96) were females. The mean age of patients with giardiasis was 28±17 years, while that of patients without giardiasis was 40±18 years ($P<0.001$). Abdominal pain was present in 71% (68/96) patients with giardiasis and in 56% (69/124) patients without giardiasis ($P = 0.02$), diarrhea was present in 29% (28/96) patients with giardiasis and in 14% (17/124) patients without giardiasis ($P = 0.005$, Table 1).

Table 1 Clinical details of patients with and without endoscopic giardiasis

Variables	Giardiasis positive (n = 96) (%)	Giardiasis negative (n = 124) (%)	*P*	OR (95%CI)
Age groups (yr)				
<22	34 (35)	21 (17)		1
22–31	29 (30)	27 (22)		0.7 (0.3–1.5)
32–48	20 (21)	35 (28)		0.4 (0.2–0.9)
>48	13 (14)	41 (33)	<0.001	0.2 (0.1–0.5)

Abdominal pain	68 (71)	69 (56)	0.021	1.9 (1.1–3.4)
Diarrhea	28 (29)	17 (14)	0.005	2.6 (1.3–5.1)
Weight loss	9 (9.4)	6 (5)	0.186	2.0 (0.7–5.9)
Endo-duodenitis	24 (25)	53 (43)	0.007	0.4 (0.2–0.8)
Histological duodenitis	65 (68)	58 (46)	0.002	2.5 (1.4–4.4)
Lamina propria inflammation	73 (76)	53 (42)	<0.001	4.4 (2.4–8.1)
Villus shortening	5 (5)	–	–	–

Results are presented as number (percentage), Odds ratio (95%CI).

Stool examination

Stool examination was carried out in 88.5% (85/96) cases, 6% (5/85) were positive for giardia cysts and trophozoites.

Endoscopy

On EGD, antral gastritis was present in 46% (44/96) patients with giardiasis and in 75% (93/124) patients without giardiasis ($P<0.001$); duodenitis was present in 25% (24/96) patients with giardiasis and in 50% (53/124) patients without giardiasis ($P = 0.006$); duodenal ulcer was present in 4% (4/96) patients with giardiasis and in 72% (89/124) patients without giardiasis ($P<0.001$, Table 1).

Histopathology

On histopathology of gastric antral biopsy, *H. pylori* was seen in 42% (40/96) patients with giardiasis and in 54% (67/124) patients without giardiasis ($P = 0.06$); antral gastritis was found in 53% (51/96) patients with giardiasis and in 81% (100/124) patients without giardiasis ($P<0.001$). Duodenitis was seen in 68% (65/96) patients with giardiasis and in 46% (58/124) patients without giardiasis ($P = 0.002$); villus shortening was seen in 5% (5/96) patients with giardiasis and absent in patients giardiasis negative; lamina propria inflammatory infiltration with increased intraepithelial lymphocytes and plasma cells was seen in 76% (73/96) patients with giardiasis and in 42% (53/124) patients without giardiasis ($P<0.001$, Table 1).

DISCUSSION

It is sometimes difficult to establish the diagnosis of giardiasis. Tests for parasitic antigen in stool are at least as sensitive and specific as good microscopic examination and are easier to perform. All these methods occasionally yield false-negative results.

The implications of this study are that no symptom complex is associated with the giardiasis. Giardiasis may present with abdominal pain alone and it should be considered even in the absence of diarrhea. Abdominal pain is the most common presentation and diagnosis, and investigations carried out are more often for gastritis or peptic ulcer disease with or without *H pylori* infection. Abdominal pain has also been previously found to be significantly associated with the presence of giardiasis[8]. In our study, the incidence of giardiasis was higher in males, which is in agreement with the other studies[9-11]. However, the mean age of our patients was lower and might be attributed to more frequent exposure to this water borne infection because of social activities that involve frequent restaurants beside others. Diarrhea was seen in only 29% of cases. *G lamblia* infestation or other infectious causes were not considered because of the absence of diarrhea in most of these cases and hence a single stool examination was carried out. It is generally held that giardiasis may present with atypical gastrointestinal symptoms but this would be expected in combination with diarrhea[12]. The sensitivity for examination of a single random stool specimen is only 30-50%[13-14]. Hence this might explain the 6% low yield of stool examination in the cases for giardia cysts and trophozoites. Microscopic examination of a single stool sample cannot exclude *G lamblia* infection; therefore, at least three stool specimens should be examined before other diagnostic procedures. As only saline or Lugol's iodine examination of fecal smear was employed, it may have been insufficient in the absence of numerous parasites[14]. Other useful methods such as zinc sulfate floatation, a concentration technique for cysts, were also not employed in our study.

Duodenal ulcer is not a feature of giardiasis, while duodenitis was seen in 25% on endoscopy and in 68% on histology ($P = 0.002$). EGD with duodenal biopsy helps ruling out peptic ulcer as the only cause of symptoms. Giardiasis was associated with the normal endoscopic findings in the duodenum in 75% cases (Table 1). Hence duodenal biopsy should be considered with EGD in patients with abdominal pain as antral biopsy alone may prove inadequate for determining the cause of abdominal pain in a developing country. This is in agreement with the opinion held by some investigators that routine duodenal biopsies should be done in patients undergoing upper intestinal endoscopy[15,16]. In this study, most of our cases on EGD showed normal duodenal mucosa but duodenal biopsy with H&E staining demonstrated *G lamblia* trophozoites (Table 1). Although special stains such as Giemsa or phosphotungstic acid hematoxylin can occasionally be helpful, routine hematoxylin and eosin staining is almost always satisfactory[17].

The data suggesting the role of giardiasis in dyspeptic patients are in contradiction to a previous prospective study[17]. Carr *et al*.[18] carried out a study in an area which is not endemic for Giardia, and demonstrated Giardia in 15.5% of patients presenting with dyspepsia and its prevalence is similar with or without obvious lesions at endoscopy. In their study, only 52% patients presented with abdominal pain, and patients with vomiting and diarrhea as presentation had a significantly increased prevalence of Giardia. However, our data originates from a developing country located in an area endemic for the acquisition of Giardia. In our study, patients more commonly presented with abdominal pain than diarrhea (Table 1). The discrepancy describing a lower frequency of endoscopic duodenitis and higher frequency of histologic duodenitis in infected patients than in non-infected group might be due to a higher prevalence of *H pylori* infection in the latter. However, this was a retrospective observational study with its selection bias and limitations in diagnostic methods. Serial stool examinations were not carried in all patients.

The presentation of giardiasis varies and for diagnosis it requires a high degree of suspicion in the appropriate clinical setting. Examination of duodenal biopsy from patients presenting with abdominal pain should be considered so as to prevent missing diagnosis of giardiasis. Giardiasis is diagnosed more often on EGD with duodenal biopsy rather than on stool examination. As cyst excretion is variable and may be undetectable at times, repeated

examination of properly preserved stool samples and biopsy of the small intestine may be required to detect the parasites. A prospective study is under way to confirm the results of this study.

Abstract

AIM: To determine the fasting plasma carnitine ester in patients with celiac disease.

METHODS: We determined the fasting plasma carnitine ester profile using ESI triple quadrupol mass spectrometry in 33 adult patients with biopsy-confirmed maturity onset celiac disease maintained on long term gluten free diet.

RESULTS: The level of free carnitine did not differ as the celiac disease patients were compared with the healthy controls, whereas the acetylcarnitine level was markedly reduced (4.703 ± 0.205 *vs* 10.227 ± 0.368 nmol/mL, $P<0.01$). The level of propionylcarnitine was 61.5%, butyrylcarnitine 56.9%, hexanoylcarnitine 75%, octanoylcarnitine 71.1%, octenoylcarnitine 52.1%, decanoylcarnitine 73.1%, cecenoylcarnitine 58.3%, lauroylcarnitine 61.5%, miristoylcarnitine 66.7%, miristoleylcarnitine 62.5% and oleylcarnitine 81.1% in the celiac disease patients compared to the control values, respectively ($P<0.01$).

CONCLUSION: The marked decrease of circulating acetylcarnitine with 50-80 % decrease of 11 other carnitine esters shows that the carnitine ester metabolism can be influenced even in clinically asymptomatic and well being adult celiac disease patients, and gluten withdrawal alone does not necessarily normalize all elements of the disturbed carnitine homeostasis.

Key words: Plasma carnitine ester profile; Celiac disease

INTRODUCTION

The adult celiac disease (CD) is a complex autoimmune type of gastrointestinal disorder which can be induced by gluten as a nutritional etiological factor in genetically susceptible persons[1,2]. Metabolism of lipids and lipoproteins is disturbed in the disease[3-7]. The therapy includes withdrawal of the alimentary gluten, introduction of the diet usually results in dramatic clinical improvement and normalization of numerous metabolic deteriorations[1-3]. However, in the case of certain nutriments the diet alone is not enough and supplementation is also necessary.

The primary biochemical function of carnitine is related to its ester-forming capability[8]. In addition to its involvement in ß-oxidation of the long-chain fatty acids, it can form ester with several medium- and short-chain endogenous or exogenous fatty acids[8,9]. In mammals, the body stores of carnitine have exogenous and endogenous origin[10,11]. Several lines of evidence suggest that in human carnitine should be considered as a vitamin-like compound, since the majority of the body stores are of exogenous origin[10,12,13]. The sites of absorption are located in the small intestine[14,15]. These considerations prompted us to obtain information on plasma carnitine esters in patients with CD using tandem mass spectrometry profiling.

MATERIALS AND METHODS

Patients

We examined 33 patients with classic form of celiac disease (9 males, 24 females, mean age: 32.2 ± 2.5 years) and 35 carefully selected clinically healthy age, sex, weight and height matched control subjects (22 males, 13 females, mean age: 31.0 ± 1.9 years; Table 1).

The diagnostic criteria of established CD in our patients included: verification of the specific histological features in small intestinal biopsy specimens, according to

Table 1 Selected clinical and laboratory parameters of patients with celiac disease and control subjects (means ± SE)

	Celiac disease patients $n = 33$		Controls $n = 35$

the modified Marsh classification[16], positive serological results (antiendomysial antibody and tissue transglutaminase), unequivocally favorable clinical response to the administration of gluten free diet. Patients with any of the rare manifestations of the disease were excluded. All the CD patients were at least 17 years old upon diagnosis, and adhered to gluten free diet for at least one year. All patients received long-term oral iron replacement therapy. Exclusion criteria in both groups were as follows: secondary causes of intestinal atrophy, systemic diseases, any malformations, endocrine disorders, consumption of any drugs, evidence of intestinal bacterial infection, history or evidence for any inherited metabolic disease including those with impairment of glucose and lipid metabolism, smoking, hepatic or renal disease, and pregnancy.

The clinical and laboratory data from the time of diagnosis were from the records of the patients, while the actual results of the current study were from measurements performed from sample aliquots of a blood collection done after an overnight fast precisely between 8:00 and 8:30 AM, both in the celiac disease patients and in the healthy control subjects. This strict postailmental time scheduling was introduced to prevent the diet or fasting time induced dynamic changes of carnitine esters in the circulation[17].

Informed consent was obtained from each participant of the study and the study design was approved by the departmental ethics committee.

Methods

Plasma calcium, iron and albumin levels were determined by routine methods. The blood pictures, including hemoglobin (Hb), mean corpuscular volume (MCV), red blood cell distribution width (RDW) were measured by automated analysis (SYSMEX XE 2100, Japan). The body mass index (BMI) was calculated as body weight/height^2 (in kilograms/m^2).

Acylcarnitines were analyzed as butyl esters using a Micromass Quattro Ultima ESI triple-quadrupole mass spectrometer, combined with a Waters 2795 HPLC system for sample introduction. The procedure was a modified method described previously by Vreken *et al*.[18]. Essentially, 10 μL plasma was first spotted and dried onto a filter paper, then the plasma dot was excised and the excised piece was placed into an Eppendorf tube. Then 200 μL of methanolic stock solution of internal deuterated standards (containing 0.76 μmol/L [^{2}H$_3$]-free carnitine, 0.04 μmol/L [^{2}H$_3$]-propionylcarnitine, 0.04 μmol/L [^{2}H$_3$]-octanoylcarnitine and 0.08 μmol/L [^{2}H$_3$]-palmitoylcarnitine) was added. After 20 min of agitation the supernatant was dried under nitrogen at 40 °C. Derivatization was carried out at 65 °C for 15 min with an addition of 100 μL 3mol/L butanolic HCl. The resulting mixtures were dried again under nitrogen at 40 °C and redissolved in 100 μL mobile phase (acetonitrile:water 80:20). With the help of the autosampler 10 μL of sample aliquots was injected into the mass spectrometer. During the ESI-MS/MS analysis free carnitine and acylcarnitines were measured by positive precursor ion scan of m/z 85, with a scan range of m/z: 200-550. The applied capillary voltage, cone voltage and collision energy were 2.52 kV, 55 V and 26 eV, respectively. The flow rate was 100 μL/min and the total analysis time was 4 min per sample. For each sample the measurements were performed in triplicates beginning with the injection step and the means of the three determinations were used for further calculations.

For statistics Student's t test for unpaired samples was used. The values were expressed as means ± SE, in three decimals for the carnitine esters with respect to the low levels of the long-chain carnitine esters.

RESULTS

Major clinical and laboratory parameters, including those regarded generally as activity markers of CD[19-23] are shown in Table 1. The levels of plasma iron and Hb, and the value of MCV and BMI determined at the time of diagnosis were significantly lower in patients with CD as compared either to the values of the CD patients in the present study, or to the control subjects. In the current study all the previous parameters increased compared with the initial values, but decreased for the plasma iron, Hb and MCV (Table 1).

The plasma circulating carnitine ester profiles are shown in Table 2. The plasma level of free carnitine did not differ between CD patients and controls. By contrast, a marked decrease was found in the acetylcarnitine level in CD patients, which corresponded to 46% of the control value. A significant decrease was also found in the levels of propionyl- (61.5%), butyryl- (56.9%), hexanoyl- (75%), octanoyl- (71.1%), octenoyl- (52.1%), decanoyl- (73.1%) cecenoyl- (58.3%), lauroyl- (61.5%), miristoyl- (66.7%), miristoleyl- (62.5%) and oleylcarnitine (81.1%) in the CD patients as compared with the controls (the rates of decrease are expressed throughout as percent in parentheses taking the controls as 100%).

As a result of the decrease of individual carnitine esters, the plasma level of total esters was lower in CD patients than in controls (6.087 ± 0.571 *vs* 12.166 ± 0.978, $P<0.001$). The ratio of acetylcarnitine/total carnitine esters was 0.773 in the patients and was 0.841 in the controls.

DISCUSSION

We found a marked decrease in acetylcarnitine concentration and a significant decrease in the level of 11 further carnitine esters in plasma of CD patients on long-term gluten free diet. The pattern of the carnitine ester profile found in our patients differs from that found during fasting[17] and differs from the features seen in any of the known metabolic diseases[18,24,25]. The changes observed in the present study could be the result of impaired carnitine homeostasis, consequence of influenced metabolism of the acyl groups derived mainly from the fatty acid metabolism, and combination of thereof.

Damage of the intestinal mucosa can play a central role in the events leading to the changes observed in the current work. Majority of the carnitine reserves are derived from alimentary sources[26,27], the site of the absorption is located in the small intestines[14,15]. The epithelial cells are actively involved in the carnitine- and carnitine ester: contain different carnitine acyltransferases[8] such as the OCTN2 carnitine transporter[28] and the first three enzymes of the mammalian carnitine biosynthesis[29]: trimethyllysine hydroxylase, EC 1.14.11.8; hydroxytrimethyllysine aldolase, EC 4.1.2.'X'; and trimethylaminobutyraldehyde dehydrogenase, EC 1.2.1.47. On the other hand, the mucosa in the small intestine participates in the absorption of triglycerides and plays a complex role in the metabolism of lipoproteins, including chylomicrons, very-low-density lipoproteins, high-density lipoproteins and various apolipoproteins[30-34]. The mucosal damage in CD is classically known to cause fat malabsorption[1,2]. Untreated patients with the classic form of celiac disease may be malnourished and have impaired dietary substrate utilization, including impairment of the metabolism of fats and lipoproteins. It should be noted, that the long-term gluten free diet leads to improvement of several parameters of lipid metabolism[3]. However, the recovery is not necessarily complete for a number of metabolites of lipid metabolism[35,36].

Paradoxically, though the knowledge is growing on the circulating carnitine ester profile features in various disease conditions, very little is known about its normal regulation. Carnitine releases into the circulation by the liver primarily as acetylcarnitine[37] and the actual ester pattern is a result of the uptake/release action of the peripheral tissues. In the present study mainly the short-chain and medium chain carnitine esters were affected. Except for the propionylcarnitine, which can be also derived from the catabolism of amino acids methionine, valine and isoleucine, these acyl groups are mainly degradation products of the longer chain fatty acid oxidation[17], altered profile of the esters found in our asymptomatic patients likely reflects the still affected fatty acid metabolism.

Lipid and lipoprotein metabolism has been extensively investigated in CD, but carnitine homeostasis has hardly been studied. In 1994, Lerner *et al*.[38] investigated the carnitine concentrations in sera of pediatric CD subjects, and found that the total serum carnitine concentration is decreased in patients with active disease as compared with

Table 2 Plasma carnitine ester profiles in celiac disease patients and controls (mean±SE, μmol/L)

	Patients $n = 33$	Controls $n = 35$
Free carnitine (C0)	27.191 ± 1.194	30.029 ± 1.902

[b]$P < 0.01$ *vs* controls

normal subjects, while it was unchanged in CD patients with gluten withdrawal - associated non-active disease[38]. The decrease of carnitine reserves in active disease is likely secondary to the mucosal injury associated damage of the absorption. Albeit similar study on adult subjects is not presented in the literature, after this single pediatric paper the possible development of carnitine deficiency in untreated CD has become widely accepted[39].

In our patients the decrease of total carnitine esters could also reflect shortening of the reserves. It is known that even in patients strictly adhering to a gluten free diet the recovering mucosa can exhibit functional limitations. Therefore, carnitine absorption can be influenced on the one side. On the other side, the mucosa also participates in the trimethyllysine-butyrobetaine conversion, since the first three enzymes of the carnitine biosynthesis are expressed in it[29]. Residual damage can influence this procedure. In addition, trymethyllysine hydroxylase requires Fe^{2+} ion as cofactor[11]. Our patients had improvement after iron replacement therapy, but their plasma iron, Hb and MCV remained decreased. This phenomenon is common in the disease[22]. The decreased tissue iron reserves can also theoretically act on the enzyme activity.

In the recent years there has been increasing recognition that besides the classical major presentations of CD with a malabsorption syndrome and a flat jejunal mucosa, a broad spectrum of metabolic alterations can associate primarily or secondarily with the disease[40,41]. Some of them can be theoretically an early hallmark and predisposing factor for a clinical symptom manifested at a later stage of CD. Inhibition of oxidative metabolism of fatty acids, leading to myopathy with hypotonia and hyporeflexia, hypoglycemia, cardiomyopathy, encephalopathy and disturbed liver function, which are also among the rare extraintestinal manifestation of CD, may be results of carnitine insufficiency[42]. Whether supplementation of carnitine has rationale in the treatment of the disease similar to other metabolic nutriments used routinely in clinical practice[43] remains to be elucidated.

Abstract

AIM: To examine the sensory and motor response(s) of the stomach following fundic distention and to assess whether cholinergic mechanisms influence these responses.

METHODS: Fundic tone, gastric sensory responses and antral motility were evaluated in eight healthy volunteers after a probe with two sensors was placed in the antrum and a highly compliant balloon in the fundus. Isobaric balloon distentions were performed with a barostat. Study was repeated in six volunteers after intravenous atropine was given.

RESULTS: Fundic distention induced large amplitude antral contractions in all subjects. The area under the curve was higher ($P<0.05$) during fundic distention. First sensation was reported at 12±4 mmHg, moderate sensation at 18±4 mmHg and discomfort at 21±4 mmHg. Discomfort was associated with a decrease in antral motility. After atropine was given, the area under the curve of pressure waves and fundic tone decreased ($P<0.05$). Sensory thresholds were not affected.

CONCLUSIONS: Fundic balloon distention induces an antral motor response, the fundo-antral reflex, which in part may be mediated by cholinergic mechanisms.

Key words: Gastric motility; Reflex; Fundo-antral reflex; Sensation

INTRODUCTION

The stomach performs several important functions. It subserves the function of accommodation and thereby acts as a storage organ. It also functions as a grinder that triturates food into smaller particles and as a pump that transports chyme into the small bowel in a controlled fashion[1]. These functions depend on a complex mix of neurohumoral mechanisms, visceral sensation, intrinsic reflexes, intragastric transport, nutrient composition, particulate size, and the coordinated motor activity of the gastroduodenal unit[2,3].

In ferrets, distension of the corpus produces phasic activity in the antrum, a response termed as excitatory corporo-antral reflex. This is probably mediated by cholinergic mechanisms and intramural gastric pathways[4,5]. Intramural excitatory and inhibitory reflexes have also been demonstrated in isolated gastric preparations[6–9]. Recent studies have suggested that balloon distention of the stomach may increase phasic activity in the antrum and duodenum[10,11]. Whether this phasic activity represents an intrinsic gastro-gastric reflex has not been well characterized.

Furthermore, previous studies have assessed some of the individual components of gastric function[12,13]; whereas an integrated assessment of the biomechanical and sensory properties of the stomach has been scarcely performed. Also, there is very little information regarding the integrated role of the stomach as a sensory, motor and reflex organ. Our hypothesis is that fundic balloon distention may induce reflex antral pressure activity and this response may be mediated by cholinergic mechanisms.

Our objectives were to examine the antral motor responses during step-wise balloon distentions of the fundus, to simultaneously assess the sensory and tone responses of the stomach and to examine if the sensory and motor effects were mediated by cholinergic mechanisms.

METHODS

Study population

Eight healthy volunteers (m/f = 4/4) were recruited for this study. Their mean age was 32±4.95 years. None of them had a history of gastrointestinal or systemic ailments and none was using any medications. All had a normal physical examination. All participants gave written

informed consent and the study protocol was approved by the Human Investigation Review Board of the University of Iowa College of Medicine.

Manometry and barostat assembly

A double lumen plastic-probe (6 mm in diameter) containing a 10 cm long, highly-compliant balloon was used (MUI Scientific; Toronto, ON, Canada). The capacity of the balloon was 600 mL. The balloon was connected to a barostat (GMB Distender II; G&J Electronics Inc., Toronto, Canada). The probe had two perfusion side holes, 5 and 8 cm from the distal end of the balloon. These holes were perfused with gas-free distilled water at a rate of 0.2 mL/min (15 psi) using a low-compliance pneumohydraulic perfusion system (Arndorfer Medical Specialties, Inc., Milwaukee, WI, USA) that connected to transducers (Medex Inc.; MX860-G8618, Hilliard, OH, USA). Intraluminal pressures were relayed to an analog data recorder/amplifier (Medtronics Polygraph, Medtronics Functional Diagnostics; MN, USA) and displayed on a computer monitor using a software program (Polygram for Windows; Synectics Medical AB). The balloon volume and pressure data from the barostat were fed to the polygraph via an interface (Golden Gate; G&J Electronics Inc.).

Thus, the computer display consisted of the intragastric balloon volume, intra-balloon pressure as well as the intraluminal pressure changes in the antrum. The manometric data and the ultrasound images were simultaneously fed into a digital splitter (American Dynamics Ao1479, Orangeburg, NY, USA).

The ultrasonographic image of the cross-sectional diameter of the gastric antrum allowed visualization of antral contractions and assurance that the probe was properly positioned (Acuson 128XP with a 3 mHz sector transducer). The digital splitter synchronized the two images and displayed these images on a monitor screen (VM-17; Javelin, Los Angeles, CA, USA) such that one half of the screen showed the combined manometry and barostat recording and the other half displayed the ultrasound image. These images were recorded on a VHS tape for future analysis.

Study protocol

After an overnight fast, the oropharynx was sprayed with a local anesthetic, pontocaine (Abbott Laboratories, North Chicago, IL, USA). Then the probe with the balloon was placed through the mouth into the stomach. The volunteers were asked to sit in a semi-recumbent position, such that the head end was elevated by 45°. The balloon was distended with 250 mL of air and the probe was slowly retracted until a "tug" was felt signaling that the proximal end of the balloon was located in the fundus. Subsequently, ultrasound images were obtained to check the probe location. The location of pressure sensors in the antrum was also confirmed by the occurrence of typical antral motor pattern consisting of 3-cycle/min activity. The balloon was deflated and the probe was anchored to the cheek with a tape.

After a rest period of 15 min, the balloon was distended by 1 mmHg increments to assess the minimum distending pressure, a pressure at which diaphragmatic oscillations are clearly visible[14]. The intraoperating pressure (IOP) was set at a value of 2 mmHg above the minimum distending pressure using previous criteria[9-11]. Subsequently, a baseline recording of intragastric tone was performed for a period of 20 min. Then isobaric balloon distentions were performed at 3 mmHg increments. Each distention was maintained for 8 min followed by a rest period of 8 min. Thirty seconds after each distention, the subject was asked to rate their sensation on a scale of 0-6 as published previously[14], 0 = no sensation, 1 = vague perception of mild sensation, 2 = definite perception of mild sensation, 3 = vague perception of moderate sensation, 4 = definite perception of moderate sensation, 5 = discomfort, and 6 = pain. If the subject reported discomfort at two incremental distentions or pain at any one distention, the balloon distentions were discontinued. Abdominal ultrasonography was performed intermittently to visualize the antral configuration and morphology. Blood pressure and heart rate were monitored throughout the study.

We administered intravenously 0.6 mg of atropine sulfate in six volunteers (4 m/2 f) after a rest period of 60 min. Five minutes after administration of atropine, the balloon distentions were repeated as described above. Ultrasound images were obtained once again to confirm the location of antral sensors.

Manometric responses

Manometric recordings from the two antral pressure sensors were analyzed visually and manually with the assistance of Polygram for Windows software (Synectics Medical AB). Pressure waves that were $\geqslant$8 mmHg and $\geqslant$3 s in duration were included in the analysis. Artifacts were identified and excluded. There was good quality pressure activity at both channels in approximately 50% of the recordings and therefore an average of the pressure activity at the two antral channels was used. In the rest of the recordings, the pressure activity was more prominent in one of the antral channels and this channel was used for data analysis. The maximum amplitude, duration and area under the curve of each wave were calculated. We also measured the time interval between balloon distention and the onset of the first antral pressure wave as well as the total number of propagating pressure waves in the antrum during each inflation and deflation periods. Propagating waves were defined as pressure waves, which migrated across the antral leads within 6 s of each other and were categorized as either antegrade or retrograde depending on which of the two leads they first appeared in. A similar analysis of the antral pressure waves was performed after atropine injection.

Barostat responses

Gastric tone was assessed by measuring the area under the curve of the gastric volume during isobaric balloon

distentions as previously described[15-17]. The tone changes during and after distention were compared. Likewise, the tone changes obtained during the baseline study were compared with those after atropine injection.

Visceral sensory responses

During intragastric balloon distention, the minimum distending pressure that induced the first perception (a sensation of fullness and discomfort) were calculated. Likewise the sensory responses obtained after administration of atropine were compared to those obtained during the baseline study.

Statistical analysis

The data were presented as mean±SE. The number of pressure waves in the antrum during and after each balloon distention as well as before and after atropine injection was compared using Student's *t*-test. The thresholds for sensory perception and the gastric tone changes before and after atropine injection were compared using ANOVA.

RESULTS

Effects of fundic distention on antral pressure activity

Fundic balloon distention induced antral pressure waves, typically with an amplitude of ⩾50 mmHg (Figure 1). Occasionally, the distention-induced pressure activity persisted for several seconds even after the balloon was deflated, but in most instances the pressure activity ceased after deflation. Incremental balloon distention was associated with a steady increase in antral motility of up to 15 mmHg, but thereafter and particularly at 18 mmHg pressure there was a decrease in antral motility (Figure 2). Interestingly, during successive deflation periods, there was a trend towards progressive decrease in the area under the curve of pressure waves possibly reflecting a recovery of muscle tone.

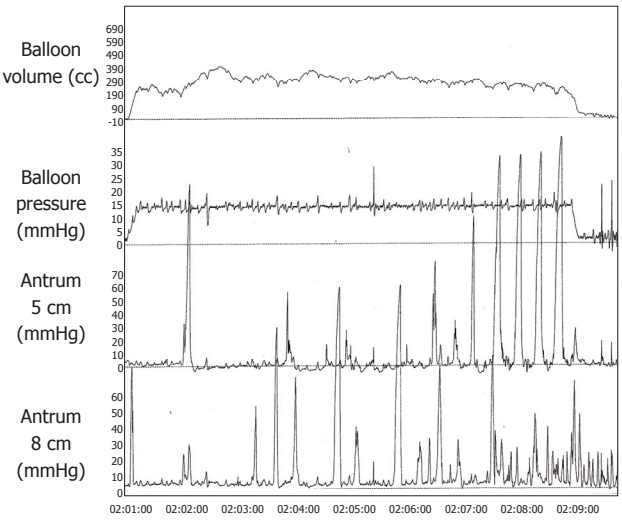

Figure 1 Typical example of the fundo-antral reflex. Channel 1: the fundic balloon volume; channel 2: the balloon pressure; channels 3 and 4: the pressure changes in the antrum.

The mean amplitude of antral pressure waves was also higher ($P<0.05$) during balloon distention than during balloon deflation. For example at balloon distending pressures of 6, 12, and 15 mmHg, the amplitudes were (inflation *vs* deflation) 60(11) *vs* 42(9), 70(14) *vs* 33(7), and 65(11) *vs* 23(7) mmHg respectively. The area under the curve (AUC) of the pressure waves was also significantly higher ($P<0.05$) during balloon distention (Figure 2A).

Visceral sensory responses

The subjects reported a first sensation at distending pressures ranging from 6 to 15 mmHg, a definite perception between 6 and 18 mmHg, a vague perception of moderate sensation between 11 and 21 mmHg, a definite sensation of moderate fullness between 12 and 24 mmHg and definite discomfort between 15 and 28 mmHg (Figure 2B).

Effects of atropine on gastric motor and sensory function

Visceral sensory responses The thresholds for first perception, fullness, and discomfort tended to be lower after administration of atropine but the difference was not significant (Figure 2C).

Antral pressure activity The area under the curve of pressure waves was significantly lower ($P<0.05$) after administration of atropine, particularly at balloon pressures of 6, 9, and 15 mmHg, but not at higher distending pressures (Figure 2D).

Fundic tone responses After administration of atropine, there was a significant increase ($P<0.05$) in balloon volume (Figure 2E) for the same corresponding level of intra balloon pressure, suggesting a decrease in fundic tone.

Cardiovascular responses The mean heart rate/min increased significantly ($P<0.05$) after administration of atropine during most of the distention except at 18 mmHg. There was no significant change in blood pressure.

DISCUSSION

We found that graded balloon distentions of the fundus induced antral pressure waves starting at thresholds that were not perceived by our healthy volunteers. This response was seen in all of our subjects. The area under the curve of pressure waves was significantly higher during the balloon inflation period than during the baseline period or the deflation period. Typically, the waves were ⩾50 mmHg in amplitude. Ultrasound images confirmed that these pressure events were often lumen-occluding contractions. The contractions began within a few seconds after balloon distention. These features suggest the existence of an excitatory gastro-gastric reflex in human beings, wherein distention of the fundus induces antral contractions. In a previous uncontrolled pilot study, we showed that fundic balloon distention may induce antral and duodenal phasic activity[10]. However, in the previous study, gastric visceral sensation or tone was not assessed and likewise the possible role of cholinergic mechanism(s) was not explored.

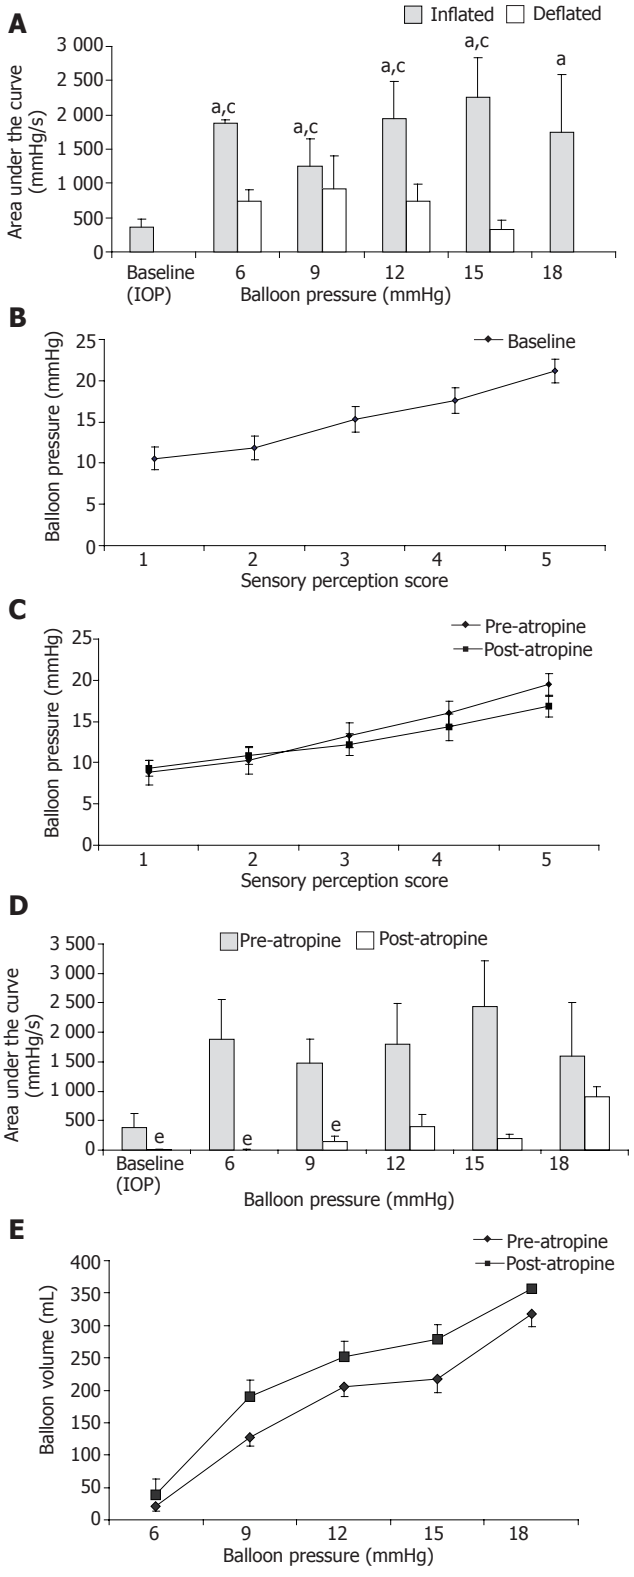

Figure 2 [a]*P*<0.05 inflation *vs* deflation. [c]*P*<0.05 baseline *vs* balloon inflation, [e]*P*<0.05 pre- *vs post*-atropine (**A-E**).

One of the limitations of our study is that we recorded motility from only two antral pressure sensors and it is possible that some of the antral activities may have been missed. However, the number of distention-induced contractions and the area under the curve of pressure waves gradually increased to a distending pressure of 15 mmHg, but thereafter their incidence declined, suggesting that there appears to be some correlation of antral motor responses with the visceral sensory responses. All of our subjects tolerated balloon distentions up to a pressure of 15 mmHg above IOP. Beyond this level of distention, some subjects reported discomfort or pain which was associated with a decrease in pressure activity. Thus, it appears that fundic distention at either subthreshold levels of perception or at thresholds that produce first sensation or fullness may induce reflex antral contractions, whereas higher distending pressures that induce discomfort or pain may cause an attenuation of this response.

After administration of atropine, there was a significant increase in heart rate and decrease in the resting gastric tone. Furthermore, the antral motor activity was also significantly attenuated, particularly at lower levels of balloon distention. At higher distending pressures ($\geqslant$12 mm Hg), some antral pressure activities were seen, though its incidence was lower than those observed before administration of atropine, suggesting that there is an adequate anti-cholinergic response and that the fundo-antral reflex may be partially mediated by cholinergic mechanisms[15]. However, we used a single dose of atropine and it is possible that over time there may have been a loss of anti-cholinergic effect. Also, there was no placebo arm, which is a limitation of this study. Nonetheless, these features suggest that either neuronal or drug-induced inhibition of cholinergic neurotransmission may partly affect gastric motor function. The sensory thresholds were either unchanged or somewhat decreased after administration of atropine, suggesting that gastric sensory responses may not be affected by cholinergic mechanisms, though the study was underpowered to assess this more completely.

Our study showed the possible existence of an intrinsic gastro-gastric reflex that can be induced by fundic distention. This response is different from the fundic relaxation that can be induced by antral distention[7,8] and appears to be partially mediated by cholinergic mechanisms and may in part be related to gastric sensation. Furthermore, unlike the Starling's Law which states that distention of an intestinal segment is associated with proximal contraction and distal relaxation, our result shows that in the human stomach, distention of the fundus is not necessarily associated with antral relaxation. Whether this response plays a role in the trituration of food or in the transport of gastric contents remains to be examined. Also, whether an attenuated or absent fundo-antral reflex plays a role in the pathogenesis of diabetic gastroparesis or functional dyspepsia remains to be explored.

Abstract

AIM: To validate the accuracy of four rapid blood tests in the diagnosis of *Helicobacter pylori*.

METHODS: Consecutive dyspeptic patients scheduled for endoscopy at the National University Hospital, Singapore, were interviewed and had blood drawn for serology. The first 109 patients were tested with BM-test (BM), Pyloriset Screen (PS) and QuickVue (QV), and the next 99 subjects were tested with PS and Unigold (UG). Endoscopies were performed blinded to rapid blood test results and biopsies were taken for culture and rapid urease test. Urea breath tests were performed after endoscopies. The rapid blood test results were compared with four reference tests (rapid urease test, culture, serology, and breath test).

RESULTS: The study population composed of 208 patients (mean age 43.1 years; range 18-73 years; 119 males; 174 Chinese). The number of evaluable patients for BM, QV, UG and PS were 102, 102, 95, and 197, respectively. The sensitivity and specificity, respectively were: PS 80.2%, 95.8%; UG 55.9%, 100%; QV 43.3%, 100%; BM 67.2%, 97.1%.

CONCLUSION: The rapid blood test kits showed high specificity and positive predictive value (97-100%), while sensitivity and negative predictive value ranged widely (43%-80% and 47%-73%, respectively). Among test kits, PS showed the best sensitivity (80%), best negative predictive value (73%) and best negative likelihood ratio (0.207). PS had a specificity of 96%, positive predictive value of 97% and positive likelihood ratio of 19.1.

Key words: *Helicobacter pylori*; Rapid blood test

INTRODUCTION

There are a variety of methods available for the detection of *Helicobacter pylori (H pylori)*, but many of these are invasive (such as biopsies for rapid urease test, culture, histology, and polymerase chain reaction) or require laboratories (such as urea breath test and serology). Recently, *H pylori* rapid test kits have become available. Rapid blood tests detect *H pylori* antibodies in whole or capillary blood, are easy to use, and yield results in a few minutes, making it a convenient point-of-care test for screening *H pylori*.

The 1997 Asia Pacific Consensus Conference on the management of *H pylori* infection[1] recommended that any blood test must be locally validated, with two or more alternative means of testing, before its widespread application.

Rapid blood test kits have not been widely validated in the Asian populations[2-5]. Local validation is important because the performance characteristics of blood test kits and population prevalence of *H pylori* vary in different populations. In Asian countries, the prevalence of *H pylori* infection is generally higher than in the developed Western nations (such as the United Kingdom, Australia, and France)[6]. In addition, the test performance of rapid blood kits may vary because local *H pylori* strains may be different[7,8].

Our prospective study aimed to validate four rapid blood test kits in the diagnosis of *H pylori* infection in a multi-ethnic Asian population. Amongst the Asian studies till date[2-5], none was conducted in a multi-ethnic population, and all were tested with less than four rapid blood test kits.

MATERIALS AND METHODS

Consecutive patients who were referred from general practice or outpatient clinics and scheduled for endoscopy for initial evaluation of dyspepsia at the National University Hospital, Singapore, were included for the

study. Exclusion criteria included patients with known peptic ulcer or gastric cancer, subjects with prior *H pylori* treatment, and those who had taken antibiotics, bismuth or proton pump inhibitors in the previous one month.

At entry, patients were interviewed using a standard questionnaire. Ten cubic centimeter of blood was drawn from each patient for serology. Each of the first 109 patients were tested with BM-test (BM, Boehringer Mannheim, East Essex, UK), QuickVue (QV, Quidel, CA, USA) and Pyloriset Screen (PS, Orion Diagnostica, Espoo, Finland). The kit with the best sensitivity was retained for continued testing in the next 99 patients together with an additional kit, Unigold (UG, Trinity Biotech, NY, USA). Endoscopy was then performed in the routine fashion by experienced endoscopists blinded to earlier results and three antral biopsy specimens were taken from each patient. Two biopsy specimens were sent for culture and one specimen was sent for the rapid urease test.

A ^{13}C urea breath test was performed directly after endoscopy. The technician doing the urea breath test was blinded to the results of the endoscopy. The results from the rapid blood test, rapid urease test, serology, culture, urea breath test and endoscopy were recorded on a standard data form.

The results of the rapid blood tests were compared with four reference tests: serology using HEL-p Test kit (AMRAD Operations Pty. Ltd, Australia), which had been validated locally[9], culture, rapid urease test, and urea breath test. *H pylori* infection was diagnosed, if any two reference tests were positive. If all the four reference tests were negative, it was assumed that infection was absent. Patients with a single positive test out of the four reference tests were classified as having indeterminate results.

Sample size was estimated based on reference tables[10]. Based on sensitivity of 80% and specificity of 90%, absolute precision of 0.10 and confidence interval of 95%, we needed a minimum of 62 *H pylori*-positive and 35 *H pylori*-negative patients.

The study was approved by the Research and Ethics Committee, National University Hospital, Singapore.

RESULTS

The characteristics of recruited patients are described in Table 1. One hundred and nine patients were tested with BM, QV, and PS (102 evaluable, 7 indeterminate results), and the next 99 subjects with PS and UG (95 evaluable, 4 indeterminate results).

Table 2 shows the sensitivity, specificity, predictive values and likelihood ratios of the respective rapid blood tests for *H pylori*. The rapid blood kits tested all showed specificities above 95% and very good positive predictive values exceeding 97%. There was a wide range in sensitivity between 43% and 80%, negative predictive value ranged from 48% to 73%, and negative likelihood ratios ranged from 0.207 to 0.567. PS had the best sensitivity of 80%, the best negative predictive value of 73%, and the best negative likelihood ratio of 0.207. PS had a high specificity of 96%, a good positive predictive value of 97.1% and a high positive likelihood ratio of 19.1.

Table 1 Characteristics of recruited patients

Kits used	PS, QV, BM	PS, UG	All
Number	109	99	208
Male:female	56:53	63:36	119:89
C:I:M:O[1]	91:12:4:2	83:7:6:3	174:19:10:5
Mean age (range)	44.7 (18–73)	41.3 (20–68)	43.1 (18–73)
H pylori positive	67	59	126
H pylori negative	35	36	71
Indeterminate results	7	4	11

[1]C = Chinese; I = Indian; M = Malay; O = Others.

Table 2 Sensitivity, specificity, predictive values, and likelihood ratios of rapid blood test for *H pylori* infection

Performance characteristics	BM	QV	UG	PS
Sensitivity (%)	67.2	43.3	55.9	80.2
Specificity (%)	97.1	99	99	95.8
Positive predictive value (%)	97.8	98	99	97.1
Negative predictive value (%)	60.7	47.9	58.1	73.1
Positive likelihood ratio	23.2	31.2	41.3	19.1
Negative likelihood ratio	0.338	0.567	0.441	0.207

DISCUSSION

Among the kits tested in our study, PS showed the best sensitivity (84%). Our study showed a wide range in the performance characteristics of the rapid tests. This may be attributable to the antigens used[11] or test kit designs.

The same rapid blood test kit might vary in performance between different populations. For example, QV's sensitivity for *H pylori* was 43.3% in our Singapore population, compared with 81% in Europe[12] and 82% in America[13]. These factors make it important that kits are locally tested and validated before use. A meta-analysis had shown that rapid tests are less accurate than reference tests, with sensitivity and specificity averaging 80-85% and 75-80%, respectively[14].

We conducted this study in an institution. For better evaluation of the potential of rapid blood test as a screening method in primary care, local studies conducted in general practice would be needed. Talley *et al.* reported that when used in general practice in Australia, rapid blood test had a sensitivity of 60% and specificity of 90%[15] Data on the performance characteristics of *H pylori* rapid blood test kits in general practice in the Asian population is lacking.

The Maastricht 2-2000 Consensus report[16] recommended a 'test and treat' approach in the primary care for *H pylori* infection. However, there is a strong association between *H pylori* infection and gastric cancer, especially in the Asian population, which has a high incidence of gastric cancer. Therefore, the use of 'test and treat' approach in Asians remains controversial and awaits further study. PS had a good sensitivity and specificity for the detection of *H pylori* infection, with the positive likelihood ratio of above 10, providing convincing diagnostic evidence, and negative likelihood ratio of 0.2, giving a strong diagnostic evidence. PS might therefore be potentially useful for 'test

and referral' strategy in general practice. Our study, which validated the point-of-care rapid blood test kits in a multi-ethnic Asian population, is an important step for future studies in this area.

In conclusion, there was a wide range in the performance characteristics of rapid blood test, making it important for the kits to be tested and validated locally before being used. Of the rapid blood kits tested, the best sensitivity for *H pylori* detection was 80% (PS). The validation of rapid blood test kits in the local population facilitates future studies on the 'test and treat' or 'test and referral' approach in the Asian population.

ACKNOWLEDGMENTS

We would like to thank Mrs Lim Thiew Peng who performed the *H pylori* serology and our research nurse Ms Lai Shuet Ting, for their kind assistance.

Abstract

AIM: To investigate the effects of *Nigella sativa* L (NS) and *Urtica dioica* L (UD) on lipid peroxidation, antioxidant enzyme systems and liver enzymes in CCl_4-treated rats.

METHODS: Fifty-six healthy male Wistar albino rats were used in this study. The rats were randomly allotted into one of the four experimental groups: A (CCl_4-only treated), B (CCl_4+UD treated), C (CCl_4+NS treated) and D (CCl_4+UD+NS treated), each containing 14 animals. All groups received CCl_4 (0.8 mL/kg of body weight, sc, twice a week for 60 d). In addition, B, C and D groups also received daily i.p. injections of 0.2 mL/kg NS or/and 2 mL/kg UD oils for 60 d. Group A, on the other hand, received only 2 mL/kg normal saline solution for 60 d. Blood samples for the biochemical analysis were taken by cardiac puncture from randomly chosen-seven rats in each treatment group at beginning and on the 60th d of the experiment.

RESULTS: The CCl_4 treatment for 60 d increased the lipid peroxidation and liver enzymes, and also decreased the antioxidant enzyme levels. NS or UD treatment (alone or combination) for 60 d decreased the elevated lipid peroxidation and liver enzyme levels and also increased the reduced antioxidant enzyme levels. The weight of rats decreased in group A, and increased in groups B, C and D.

CONCLUSION: NS and UD decrease the lipid peroxidation and liver enzymes, and increase the antioxidant defense system activity in the CCl_4-treated rats.

INTRODUCTION

Carbon tetrachloride (CCl_4) is one of the oldest and most widely used toxins for experimental induction of liver fibrosis in laboratory animals[1]. This model has been used in various studies on examined the deposition of extracellular matrix in the fibrotic and cirrhotic liver[2,3].

CCl_4 is a selective hepatotoxic chemical agent. CCl_4-induced reactive free radicals initiate cell damage through two different mechanisms of covalent binding to the membrane proteins and cause lipid peroxidation. A number of investigators have utilized this chemical to produce liver cirrhosis in experimental animals[4]. Production of reactive oxygen species and lipid peroxidation induced by iron overload[5], cholestatic injury[6] and intoxication by ethanol[7] and CCl_4[4] is associated with liver fibrosis and cirrhosis. These effects are partially prevented by antioxidant compounds including α-tocopherol[4,8], silymarin[9] and salvianolic acid[10].

The seed of *Nigella sativa* L (NS), an annual *Ranunculaceae* herbaceous plant, has been used traditionally for centuries in the Middle East, Northern Africa, Far East and Asia for the treatment of asthma. NS contains more than 30 of a fixed oil and 0.40-0.45 w/w of a volatile oil. The volatile oil has been shown to contain 18.4-24% thymoquinone and 46% many monoterpenes such as p-cymene, and α-pinene[11]. Recently conducted clinical and experimental researches have shown many therapeutic effects of NS extracts such as immunomodulator[12], anti-inflammatory[13] and anti-tumour agents[14].

Urtica dioica L (UD) is a plant belonging to the plant family *Urticaceae*. Its seeds are widely used in folk medicine in many parts of Turkey, especially in the therapy of advanced cancer patients. Polar extract of the UD contains lignans (+)-neoolivil, (-)-secoisolariciresinol, dehydrodiconiferyl alcohol, isolariciresinol, pinoresinol, and 3,4-divanillyltetrahydrofuran, and has antiinflammatory

effects[15] and stimulates the proliferation of human lymphocytes[16].

The present study aimed to investigate the preventive effects of NS and UD on lipid peroxidation, antioxidant enzyme systems and some liver enzymes in CCl_4-treated rats.

MATERIALS AND METHODS

Plant materials and extraction procedure

The NS and UD seeds were purchased from a local herb store, Zonguldak, Turkey. Voucher specimens were kept at the Department of Biochemistry, Zonguldak Karaelmas University, Zonguldak, Turkey for the future reference. The seeds of NS were powdered in a mixer, placed in a distillation flask and the volatile oil with 0.2 % yield was collected by a steam distillation. The fixed oil of UD was extracted with the help of a rotary evaporator using diethyl ether as solvent.

Treatment of rats

Fifty-six male Wistar albino rats, weighing 150-200 g, averaging 16 wk old, were used in this study. The rats were randomly allotted into one of the four experimental groups: A (CCl_4-only treated), B (CCl_4+UD treated), C (CCl_4+NS treated) and D (CCl_4+UD+NS treated), each containing 14 animals. All groups received CCl_4 (Merck; 153.82 g/moL, 1.59 kg, Germany, 0.8 mL/kg of body weight, sc, twice a week for 60 d). In addition, B, C and D groups also received the daily ip injection of 0.2 mL/kg NS or/and 2 mL/kg UD oils for 60 d. Group A, on the other hand, received only 2 mL/kg normal saline solution for 60 d. The animals were housed in macrolon cages under standard laboratory conditions (light period 7.00 a.m. to 7.00 p.m., 21±1 °C, rat chow and tap water freely available). All animals received human care according to the criteria outlined in the "Guide for the Care and Use of Laboratory Animals" prepared by the National Academy of Sciences and published by the National Institutes of Health. The experiment lasted for 60 d.

Biochemical analysis

Blood samples for the biochemical analysis were taken from each treatment group at beginning and on the 60th d of the experiment. Rats from which blood samples were taken were excluded from the experiment to eliminate the haemorrhage- and stress-induced complications. At the end of the experiment, rats in all groups were starved overnight, and sacrificed under chloralhydrate (6 mL of 7% chloralhydrate/kg, Sigma, St. Louis, MO, USA) anaesthesia. Blood samples were collected by cardiac puncture using heparinised syringes. Leukocytes and plasma components were seperated by centrifugation of the blood. Erythrocytes were washed three times with 0.9% NaCl solution and packed, and then stored at -70 °C until study.

Blood MDA (mmol/L) was determined by the double heating method of Draper and Hadley[17]. The principle of the method is spectrophotometric measurement of the colour produced during the reaction to thiobarbituric acid (TBA) with MDA. For this purpose, 2.5 mL of 100 g/L trichloroacetic acid solution was added to 0.5 mL erythrocytes in each centrifuge tube and placed in a boiling water bath for 15 min. After cooled in tap water, the mixture was centrifuged at 1 000 r/min for 10 min, and 2 mL of the supernatant was added to 1 mL of 6.7 g/L TBA solution in a test tube and placed in a boiling water bath for 15 min. The solution was then cooled in tap water and its absorbance was measured using a Shimadzu UV-1601 (Japan) spectrophotometer at 532 nm. The concentration of MDA was calculated by the absorbance coefficient of MDA-TBA complex 1.56×10^5 /cm, and expressed in μmol/g Hb erythrocytes and μmol/g tissue protein.

Blood GSH concentration was measured by the method described by Beutler *et al.*[18]. Briefly, 200 μL of whole blood was added to 1.8 mL of distilled water. Three ml of the precipitating solution was mixed with the hemolysate. The mixture was allowed to stand for approximately 5 min and then filtered. Two milliliters of filtrate were taken and added into another tube, and then, 8 mL of the phosphate solution and 1 mL of the DTNB [5,5'dithiobis-(2-nitrobenzoic acid)] were added. A blank was prepared with 8 mL of the phosphate solution, 2 mL of the diluted precipitating solution (three parts to two parts of the distilled water), and 1 mL of the DTNB reagent. A standard solution of glutathione was prepared (40 mg/100 mL). The optical density was measured at 412 nm with a spectrophotometer.

Serum ceruloplasmin *p*-phenylenediamine (PPD) oxidase activity was measured according to Sunderman and Nomoto[19]. At pH 5.4, ceruloplasmin catalyze the oxidation of PPD to yield a colored product. The rate of formation of the colored oxidation product was proportional to the concentration of serum ceruloplasmin if a correction was made for nonenzymatic oxidation of PPD.

Vitamin E was analyzed colorimetrically with 2,4,6-tripridyl-s-triazin and $FeCl_3$ after the extraction with absolute ethanol and xylene[20]. Serum vitamin C level was determined after derivatisation with 2,4-dinitrophenylhydrazine[21]. The levels of β-carotene at 425 nm and retinol at 325 nm were detected after the reaction of serum : ethanol : hexane at the ratio of 1 : 1 : 3 respectively[22].

Alanine aminotransferase (ALT), aspartate aminotransferase (AST) and alkaline phosphatase (ALP) levels were determined by an autoanalyzer (Roche-Hittachi, Japan) using commercial kits (Roche, Basel, Switzerland).

Statistical analysis

The data were expressed as mean±SD and analysed by repeated measures of variance. Tukey test was used to test for differences among means when ANOVA indicated a significant ($P\leqslant0.05$) F ratio.

RESULTS

The levels of blood MDA, antioxidants of all groups and the levels of serum liver enzymes are shown in Table 1-3, respectively. The CCl_4 treatment for 60 d significantly ($P<0.05$) increased the MDA and liver enzymes, and also decreased ($P<0.05$) the antioxidant levels. NS or UD treatment (alone or in combination) for 60 d significantly ($P<0.05$) decreased the elevated MDA and liver enzyme levels and also increased ($P<0.05$) the reduced antioxidant levels. The weight of rats decreased ($P<0.05$) in group A, and increased ($P<0.05$) in groups B, C, and D (Table 4).

DISCUSSION

Treatment of animals with CCl_4 is known to cause severe hepatic injury[23]. In our study, we showed that repeated CCl_4 treatment for 60 d increased the lipid peroxidation and liver enzymes, and also decreased the antioxidant enzyme levels. It has been suggested that the lipid peroxidation may be a link between tissue injury and liver fibrosis by modulating collagen gene expression[24]. It was reported that CCl_4 is suitable to induce lipid peroxidation in experimental animals within a few minutes after administration and its long-term use results in liver fibrosis and cirrhosis by lipid peroxidation pathway[25]. It is generally thought that CCl_4 toxicity is due to reactive free radical (CCl_3.), which is generated by its reductive metabolism by hepatic cytochrome P450. The reactive intermediate is believed to cause lipid peroxidation and breakdown of cellular membranes[26].

Recent experimental studies have investigated the role of antioxidative vitamins, minerals, drugs and plant-derived compounds in the prevention and therapy of liver fibrosis. Parola *et al*.[4] showed that an increased liver content of vitamin E leads to a significant degree of protection against carbon tetrachloride-induced chronic liver damage and cirrhosis in rats. Ianas *et al*.[27] have described the all-round beneficial action of a selenium preparation upon the organism in rats exposed to CCl_4 as well as a strong antioxidative effect, confirming the essential role of selenium in maintaining cellular integrity.

Several plant derived compounds such as colchicine (Colchicum dispert), silymarin (Slybum marianum), polyenylphosphatidyl choline (soy bean), ellagic acid (cruciferous vegetables), Gingko biloba composita and recently Sho-saiko-to (extract of seven herbs in Chinese folk medicine) have been proposed as antioxidants and antifibrotics in the treatment of chronic liver disease[28-30]. The antioxidative and hepatoprotective effects of chitosan against CCl_4-induced liver toxicity in rats have been under investigation by measuring thiobarbituric acid reactive substances (TBARS) and antioxidant enzyme activities[31]. The antioxidant systems such as antioxidant vitamins (A, C, and E), superoxide dismutase (SOD), catalase, glutathione (GSH), ceruloplasmin and glutathione peroxidase (GSH-Px) protect the cells against lipid peroxidation, which is the base of many pathologic processes [32,33].

In our study, we found that NS or UD treatment (alone or combination) for 60 d decreased the elevated MDA and liver enzyme levels and also increased the reduced antioxidant enzyme levels in CCl_4-treated rats. Previously performed clinical and experimental investigations have shown that NS has a protective effect against oxidative damage in isolated rat hepatocytes[34]. It was found that the fixed oil of NS has both antioxidant and anti-eicosanoid effects greater than thymoquinone which is its active

constituent[13]. Furthermore, NS has antioxidant activity by suppressing the chemiluminescence in phagocytes[35].

Recently, Turkdogan *et al.*[36] observed that NS has a significant hepatoprotective effect in CCl_4-administrated rabbits, ans that hepatocellular degenerative and necrotic changes are slight without advanced fibrosis and cirrhotic process in NS-treated group. However, Turkdogan *et al.*[37] found that NS can prevent liver fibrosis and cirrhosis, suggesting that NS protects liver against fibrosis possibly through immunomodulator and antioxidant activities.

There are no comprehensive studies on the therapeutic effects of UD. Only one study reported that UD extract can inhibit *in vitro* prostate cancer cell proliferation[38]. It has been suggested that the extract of UD is effective in inducing glutathione S-transferase, SOD and catalase activity in the forestomach and SOD and CAT activity in the lung at both dose levels[39]. However, Turkdogan *et al.*[36] showed that NS and UD can significantly prevent CCl_4-induced hepatotoxicity in rats. Our biochemical results demonstrated that NS and UD treatment prevented CCl_4-induced hepatotoxicity in rats by decreasing the lipid peroxidation and increasing the antioxidant defense system activity. However, Kanter *et al.*[40] also showed the NS and UD increase the antioxidant defense system activity in experimentally CCl_4-treated rats.

In conclusion, NS and UD decrease lipid peroxidation and liver enzymes, and increase antioxidant defense system activity in the CCl_4-treated rats. They also prevent weight lose induced by the CCl_4 treatment. Further studies are required to evaluate the possible hepatoprotective effect of NS and UD which are traditionally used as a medicine for many complaints including liver diseases.

Abstract

AIM: To elucidate the immunologic parameters for the outcome of patients with malignant tumors, especially esophageal squamous cell carcinoma (ESCC) associated with high malignant potential.

METHODS: Clinicopathologic features were compared between patients with lower and higher CD4 and CD8 values as well as CD4/CD8 ratio in peripheral blood.

RESULTS: The survival rate of patients with higher CD4 value was significantly better than that in patients with lower CD4 value (P = 0.039). The survival rate of patients with higher CD8 value was significantly worse than that of patients with lower CD8 value (P = 0.026). Similarly, the survival rate of patients with higher CD4/CD8 ratio was significantly better than that of patients with lower CD4/CD8 ratio (P = 0.042). Additionally, multivariate analysis demonstrated that lower CD8 and lower CD4/CD8 ratio were factors independently associated with worse prognosis of patients.

CONCLUSION: All the immunologic parameters can predict the outcome of patients with ESCC.

Key words: Lymphocyte sub-population; Esophagus; Squamous cell carcinoma; Prognostic indicator

INTRODUCTION

Impaired immunity is well known to be correlated with the tumorigenesis and/or progressive behavior of human tumors[1-3]. Therefore, it is important to assess the immunologic dynamics of patients with malignant tumors, especially esophageal carcinoma.

We have reported the significance of preoperative assessment of such immunological parameters as serum C-reactive protein concentration[4], prognostic nutritional index[5], and phytohemagglutinin (PHA) response test[6] as a prognostic indicator in esophageal carcinoma.

CD8+, cytotoxic T lymphocytes, plays an immunologic role as the specific tumor terminator and CD4+, helper T lymphocyte, serves the function of controlling CD8+ T-cell-dependent tumor termination[7]. However, only a few investigations are available on the clinicopathologic significance of these lymphocytes in controlling esophageal carcinoma[8-10].

It was reported that lower CD4/CD8 ratio in peripheral blood can be used as an indicator for worse prognosis of patients with esophageal carcinoma[11]. In the current study, we investigated the clinical significance of the serum values of CD4 and CD8, and the CD4/CD8 ratio in patients with esophageal squamous cell carcinoma (ESCC).

MATERIALS AND METHODS

One hundred and thirty-four patients (118 men and 16 women) with ESCC, who underwent esophageal resection and reconstruction of the digestive tract in our institute between 1990 and 1997, were enrolled in this study. The patients had a median age of 62 years (range, 41-82 years).

Follow-up was continued until their death. The interval of follow-up ranged from 29 d to 8 years and 9 mo averaged 2 years and 11 mo. Serum values of lymphocyte sub-populations, CD4 and CD8, were measured as previously described[11].

Pathological features were presented according to the guidelines for clinical and pathologic studies on carcinoma of the esophagus established by the Japanese Society for Esophageal Diseases[12], and clinical stages were determined by the TNM classification of malignant tumors approved by the International Union Against Cancer[13]. Clinicopathologic features were compared between patients with lower and higher values of CD4 and

CD8 as well as CD4/CD8 ratio.

Chi-square test and Student's *t* test were used to compare the clinicopathologic data. The cumulative survival rates were calculated by the Kaplan-Meier method and the survival curves were tested by the Mantel-Cox method. $P<0.05$ was considered statistically significant.

RESULTS

Among the clinicopathologic factors, the mean age of patients with higher CD4 value (group H-CD4) was significantly lower than that of patients with lower CD4 value (group L-CD4, $P = 0.046$). However, no significant difference was observed in other factors including tumor-related factors (Table 1). The 1-, 3-, and 5-year survival rates were 82.2%, 60.4% and 48.4%, respectively, in group H-CD4 and 70.8%, 36.9% and 32.7%, respectively, in group L-CD4 ($P = 0.039$, Figure 1A).

No significant difference was found in the clinicopathologic factors between patients with higher (group H-CD8) and lower CD8 value (group L-CD8, Table 2). The 1-, 3-, and 5-year survival rates were 69.7%, 38.5% and 30.0%, respectively, in group H-CD8 and 82.7%, 57.7%, and 49.0%, respectively, in group L-CD8 ($P = 0.026$, Figure 1B).

Significant difference between patients with higher (group H-CD4/8) and lower CD4/CD8 ratio (group L-CD4/8) was observed only in gender proportion ($P = 0.036$, Table 3). The 1-, 3-, and 5-year survival rates were 80.9%, 62.9%, and 52.9%, respectively, in group H-CD4/8 and 74.0%, 40.3% and 33.0%, respectively, in group L-CD4/8 ($P = 0.042$, Figure 1C).

Multivariate analysis demonstrated that lower CD8 (95%CI, 2.07, 1.26–3.38; $P = 0.004$) and lower CD4/CD8 ratio (95%CI, 1.73, 1.02-2.93; $P = 0.043$) were factors independently associated with worse prognosis of patients.

DISCUSSION

With the development of monoclonal antibodies in detecting lymphocytes subpopulation[14], lymphocyte subtypes in peripheral blood were examined to investigate their functions in immune-surveillance. Among the subpopulations of lymphocytes, investigations of cancer immunology have been focused on CD8, suppressor/

Well = well differentiated squamous cell carcinoma; Moderately = moderately differentiated squamous cell carcinoma; Poorly = poorly differentiated squamous cell carcinoma.

cytotoxic T lymphocyte responses. Attention has also been paid to CD4, helper/inducer T lymphocytes, as a critical component of the anti-tumor immune response[15].

Tumor-specific immune response depends on the function of activated CD4 cells[16], and therefore the deficiency in the function of activated CD4 cells might be directly correlated with the immune-deficiency of the host. CD4 helper/inducer T lymphocytes produce lymphokines, thus promoting the cytotoxic activity of CD8 T lymphocytes[17,18]. Therefore, activation of both CD4 and CD8 can exert a synergistic immune response to the termination of tumor cells.

Though some investigations have demonstrated an immunologic anti-tumor effect of CD4 and CD8[8], the clinical significance of CD4/CD8 ratio in tumor infiltrating lymphocytes and/or in peripheral blood as an indicator of progressive gastrointestinal tumor and/or worse prognosis of patients has been occasionally reported[19-21]. Diederichsen *et al.*[19] reported that low CD4/CD8 ratio in tumor infiltrating lymphocytes is an independent prognostic indicator in patients with colorectal carcinoma. Decrease of the CD4/CD8 ratio is correlated with progressive behavior of the tumor indicated by such tumor-related factors as stage of the tumor, tumor invasion, lymph node metastasis, and size of the tumor in gastric cancer[20]. Moreover, severe pre-

operative cellular immune-suppression, where CD4/CD8 ratio was less than 1.0, is a predictive parameter for mortality in patients with gastric cancer[21].

CD8 expression in TIL in tumor tissue can serve the function of suppressing the proliferation of ESCC[9], and similarly CD8 infiltration into the tumor is an independent prognostic indicator for ESCC[10]. Recently, increase of the number of CD4 and CD8 T lymphocytes in tumor nests and stroma has been found to be an independent indicator of favorable prognosis of patients with ESCC[8].

These results suggest that CD8 T-lymphocyte infiltration, as have been investigated in some other tumors[22,23], plays a pivotal role in immune-potential against ESCCs.

However, it was reported that the prognosis of patients with lung carcinoma associated with more CD8 expressing T cells within cancer nests is significantly worse than that of patients with tumors of fewer CD8 expressing T cells[24]. High percentage of activated CD8-positive cells in postoperative peripheral blood is an indicator of worse prognosis for renal cell carcinoma[25].

The different methods used to evaluate the value or expression of CD8, histological type of the tumor, or balance between immunologic dynamics of the tumor and the host might explain this possible discrepancy in the significance of CD8 T lymphocytes in anti-tumor immune.

In the current study, the decreased CD4/CD8 ratio as well as the increased CD8 and the decreased CD4 in peripheral blood could predict the worse prognosis in patients with ESCCs. Preoperative coexistence of impaired immunity could influence the postoperative complications[5]. The incidence of postoperative complications is an independent indicator of worse prognosis in patients with esophageal carcinoma[26]. Therefore, preoperative impaired immunity seems not to be negligible as the cause of death, other than esophageal carcinoma.

Assessment of preoperative immunity in patients seems to be of great importance in predicting the subsequent outcome of patients with ESCCs.

Abstract

AIM: To determine the DNA binding activity and protein levels of the Ku70/80 heterodimer, the functional mediator of the NHEJ activity, in human colorectal carcinogenesis.

METHODS: The Ku70/80 DNA-binding activity was determined by electrophoretic mobility shift assays in 20 colon adenoma and 15 colorectal cancer samples as well as matched normal colonic tissues. Nuclear and cytoplasmic protein expression was determined by immunohistochemistry and Western blot analysis.

RESULTS: A statistically significant difference was found in both adenomas and carcinomas as compared to matched normal colonic mucosa (P<0.00). However, changes in binding activity were not homogenous with approximately 50% of the tumors showing a clear increase in the binding activity, 30% displaying a modest increase and 15% showing a decrease of the activity. Tumors, with increased DNA-binding activity, also showed a statistically significant increase in Ku70 and Ku86 nuclear expression, as determined by Western blot and immunohistochemical analyses (P<0.001). Cytoplasmic protein expression was found in pathological samples, but not in normal tissues either from tumor patients or from healthy subjects.

CONCLUSION: Overall, our DNA-binding activity and protein level are consistent with a substantial activation of the NHEJ pathway in colorectal tumors. Since the NHEJ is an error prone mechanism, its abnormal activation can result in chromosomal instability and ultimately lead to tumorigenesis.

Key words: Colorectal cancer; Colon adenoma; DNA-dependent protein kinase; Ku70/80 heterodimer; Mismatch repair; Non-homologous end joining; Double strand break repair; Chromosomal instability

INTRODUCTION

Colorectal cancer is a significant cause of morbidity and mortality in Western populations[1]. This cancer progresses through a series of defined histopathological stages, going from a small benign tumor (adenomatous polyps) to a malignant cancer (carcinoma)[2]. During tumor progression, a stepwise accumulation of genetic changes is observed, leading to inactivation of tumor suppressor genes (e.g. APC, p53) and activation of oncogenes (e.g. K-ras, β-catenin)[2]. The number of genomic alterations in cancer appears to exceed the level possibly due to the accumulation of mutations in cells with normal mutation rates. A number of intricate networks have evolved in eukaryotic cells to respond to exogenous and endogenous genotoxic stimuli[3]. Genes involved in these pathways play

a crucial role in maintaining DNA integrity and a defect in these processes may result in hypersensitivity to DNA damaging agents and genomic instability[4]. Two main forms of genetic instability are associated with tumors. One arises from the inactivation of DNA mismatch repair (MMR) genes[5], leading to instability at the nucleotide sequence level (microsatellite instability, MSI). The other results from a disruption of the pathways intending to protect the cells from chromosomal breakage (double-strand breaks, DSBs), which leads to gross chromosomal rearrangements (chromosomal instability, CIN)[6]. Of the many types of DNA damage, DSBs are the most dangerous, because of the intrinsic difficulty of their repair as compared to other types of DNA damage[6]. In physiological conditions, DNA-DSBs are generated by homologous recombination (HR) during meiosis and occur in other events, such as V(D)J recombination and immunoglobulin class switch[6]. In addition, DSBs can result from both exogenous agents such as ionizing radiation or chemotherapeutic agents and endogenously generated reactive oxygen species[6]. Erroneous rejoining of the broken DNA-DSBs may cause loss or amplification of chromosomal material and even translocations, ultimately leading to tumorigenesis[4].

There are two distinct and complementary mechanisms for DNA-DSB repair: the NHEJ and the HR[4]. Recently, a caretaker role in preventing carcinogenesis has been proposed for the NHEJ pathway[7-9]. At present, five proteins involved in the NHEJ pathway have been identified; namely, the ligase IV and its associated protein XRCC1, and the three components of the DNA-dependent protein kinase (DNA-PK) complex, Ku70, Ku86, and the catalytic subunit PKcs[10]. Mutational analysis has shown that activation of the DNA-PK well correlates with Ku protein heterodimerization and DNA-end binding[11]. Once anchored to the DNA, the Ku70/80 heterodimer translocates along the molecule and facilitates recruitment of the catalytic subunit to the site of the break, to form an activated DNA-PK complex[11]. Numerous studies have investigated the role of MMR pathway in colorectal carcinogenesis, but little is known about the involvement of the DSB repair pathway in the adenoma/carcinoma sequence[11-13]. In the attempt to better understand this role, we analyzed the DNA-binding activity of the Ku70/80 heterodimer and the protein expression of the two Ku subunits in colon adenomas, colorectal cancers and matched normal tissues. Ku70/80 DNA binding activity was increased in approximately 50% of adenoma and carcinoma samples, as compared to matched normal tissues. In tumors with increased DNA-binding activity, Ku70 and Ku86 protein expression correlated with the heterodimer binding activity.

MATERIALS AND METHODS

Patients characteristics and tissue samples

Twenty patients with colon adenoma and 15 patients with colorectal carcinoma were recruited in the study. The patients underwent endoscopic polypectomy or surgical resection between 1999 and 2002, at the Departments of Gastroenterology and General Surgery, Campus Bio-Medico University of Rome, Italy. None of the patients were affected by familial polyposis or HNPCC. Subjects included 20 males (57%) and 15 females (43%), with a mean age of 69.5±12 years (range 35-82 years). None had pre-operative chemotherapy or irradiation. All the patients gave informed consent for the study. Thirty-one lesions (89% including adenomas and carcinomas) were located in the colon and 4 (11%) in the rectum. Adenomas were classified according to the National Polyp Study Cohort and WHO recommendations on the basis of size and grade of dysplasia[14,15]. Clinical staging of colorectal cancer was assessed according to the Dukes' classification[13].

Preparation of cell and nuclear extracts

Following surgical resection, tissue samples were immediately frozen at -80 °C. For each case, before protein extraction, one 3-μm hematoxylin-eosin stained slide was analyzed to ensure that tumor samples contained at least 70% cancer cells. Protein extraction was performed as previously described[16-18]. Briefly, frozen samples were mechanically fractionated to obtain a cellular suspension. Nuclear and cytoplasmic fractions were separated by centrifugation at 10 000 *g* and stored at -80 °C.

Protein content in nuclear and cytoplasmic extracts was determined in triplicate by Bradford assay (Bio-Rad Protein Assay, Bio-Rad Laboratories, Munchen).

Gel-shift assay

Electrophoretic mobility shift assay (EMSA) was performed as described previously[18,19]. Briefly, DNA binding reactions contained 50 000 cpm of the labeled probe, nuclear (2 μg) or cytoplasmic (5 μg) extracts with closed circular plasmid DNA pUC-19 (1 μg) as the unspecific competitor. For each sample, three single shift assays were performed. As controls, 33 normal human tissues from patients without colon tumor were analyzed (mammary gland $n = 8$, bladder mucosa $n = 8$, and skin $n = 17$).

To normalize all the samples, electrophoretic mobility shift assays were performed by incubating the nuclear extracts (3 μg) with 50 000 cpm/sample of ^{32}P-end labeled Sp-1 oligonucleotide (Promega Corporation, Madison, WI, USA) in a binding buffer, with 1 μg of poly (dI-dC) as the unspecific competitor. The correction factor (CF) was calculated as follows: *SP1 binding activity in the sample/mean SP1 binding activity*. Data were normalized using the following formula: *Mean Ku70/80 binding activity/CF*[20].

For gel supershift experiments, goat polyclonal anti-Ku70 and anti-Ku86 antibodies (M-19, M-20: Santa Cruz Biotechnologies Inc., CA, USA) were incubated with protein extracts for 30 min at room temperature, before the other components were added to the binding reaction. Complexes were separated on 6% non-denaturing polyacrylamide gels and exposed to X-ray films (Amersham-Pharmacia Biotech, England HP7 9NA).

The optical densities (OD) were obtained by scanning densitometry using colon carcinoma cell line CaCo-2 (ATCC) as internal control (OD = 10.7±6.4).

Supershift control experiments confirmed the specificity of the results in each gelshift assay experiment.

Immunohistochemistry

Paraffin sections from matched normal colonic mucosa were available for all the colon cancer cases entered in the study, whereas paraffin embedded blocks from matched normal tissues were available only for 10 adenomas. Paraffin sections from five subjects who showed normal colonic mucosa at colonoscopy were also analyzed. Consecutive two micron sections were immunostained for Ku70 and Ku86 following the streptavidin-biotin method, as described previously[20] . In brief, sections were deparaffinized, rehydrated in decreasing alcohol and microwave treated. Endogenous peroxidase activity was quenched by treatment with 0.03% hydrogen peroxide in absolute methanol for 30 min at room temperature. The primary antibodies were goat polyclonal anti-Ku70 and anti-Ku86 antibodies specifically validated for immunohistochemical analysis of paraffin embedded tissues (M-19, M-20: Santa Cruz Biotechnology Inc., CA, USA), in a 1:200 dilution. Biotinylated swine antigoat/mouse/rabbit IgG (Dako A/S, Denmark) was used as secondary antibody. After washing, sections were treated with streptavidin-peroxidase reagent (Dakopatts A\S, Denmark), incubated with diaminobenzidine (DAB) and counterstained with hematoxylin. Slides were examined under a two-head microscope by two pathologists, unaware of the clinical data and molecular results. No discrepant results were identified. Results of the nuclear immunostaining were expressed as percentage of positively stained cells. For cytoplasmic staining the microscopic analysis was not able to discriminate one cell from another. Thus the immunoreactivity was classified into four staining levels (SL): 0 SL (no staining); 1 SL (1-33% of positively stained area); 2 SL (33-66% of the area), and 3 SL (66-99% of the area)[21].

Western blotting

Protein extracts (10 μg) were separated in 10% SDS-PAGE, transferred to a PVDF membrane (Hybond-P, Amersham-Pharmacia Biotech, UK HP7 9NA) using an electroblotting apparatus, and incubated for 1 h at room temperature in 1% BSA, 1% skim milk (Difco Lab., Detroit, MI, USA), and 0.5% Tween 20 (USB, Cleveland, OH, USA). Membranes were stained with Ponceau S dye, to check for equal loading and homogeneous transfer. Immunodetection experiments were performed as described previously[17]. Filters were reprobed with anti β-actin (Sigma-Aldrich, St. Louis, MO 63103, USA) mouse IgG_1 monoclonal antibody, to normalize the nuclear protein levels. Filters were washed and developed using an enhanced chemiluminescence system (ECL, Amersham-Pharmacia Biotech, UK HP7 9NA). The optical densities (OD) were obtained by scanning densitometric analysis of the bands normalized for the β-actin levels, as reference protein.

Statistical analysis

All values provided in the text and figures are means of three independent experiments±standard deviations (SD). Variation rates (VR) were defined by the following formula: [(*pathological sample value–normal sample value)/pathological sample value*]×100. Mean values were compared using the one- or two-tailed Student's *t*-test, for independent samples. $P<0.05$ was considered statistically significant.

RESULTS

Nuclear and cytoplasmic Ku70/80 DNA-binding activity

EMSA were performed on nuclear extracts of colon tissues, to compare the DNA binding activity of the Ku70/80 heterodimer in adenoma and carcinoma samples as well as matched normal colonic mucosa samples (Figure 1A). We found that adenoma and carcinoma samples had an overall increase in DNA binding activity as compared to matched normal samples ($P<0.01$, Table 1). However, these variations were not homogeneous among the tumors that were tested. Since the overall increase in binding activity compared to normal was approximately 50% (Table 1), we set this value as the cut-off for better classifying our pathological samples. Of the 20 adenomas, 11 (55%) showed an increase in DNA binding activity higher than 50% ($P = 0.000$) (Figure 1A, Group I), 6 (30%) displayed an increase in DNA binding activity lower than 50% (P = NS) (Figure 2A, Group II), and 3 (15%) showed reduced levels of activity ($P = 0.04$) (Figure 2A, Group III). Of the 15 carcinomas, 7 (47%) displayed an increase in DNA binding activity higher than 50% (Figure 2B, Group I), 6 (40%) showed an increase in DNA binding activity lower than 50% ($P<0.02$) (Figure 2B, Group II), and 2 (13%) showed reduced levels of activity (P = ND) (Figure 2B, Group III).

No significant differences were found when the Ku70/80 DNA-binding activity was compared in adenoma and carcinoma samples (Table 1). We also determined, if functional Ku70/80 heterodimer was present in cytoplasmic protein extracts. Cytoplasmic Ku70/80 DNA binding activity was only found in three colorectal cancers, whereas adenomas did not show cytoplasmic activity (Figure 1B). No statistically significant correlation was found when results of nuclear and cytoplasmic Ku70/80 DNA-binding activity were compared with clinical parameters.

Table 1 Statistical summary of Ku70/80 DNA binding activity and Ku70 protein expression in pathological samples and matched normal tissues (mean±SD)

Colon	Ku70/80 DNA binding activity			Ku70 protein expression		
Tissue	Normal	Tumor	*P*	Normal	Tumor	*P*
Adenomas	2.66±2.32	5.01±3.15	<0.01	0.88±0.59	1.28±0.45	<0.01
Carcinomas	2.99±2.84	5.35±2.75	<0.001	1.09±0.80	1.77±0.83	<0.01

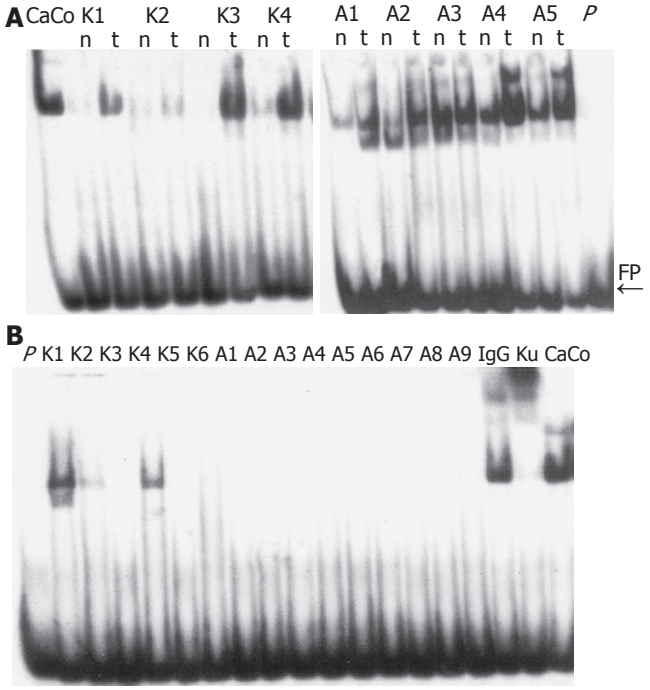

Figure 1 Representative gel shift experiments on nuclear (**A**) and cytoplasmic (**B**) extracts from human colon tissues. Panel A: Normal (n) and pathologic (t) nuclear extracts, obtained from four colorectal cancer (K1-K4) and five adenoma (A1-A5) patients, were analyzed by EMSA as described in "Materials and methods". The positions of Ku band-shifts and of the free probe (FP) are indicated. The binding activity in nuclear extracts from the CaCo-2 cell line (CaCo) has been used as a standard in order to compare the activity in the different gels. Lane P: free probe without protein extract. Panel B: EMSA was performed on pathologic cytoplasmic extracts from colorectal cancer (K1-K6) and adenoma (A1-A9) patients. Lane P: free probe without protein extract.

Ku70 and Ku86 expression in nuclear and cytoplasmic protein extracts

In adenomas and carcinomas with increased DNA-binding activity, the Ku70 nuclear levels were markedly increased as compared to matched normal samples ($P<0.000$) (Figures 3A and B, Group I), whereas protein level changes were not statistically significant in tumors with minimal increases or reduced binding activity (Figures 3A and B, Groups II and III). Representative results are shown in Figure 4.

In all the samples, Ku86 protein levels were always lower than Ku70 and in most cases it was undetectable (data not shown). Analysis of cytoplasmic protein extracts showed barely detectable Ku70 protein in normal colon tissues and a significant increase in pathologic samples with increased DNA binding activity (0.22±0.3 OD and 0.80±0.2 OD, respectively, $P = 0.001$) (data not shown). Ku86 protein subunit was undetectable by Western blot analysis on cytoplasmic extracts.

Ku70 and Ku86 immunohistochemical analysis

A significant increase in the percentage of stained nuclei was found for Ku70 and Ku86 subunits in all adenoma and carcinoma samples, as compared to matched normal tissues ($P<0.000$) but no statistically significant differences were found between adenoma and carcinoma samples (Table 3). In all cases, Ku subunits were not detected in the cytoplasm of normal colonic mucosa ($n = 25$) from patients or healthy donors ($n = 5$) (SL 0). For Ku70, a low level (SL 1) of cytoplasmic staining was detected in 11 of the 20 adenomas (55%), and in 3 of the 15 carcinomas

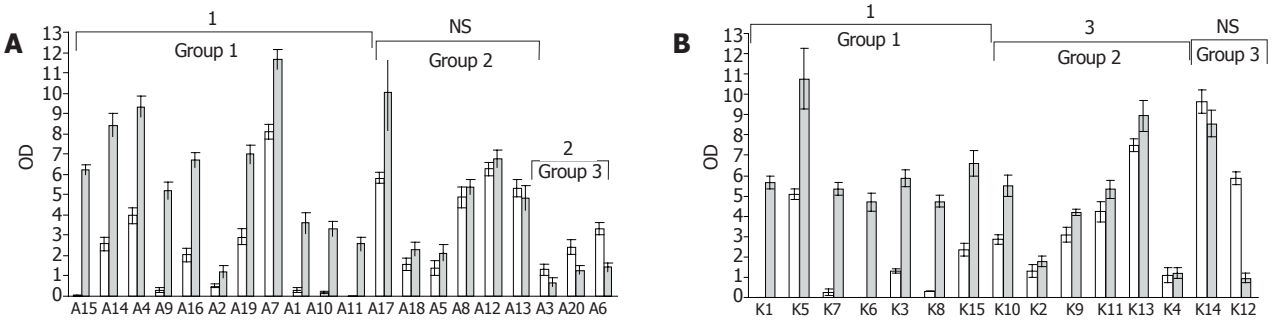

Figure 2 Changes in Ku70/Ku80 heterodimer DNA binding activity in adenoma (**A**) and carcinoma (**B**) compared to matched normal colonic mucosa. □ Normal; ▨ Tumor; vertical bars indicate standard deviation from the mean of three independent experiments. Adenomas (**A**) and carcinomas (**B**) samples characterize by: Group 1 more than 50% increase in DNA binding activity; Group 2 modest increase in binding activity; Group 3 reduced binding activity, $^1P<0.000$ *vs* group 1; $^2P<0.04$ *vs* group 3; $^3P<0.02$ *vs* group 2.

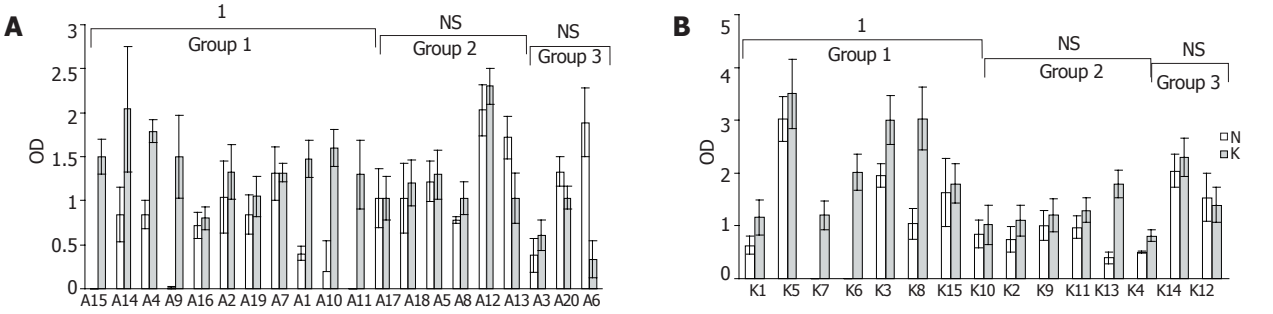

Figure 3 Changes in Ku70 protein levels determined by Western blot analysis in adenoma (**A**) and carcinoma (**B**) compared to matched normal colonic mucosa. □ Normal; ▨ Tumor; vertical bars indicate standard deviation from the mean of three independent experiments. Adenomas (**A**) and carcinomas (**B**) are grouped according to the criteria described in Figure 2, $^1P<0.000$ *vs* group 1.

(20%, $P = 0.089$). For Ku86, 17 of the 20 adenomas (85%) showed medium levels of cytoplasmic staining (SL 2-3), and 5 of the 15 carcinomas (34%) displayed cytoplasmic staining with SL 1-2 ($P = 0.004$). Ku86 cytoplasmic staining showed a typical granular pattern, probably due to the presence of protein subunit in cytoplasmic vesicles (Figure 5).

DISCUSSION

The NHEJ pathway plays a pivotal role in the repair of DSBs. Several studies on cell lines and knock-out mice suggest that a non-functional NHEJ can induce an increased level of genomic instability and lead to cancer progression[22-24]. In a previous study, we found a downregulation of the Ku70/80 DNA binding activity in advanced breast and bladder human cancers, as compared to non-invasive or low stage tumors[17]. This observation was also confirmed in a patient affected by sporadic multiple basal cell carcinoma, where we demonstrated a differential modulation of the NHEJ pathway in non-aggressive and aggressive tumors, showing that the first is an upregulation system, and the latter a strong downregulation system[20].

In the present study, we investigated the involvement of the ku70/80 heterodimer during progression from adenoma to carcinoma. Our results indicated that the NHEJ pathway was activated in approximately half of the cases, with no differences in binding activity between adenomas and carcinomas. In these tumors, the increase in DNA binding activity correlated with protein levels of the Ku subunits as determined by Western blot and immunohistochemical analysis. Moreover the cytoplasmic accumulation of the Ku70 and Ku86 protein subunits only in neoplastic tissues is also indicative of an upregulation of the NHEJ system. The NHEJ pathway repairs DSBs by modifying the two DNA broken ends prior to rejoining, and few nucleotides at each end of the DNA break are lost during this process[23]. Thus, the repair through the NHEJ can potentially lead to chromosomal alterations. Rothkamm *et al*.[25] found that after X-ray exposure, NHEJ-proficient cells form misrejoinings and multiple DSBs more frequently than NHEJ deficient cells. Also, myeloid leukemia cells characterized by gross chromosomal abnormalities show a higher end-joining efficiency but a lower DSB repair fidelity, as compared to lymphocytes from healthy donors[24]. Thus, the upregulation of the NHEJ system in adenoma and colon carcinoma may be

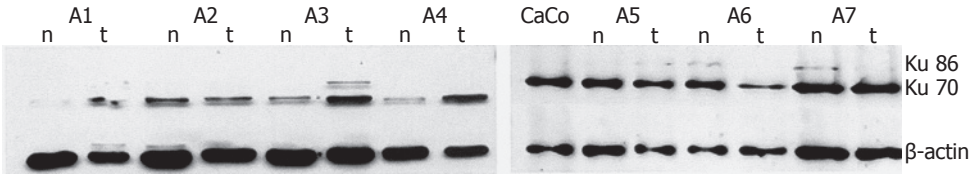

Figure 4 Representative immunoblot experiments on nuclear extracts from adenoma cases p70 and p86 protein expression was evaluated by Western blot, on normal (n) and pathologic (t) nuclear extracts from adenoma patients (A1-A7). The p86 protein was slightly detectable on this and on the other filters analyzed. CaCo-2 cell line nuclear extracts (CaCo) were used as internal standard. Filters were reprobed with anti-β-actin monoclonal antibody to normalize the protein levels.

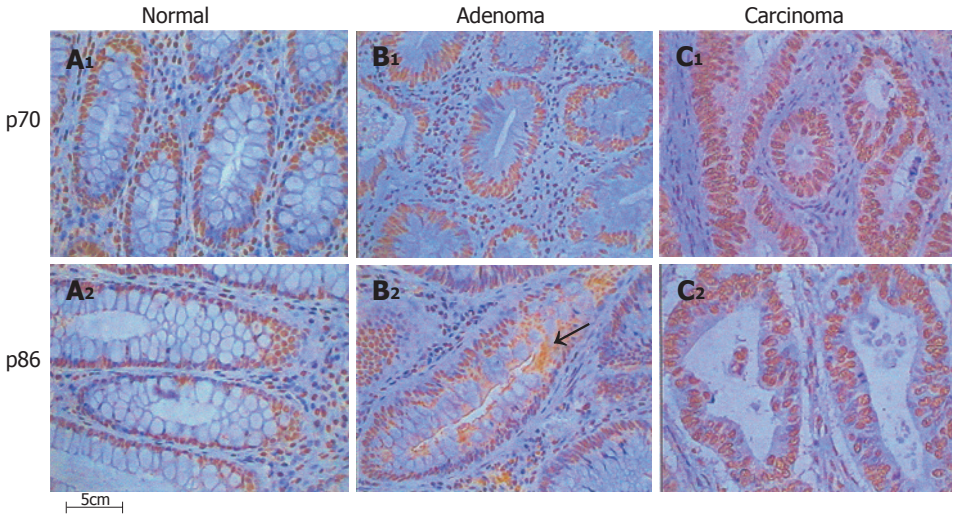

Figure 5 Expression of DNA-PK protein subunits in human colon tissues. Tissue sections were stained by immunohistochemistry for Ku70 and Ku86 proteins, as described in "Materials and methods". The increase of positively stained cells is evident in the nuclei of adenoma and carcinoma sections, respect to the normal controls. Ku70 nuclear expression is uniform and displays a higher intensity of staining as compared with p86, as described in the text. No cytoplasmic expression is evident in the normal mucosa sections for any of the protein subunits, whereas it is clearly visible in the pathologic tissues. Ku86 was expressed in the cytoplasm following a speckled pattern of staining, as evident on the adenoma section (arrow). Original magnification ×400. **A**$_{1\text{-}2}$: Normal; **B**$_{1\text{-}2}$: Adenoma; **C**$_{1\text{-}2}$: Carcinoma.

responsible for an increase in genomic rearrangements and chromosomal defects, contributing to tumor progression.

Although increase in DNA binding activity was the more frequent abnormality detected in our series of adenomas and carcinomas, we also identified a subset of colon neoplasia (approximately 15%) that showed reduced levels of DNA binding activity. Rigas *et al*.[26] have previously analyzed protein expression of the DNA-PK subunits in adenomas and colorectal cancers by IHC assay. By using a score that correlates the intensity of staining to the percentage of stained cells, a decrease in protein expression levels is demonstrated for all DNA-PK subunits in adenoma and carcinoma samples, as compared to normal tissues[26]. In our study the reduction in DNA binding activity did not correlate completely with Ku subunit protein levels. While three of the adenomas and one of the cancers showed a decrease of Ku70 expression by Western blot analysis, the remaining adenoma and carcinoma samples displayed an increase in protein expression. IHC data also showed an increase in the percentage of nuclear stained cells in the tumor as compared to the normal colonic mucosa. We can speculate that in this subset of tumors the NHEJ proteins are expressed and localized in the nuclei, but they are not functional, due to post-translational regulation mechanisms or mutations in one or more components of the NHEJ pathway.

Overall, our results indicate that the NHEJ pathway

is activated in colon adenoma and carcinoma, with only a subset of tumors showing decreased binding activity. These results however do not exclude an involvement of the NHEJ pathway in colon carcinogenesis, rather suggest the presence of colon cancer subsets that may differ in their biological behavior. Since Ku70 and Ku80 protein levels are correlated to tumor radiosensitivity and response to chemotherapy in human colorectal cancer and experimental models[27–30], the clarification of the mechanisms involved in DNA repair may ultimately lead to an improved management of colorectal cancer patients.

Abstract

AIM: To investigate the correlation between tissue ST6Gal I and serum msAFP in HCC patients, and to investigate their prognostic significance.

METHODS: Preoperative sera, paired tumorous and non-tumorous tissues were collected from 19 consecutive patients who had undergone surgical resection of HCC. ST6Gal I activities in the tissues were measured by an *in vitro* microsomal enzyme activity assay. The percentages of tumor-specific msAFP in the sera were also estimated by an isoelectric focusing-immunoblotting assay.

RESULTS: The tumor ST6Gal I activity was negatively correlated with serum msAFP percentage (r = -0.53, P = 0.019). Both decreased tumor ST6Gal I activity and increased serum msAFP percentage were associated with poor tumor cell differentiation. Univariate analyses showed that both decreased tumor ST6Gal I activity (P = 0.028), increased serum msAFP percentage (P = 0.034) and poor tumor cell differentiation (P = 0.031) were associated with shorter overall survival. Multivariate analysis using the Cox regression model showed that the preoperative serum msAFP percentage (P = 0.022) and tumor cell differentiation status (P = 0.048) were independent prognostic indicators for patient overall survival.

CONCLUSION: Our results indicate that the presence of msAFP in blood circulation is associated with a decreased activity of ST6Gal I activity in HCC. Both tissue ST6Gal I and serum msAFP are potential prognostic markers for patients with operable HCC.

INTRODUCTION

Beta-galactoside alpha-2,6-sialyltransferase (ST6Gal I) is the key enzyme for the production of alpha-2,6-linked sialoglycoconjugates. Both ST6Gal I and alpha-2,6-linked sialoglycoconjugates have been suggested to play important roles in oncogenic transformation and metastasis[1-3]. Upregulated expression of ST6Gal I has been shown in colorectal cancer[4,5], breast cancer[6], cervical cancer[7], and choriocarcinoma[8]. However, elevated alpha-2,6 sialylation inhibited formation of glioma *in vivo*[9]. Expression of ST6Gal I may have different effects in different cancer types.

Serum alpha-fetoprotein (AFP) is a conventional marker for the diagnosis of hepatocellular carcinoma. Eighty to ninety percent of patients with HCC will have levels above the reference range[10-12]. A serum concentration >500 μg/L, in an area with high incidence of HCC,

and in the appropriate clinical setting, is usually considered diagnostic of HCC. However, modestly raised levels of AFP (10-500 μg/L) are also common in non-malignant chronic liver disease, so that the specificity of the AFP test for HCC tends to be low[10,13-15]. Recent studies have shown that monosialylated AFP (msAFP), which is a hyposialylated isoform of alpha-fetoprotein (AFP), is specific to hepatocellular carcinoma (HCC)[16,17]. msAFP can be identified, measured quantitatively by isoelectrofocusing electrophoresis approach or by glycosylation immunosorbent assay[18]. msAFP percentage (msAFP%) relative to total AFP can be used as a serum marker to differentiate HCC patients with non-diagnostic total AFP from patients with chronic liver diseases[18].

Sialylation of AFP is mediated by cellular ST6Gal I. We hypothesize that downregulation of ST6Gal I plays an important role in the HCC pathogenesis, and causes the presence of msAFP in blood circulation of HCC patients. In the present study, we examined the enzyme activity and mRNA expression of ST6Gal I in the paired tumorous and non-tumorous tissues from patients with HCC. The correlation among ST6Gal I activity, serum msAFP percentage and their clinical implications were investigated.

MATERIALS AND METHODS

Clinical materials

Between December 1999 and January 2001, 19 consecutive patients who had undergone surgical resection of HCC, which contained viable tumor cells as shown by histological examination, and with serum AFP levels higher than 20 ng/mL were recruited into this study. Informed consent was obtained for using the resected tissues and sera for research studies. The patients were followed up for 2 years or until death. Preoperative sera, paired tumorous and non-tumorous tissues were collected. Sera were stored at -20 °C until further analysis. The tissues were cut into small pieces, snap frozen with liquid nitrogen, and stored at -70 °C. The AFP levels in the serum samples were quantified with a commercial sandwich-type ELISA (DAKO, Glostrup, Denmark). This study was approved by the Joint CUHK-NTEC Clinical Research Ethics Committee.

Preparation of tissue microsomal fraction

The tissues were homogenized on ice in 1 mL of sodium phosphate buffer (PBS, 10 mmol/L $NaPO_4$, 150 mmol/L NaCl, pH 7.4), containing 0.8 mmol/L protease inhibitor (Pefabloc® SC PLUS, Boehringer Mannheim, Roche Diagnostics, Germany), with a Polytron-Aggregate (Kinetica, Switzerland) using a 11-mm cutting probe at a speed setting of 5 for 15 s. After centrifugation at 4 °C for 10 min at 1 000 r/min, the supernatant fraction was saved and centrifuged again at 13 000 *g* for 30 min at 4 °C. The microsomal pellet obtained after centrifugation was then resuspended in Tris-HCl buffer (15 mmol/L Tris-HCl, pH 6.0) and stored at -70 °C until analyzed. The protein content was measured by the Bradford Coomassie Dye-Binding Protein Assay.

ST6Gal I activity assay

The assay was similar to the method described by Pousset *et al*. and Halliday *et al*. It was based on the specific binding property of *Sambucus nigra agglutinin* (SNA, Calibiochem, San Diego, USA) that preferentially binds sialic acid residues attached to terminal Galβ1, 4GlcNAc units on *N*-glycan in alpha-2,6, but not 2,3 or 2,8 linkage[19,20].

Briefly, the microsomal preparation was used as a source of alpha-2,6-sialyltransferase, and the *N*-glycan on asialofetuin (ASF) (Sigma, St. Louis, USA) was used as a sialic acid acceptor. The ST6Gal I activity assay was carried out in a mixture containing 10 μg of tissue microsome preparation, 125 μg ASF, 125 μmol/L CMP-sialic acid and 0.25 μCi CMP-[^{3}H]-sialic acid in reaction buffer (0.1% BSA, 0.1% Triton X-100, 45 mmol/L NaCl, 15 mmol/L Tris-HCl, pH 6.0) with a final volume of 20 μL. The mixture was added to 30 μL of SNA-sepharose (1 mg SNA covalently linked to 0.3 g of CNBr activated Sepharose 4B gel), mixed, and incubated at 37 °C overnight. After washing the gels four times with washing buffer (PBS containing 0.5% Tween 20), the molecules bound to the SNA-Sepharose were released by vortexing the gel in 300 μL of 1 mol/L H_2SO_4 for 30 s. Two hundred and eighty-five microliters of the supernatant was transferred to a vial, and 5 mL scintillant solution was added. The amount of radiolabeled ASF was then measured with a liquid scintillation counter. Commercial rat ST6Gal I (Sigma) was used as the calibration standard. One unit of the commercial rat ST6Gal I is defined as the amount that will transfer 1.0 μmol of sialic acid from CMP-sialic acid to asialomucin per minute at pH 6.5.

Semi-quantitation of ST6Gal I mRNA by RT-PCR-ELISA

Ten to thirty milligrams of frozen tumorous or non-tumorous liver tissue was disrupted and homogenized using a mortar and pestle (Kontes, Vineland, NJ, USA). Total RNA was extracted from the tissue sample using the RNeasy Mini Kit (Qiagen, GmbH, Germany), and reverse transcribed into cDNA by using a 1st strand cDNA Synthesis Kit (AMV, Roche Diagnostic, Boehringer Mannheim, Germany) with the oligo-$p(dT)_{15}$ primer provided. The cDNA was then used as the template for PCR amplification with primers specific to ST6Gal I (forward: 5'-CCTGAACAATTCCAGCCT GCTCCTTT-3' and reverse: 5'-GACGATGTTTCCA ATCCCCTGTACCA-3') or β-actin gene (forward, 5' -CTTCTACAATGAGCTGCGT-3' and reverse: 5'-TCAT GAGGTAGTCAGTCAG-3'). In the PCR for ST6Gal I, the cDNA, diluted in Tris–EDTA buffer (10 mmol/L Tris-HCl, 1 mmol/L EDTA, pH 8.0), was mixed with 1×PCR buffer, 2 mmol/L DIG-labeled dNTP, 2.5 mmol/L $MgCl_2$, 1 μmol/L of each primer, 0.83 U *Taq* DNA polymerase, 0.022 μmol/L TaqStart Antibody, 0.8 U uracil glycosylase in a final volume of 20 μL. The mixture was incubated at room temperature for 10 min. Then an initial denaturation step of 2 min at 94 °C was done, followed by repeating

cycles of 1 min at 94 °C, 1 min at 63 °C for primer annealing, and 1 min at 72 °C for extension. A final extension run of 7 min at 72 °C was performed to ensure complete elongation of all amplicons. In the PCR for β-actin gene, 3.5 mmol/L of $MgCl_2$ was used instead of 2.5 mmol/L, and the primer annealing temperature in each PCR cycle was 60 °C instead of 63 °C. In the initial attempts, 40 cycles of PCR were performed. The specificity of the PCR amplication was checked by agarose gel electrophoresis to see if the sizes of the amplicons were the same as the expected values, 421 bp for ST6Gal I cDNA and 305 bp for β-actin gene. A commercially available cDNA preparation of human normal liver tissues, pooled from two male/female Caucasians, was used as positive control (Clontech Laboratories, Inc., CA, USA).

For the semi-quantitative assay, 25 cycles of PCR were performed in the presence of DIG-labeled dNTP. The concentrations of the DIG-labeled amplicons were measured with the PCR ELISA (DIG-detection) kit (Roche Diagnostics), according to the manufacturer's instruction. Briefly, the DIG-labeled amplicons were first denatured, and hybridized with 7.5 pmol biotinylated DNA probe specific for the ST6Gal I (biotin-5'-TGCATTGGGC ACAATTGTAA-3') or β-actin gene (biotin-5'-GTCCAGA CGCAGGATGGCAT-3'). The DNA-probe hybrids were then captured onto an avidin-coated microplate. After washing, the amount of the DNA-probe hybrids bound to the microplate was determined by incubating with anti-DIG-HRP conjugate at 37 °C for 30 min, followed by adding the BM Blue peroxidase substrate (Roche Diagnostics). One hundred microliters of 1 mol/L H_2SO_4 was added to stop the colorimetric reaction. The optical density of the wells was determined at 450 nm with a reference wavelength of 690 nm. The ST6Gal I/β-actin mRNA ratios were calculated as the mRNA values of the tissue ST6Gal I.

Semi-quantitation of msAFP percentage by IEF-immunoblotting assay

The semi-quantitative analysis of msAFP was performed as previously reported by us[18]. AFP isoforms in the serum samples were separated by IEF on a polyacrylamide gel, which were pre-swollen with a solution containing 5 mol/L urea and 1:16 Pharmalyte 4.5-5.4 (Amersham Pharmacia Biotech, Uppsala, Sweden) in double distilled water. One microliter of pre-diluted serum samples or standard containing 5 or 10 ng/mL AFP. The total AFP was applied to the anode side of the gel after prefocusing (2 000 V, 2.0 mA, 3.5 W, 10 °C, 75 V.h). The sample was applied for 15 V.h (200 V, 2.0 mA, 3.5 W, 10 °C). The final isoelectric separation step was done for 450 V.h (2 000 V, 5.0 mA, 3.5 W, 10 °C). The focused proteins were transferred to nitrocellulose membrane, and then incubated with polyclonal rabbit anti-human AFP (DAKO), followed by horseradish peroxidase conjugated polyclonal swine anti-rabbit immunoglobulin (DAKO). After washing, the enhanced chemiluminescence detection system (ECL, Amersham Pharmacia Biotech) was used to visualize the AFP protein bands. The image of each band was scanned with a densitometer (GS-700, Bio-Rad, CA, USA), and the intensity of each band was expressed as a percentage of the total intensity of all AFP bands.

Statistical analysis

The Wilcoxon signed rank test was used to compare the differences between the paired tumor and non-tumor groups. The Mann–Whitney rank sum test and Fisher's exact test were used to compare the differences between other study groups. Correlations between the study parameters were analyzed by the Spearman's rank order correlation test. The log-rank test and Cox proportional hazards model were applied for survival analyses.

RESULTS

Two HCC subgroups with increased and decreased tumor ST6Gal I activities

The clinical features of the 19 patients with primary HCC are summarized in Table 1. The tumor ST6Gal I activity was compared to that of the paired non-tumorous tissue. Seven HCC patients fell into a group with decreased ST6Gal I activity in the tumorous tissue, whereas 12 HCC patients fell into a group with increased ST6Gal I activity in the tumorous tissue (Table 2). The tumor ST6Gal I activities in the decreased group were significantly lower than the values in the increased group ($P = 0.005$).

Absence of correlation between ST6Gal I activity and mRNA level in HCC

The specificity of the RT-PCR reaction was checked by subjecting the RT-PCR product to agarose gel electrophoresis. In all cases including the positive control (normal human liver cDNA), the RT-PCR product appeared as a single DNA band with the expected size of 421 bp for ST6Gal I, or 305 bp for β-actin. The electrophoresis results indicated that the RT-PCR amplifications were specific. Our data also confirmed that ST6Gal I gene was expressed in all the HCC tissues and the non-tumorous liver tissues (Figure 1). Two cases were omitted for the RT-PCR ELISA to measure ST6Gal I mRNA level owing to insufficient tissue materials. The measured ST6Gal I mRNA level of individual tissues was normalized by expressing the data as a ratio of β-actin mRNA level. In the non-tumorous tissues, the ST6Gal I mRNA level positively correlated with the ST6Gal I activity ($r = 0.49$, $P = 0.039$). In the tumorous tissues, no significant correlation was found between the enzyme activity ($r = -0.093$, $P = 0.72$).

Correlation between tumor ST6Gal I enzyme activity and serum msAFP

The percentages of tumor-specific msAFP (relative to total intensity of AFP isoforms) in the preoperative sera of the HCC patients were estimated, and the results of the patient groups with increased and decreased tumor ST6Gal I enzyme activity are shown in Table 2. Comparison of the

[1]Mann–Whitney test; [2]mean (median, 25th-75th percentile); [3]group 1: n = 6, group 2: n = 11; [4]N.S., not significant.

two groups shows that the percentage of msAFP in the patient group with decreased tumor enzyme activity was significantly higher than those in the group with increased activity (P = 0.031), whereas the serum total AFP levels were not significantly different. Furthermore, the msAFP percentage was negatively correlated with the relative tumor ST6Gal I enzyme activity (r = -0.53, P = 0.019).

Associations with poorly differentiated HCC

The relationships between ST6Gal I activity, msAFP percentage and various patient clinical parameters, including HBV status, tumor stage (ALTSG and AJCC), tumor size, differentiation status, vascular invasion, encapsulation, capsule invasion, metastasis and recurrent, were investigated. More cases with poorly differentiated tumor were found in the patient groups with decreased enzyme activity (P = 0.045, Figure 2). Similar to tumor ST6Gal I activity, but in an opposite manner, more cases with poorly differentiated tumor were found in the patient group with higher (>20%) msAFP percentage (P = 0.045, Figure 2).

Associations with poor overall survival

During the 2 years follow-up period, 8 out of the 19 patients died. The absolute/relative tumor ST6Gal I activity, serum msAFP percentage, serum AFP level and various patient clinical parameters were subjected to survival analyses. In univariate analyses using the Cox regression model, the preoperative serum msAFP percentage (P = 0.034), the relative tumor ST6Gal I activity (P = 0.028) and the tumor differentiation status (P = 0.031) were shown to be predictors for patient overall survival. The log-rank test results showed that the patient group with decreased tumor ST6Gal I activity had an overall survival (P = 0.0099, Figure 3A) shorter than the group with increased activity. When the cases were divided into two groups based on the preoperative serum msAFP percentage at a cut-off value of 20%, the log-rank test results showed that higher preoperative serum msAFP percentage was associated with poorer patient overall survival (P = 0.0031, Figure 3B). The log-rank test results also showed that patients with poorly differentiated tumor had poorer overall survival (P = 0.0063). In a multivariate analysis using the Cox regression model, among all the

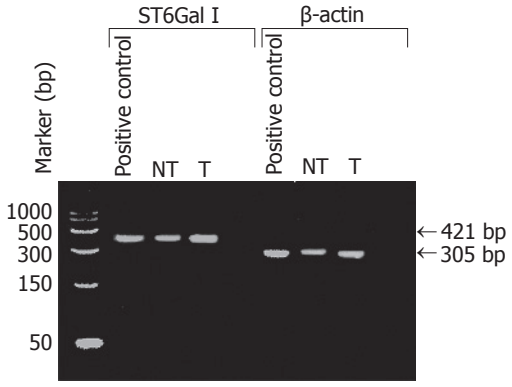

Figure 1 Electrophoresis of RT-PCR products amplified from the total RNA preparations of the tumor (T) and non-tumor liver (NT) tissues from HCC patients. For both tumor and non-tumor total RNA preparations, the RT-PCR products corresponding to ST6Gal I and β-Actin DNA showing the expected sizes (421 bp and 305 bp respectively) were obtained. Commercially available human normal liver cDNA was used as the positive control. Similar DIG-labeled RT-PCR products with the same sizes were obtained when DIG-dNTPs were used.

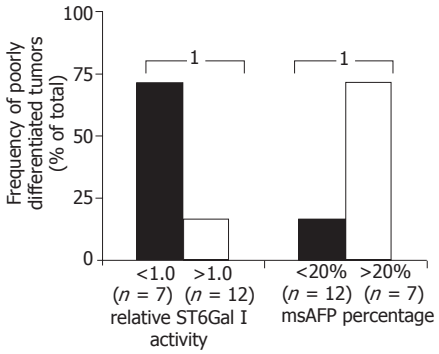

Figure 2 The frequency of poorly differentiated tumors among the 19 HCC patients with different relative tumor ST6Gal I activity or with different preoperative serum msAFP percentage. Differences between the study groups were tested by Fisher's exact test. $^1P = 0.045$.

clinical features, only the preoperative serum msAFP percentage ($P = 0.022$) and tumor cell differentiation status ($P = 0.048$) were found to be independent prognostic indicators for patient overall survival.

DISCUSSION

Both ST6Gal I and alpha-2,6-linked sialoglycoconjugates play important roles in oncogenic transformation and metastasis in various cancers[21]. However, information about the influence of ST6Gal I in human HCC tissue has been very limited. The results of the present study were consistent to the findings reported by Cao *et al*. and Dall' Olio *et al*.[22,23]. Dalli'Olio *et al*. observed that both ST6Gal I activity can undergo up- or down-regulation in different HCC patients. The present study confirmed Dalli'Olio *et al*.'s observation. Compared to non-tumorous tissue, the HCC patients could be divided into two groups with increased and decreased ST6Gal I activity in the tumorous tissue. By immunohistochemical staining, Cao *et al*. showed that expression levels of ST6Gal were decreased in poorly differentiated HCC. This is also consistent to our observation that poorly differentiated HCCs had lower ST6Gal I activities.

The present study provided additional information about ST6Gal I in HCC. We showed that changes of ST6Gal I activity in HCC positively correlated with the presence of msAFP in blood circulation. As sialylation of AFP is mediated by ST6Gal I, probably the presence of hyposialyled AFP variants in blood circulation is caused by decreased ST6Gal I activity. Furthermore, our data suggests that tissue ST6Gal I and serum msAFP are potential prognostic markers for patients with operable HCC.

In the non-tumorous tissues, ST6Gal I mRNA level positively correlated with ST6Gal I activity. This result is consistent to the observation of Svensson *et al*. when studying normal liver[24]. This result therefore could be served as a positive control to confirm the validity of our measurements of tissue ST6Gal I activity and mRNA level. No significant correlation was found in the tumorous tissues. This suggests that ST6Gal I activity in HCC is regulated at post-transcriptional level.

The present study and the studies from Cao *et al*. and Dall'Olio *et al*. strongly indicate that the functional roles of ST6Gal I in HCC are different from those in colorectal cancer and in breast cancer. An *in vitro* antisense DNA experiment has shown that upregulation of ST6Gal I plays an important role in the invasive potential of human colon carcinoma HT29 cells[3]. Furthermore, high expression levels of ST6Gal I have been correlated with poor survival in colorectal cancer patients[25]. In breast cancers, high ST6Gal I expression was associated with histoprognostic grade III, and negatively correlated to progesterone receptor expression[26]. However, no ST6Gal I expression was found in malignant gliomas or in medulloblastomas[26]. It is worth noting that elevated alpha-2,6 sialylation

inhibited formation of glioma *in vivo*[9]. All these findings indicate that expression of ST6Gal may have different effects in different cancer types.

In conclusion, HCC can be divided into two subtypes, one with decreased tumor ST6Gal I activity and one with increased tumor ST6Gal I activity. The ST6Gal I activity in HCC is not regulated at the transcription level. Downregulation of tumor ST6Gal I activity and an increase in msAFP percentage in preoperative serum are associated with poorly differentiated tumors and poor patient survival. Both ST6Gal I and msAFP percentage are potential prognostic markers for HCC. The presence of msAFP in the blood circulation probably reflects the downregulation of ST6Gal I activity in the HCC tissue.

Abstract

AIM: To determine the *in vivo* and *in vivo* effects of cysteamine (CS) on expression and activity of H^+-K^+-ATPase of gastric mucosal cells in weaning piglets.

METHODS: Eighteen litters of newborn Xinhuai piglets were employed in the *in vivo* experiment and allocated to control and treatment groups. From 12 d of age (D12), piglets in control group were fed basal diet, while the treatment group received basal diet supplemented with 120 mg/kg CS. Piglets were weaned on D35 in both groups. Six piglets from each group (n = 6) were slaughtered on D28 (one week before weaning), D35 (weaning), D36.5, D38, D42, and D45 (36 h, 72 h, one week and 10 d after weaning), respectively. Semi-quantitative RT-PCR was performed to determine the levels of H^+-K^+-ATPase mRNA in gastric mucosa. H^+-K^+-ATPase activity in gastric mucosa homogenate was also determined. Gastric mucosal epithelial cells from piglets through primary cultures were used to further elucidate the effect of CS on expression and activity of H^+-K^+-ATPase *in vivo*. Cells were treated for 20 h with 0.001, 0.01, and 0.1 mg/mL of CS (n = 4), respectively. The mRNA expression of H^+-K^+-ATPase and somatostatin (SS) as well as the H^+-K^+-ATPase activity were determined.

RESULTS: *in vivo*, both mRNA expression and activity of H^+-K^+-ATPase in gastric mucosa of control group exhibited a trend to increase from D28 to D45, reaching a peak on D45, but did not show significant age differences. Furthermore, neither the mRNA expression nor the activity of H^+-K^+-ATPase was affected significantly by weaning. CS increased the mRNA expression of H^+-K^+-ATPase by 73%, 53%, 30% and 39% on D28 (P = 0.014), D35 (P = 0.017), D42 (P = 0.013) and D45 (P = 0.046), respectively. In accordance with the mRNA expression, H^+-K^+-ATPase activities were significantly higher in treatment group than in control group on D35 (P = 0.043) and D45 (P = 0.040). *In vivo*, CS exhibited a dose-dependent effect on mRNA expression and activity of H^+-K^+-ATPase. Both H^+-K^+-ATPase mRNA expression and activity in gastric mucosal epithelial cells were significantly elevated after 20 h of exposure to the moderate (H^+-K^+-ATPase expression: P=0.03; H^+-K^+-ATPase activity: P = 0.014) and high concentrations (H^+-K^+-ATPase expression: P=0.017; H^+-K^+-ATPase activity: P = 0.022) of CS. Significant increases in SS mRNA expression were observed to accompany the elevation of H^+-K^+-ATPase expression and activity induced by the moderate (P = 0.024) and high concentrations (P = 0.022) of CS. Low concentration of CS exerted no effects either on expression and activity of H^+-K^+-ATPase or on SS mRNA expression in cultured gastric mucosal epithelial cells.

CONCLUSION: No significant changes are observed in mRNA expression and activity of H^+-K^+-ATPase in gastric mucosa of piglets around weaning from D28 to D45. CS increases expression and activity of gastric H^+-K^+-ATPase *in vivo* and *in vivo*. SS is involved in mediating the effect of CS on gastric H^+-K^+-ATPase expression and activity in weaning piglets.

INTRODUCTION

The proton pump, H^+-K^+-ATPase consisting of α- and β-subunits, is the molecular base of gastric acid production and the final common pathway mediating secretion of hydrochloric acid by gastric parietal cells. The enzyme, which is typically located in the parietal cells, mediates the electroneutral exchange of intracellular H^+ and extracellular K^+ to achieve acid secretion when parietal cells are under the stimulation of secretagogues[1]. In H^+-K^+-ATPase α-

or β-subunit deficiency mice, achlorhydria and destruction of parietal cells have been observed[2,3]. The capability of gastric acid secretion is dependent on the gastric H^+-K^+-ATPase activity[4]. Therefore, H^+-K^+-ATPase activity can serve as an accurate indicator for evaluating the ability of gastric acid secretion from parietal cells.

Gastric acid secretion is regulated by stimulatory factors such as gastrin, histamine and acetylcholine, as well as inhibitory factors including somatostatin (SS). SS is a typical brain-gut-peptide releasing from D cells in the mucous membrane of stomach. Numerous publications reported that SS inhibits gastric acid secretion directly or indirectly by inhibiting the stimulatory effects of gastrin and histamine[5,6]. We found in our previous study that gastric expression of SS mRNA is upregulated in weaning piglets[7], and that gastric acid secretion is low in piglets[8]. Therefore, it is presumed that the increased inhibitory tone of SS is responsible for retarded gastric function development and insufficient gastric acid secretion which contribute, atleast partly, to diarrhea, poor growth and even death in newborn and early-weaning piglets.

Cysteamine (CS), which is able to deplete tissue SS, induces a profound loss of biological and immunological activities of SS both *in vivo* and *in vitro*[9,10]. CS is known to increase gastric acid secretion in rats, and is often used to produce the clinical model of gastric ulcer[11-13]. CS is approved to use as a feed additive in animal production to promote growth rate and improve feed efficiency[14]. However, CS application in pig production is mostly restricted to growing and fattening stages[15]. Up to now, the possible effect of CS on gastric acid secretion in weaning piglets remains unknown. Therefore, the present study was designed to examine the effect of CS on gastric acid secretion both *in vivo* and *in vitro*, the mRNA expression and activity of H^+-K^+-ATPase in gastric mucosa tissue and cultured mucosal epithelial cells were determined as response criteria. In addition, the change of SS mRNA expression in mucosal epithelial cells responding to CS exposure was also measured for elucidating the possible mechanisms underlying the CS action.

MATERIALS AND METHODS

Animals and sampling

Eighteen litters of newborn piglets from the 2nd or 3rd farrowing Xinhuai sows were employed in the *in vivo* experiment and allocated to control and treatment groups. From 12 d of age (D12), piglets in control group were fed basal diet, while the treatment group received basal diet supplemented with 120 mg/kg CS. The diet was formulated according to the requirement of piglets and provided *ad libitum*. Piglets were weaned on D35 in both groups. Six piglets from each group were slaughtered on D28 (one week before weaning), D35 (weaning), D36.5, D38, D42 and D45 (36 h, 72 h, one week and 10 d after weaning), respectively. Samples of the gastric fundic mucosa were frozen in liquid nitrogen immediately and then stored at -70 ºC until RNA extraction.

For *in vitro* experiment, four piglets at the age of D28 were killed to collect gastric mucosa for primary cell culture. DMEM (high glucose) and HEPES were products of Gibco, Hyclone, respectively. Trypsin was bought from Sigma and fetal bovine serum was purchased from Hangzhou Sijiqing Company, China.

Cells were dispersed from freshly obtained gastric mucosa of piglets as described previously[16], with minor modifications. Briefly, the gastric mucosa was washed in D-Hank's solution containing 400 U/mL penicillin, 400 μg/mL streptomycin and dipped in D-Hank's solution for 30 min. Then the tissues were dispersed by trypsin (0.15 mg/mL) at 37 °C for 1 h, filtrated and centrifuged (1 000 r/min, 5 min). Viability of the cells exceeded 95% as judged by trypan blue exclusion. Then cells at the density of 1×10^6/mL were cultured (37 °C, 50 mL/L CO_2) in a six-well plate containing DMEM (high glucose) with 10% fetal bovine serum, 15 mmol/L HEPES buffer, and 100 U/mL penicillin, 100 μg/mL streptomycin. After 24 h, the culture medium was refreshed by a new medium containing 0, 0.001, 0.01 and 0.1 mg/mL CS, respectively. The cells were continuously cultured for 20 h, and then collected for RNA extraction and H^+-K^+-ATPase activity determination.

The experiments were undertaken following the guidelines of the regional Animal Ethics Committee.

RNA extraction and analysis

Total RNA was extracted from the tissue samples with the single-step method of RNA extraction by acid guanidinium thiocyanate-phenol-chloroform[17]. Total RNA concentration was then quantified by measuring the absorbance at 260 nm in a photometer (Eppendorf Biophotometer). Ratios of absorption (260/280 nm) of all preparations were between 1.8 and 2.0. Aliquots of RNA samples were subjected to electrophoresis through a 1.4% agarose-formaldehyde gel to verify their integrity.

Two micrograms of total RNA was reverse transcribed by incubation at 42 °C for 1 h in a 25 μL mixture consisting of 10 U avian myeloblastosis virus reverse transcriptase, 10 U RNase inhibitor, 12 μmol/L random primers, 50 mmol/L Tris-HCl (pH 8.3), 10 mmol/L $MgCl_2$, 50 mmol/L KCl, 10 mmol/L DDT, 0.5 mmol/L spermidine and 0.8 mmol/L each dNTP. The reaction was terminated by heating at 95 °C for 5 min and quickly cooling on ice.

The primers for H^+-K^+-ATPase were designed according to the cDNA sequence published on GenBank (M22724): 5'-gagaaccaccacctacaag-3' as sense primer, and 5'-caacagcgaactccaag-3' as anti-sense primer, the predicted PCR product being 362 bp in size. The SS primers were designed according to the coding region of porcine SS genomic DNA sequence (GenBank, U36385): sense, 5'-agctgctgtctgaacccaac-3' and anti-sense, 5'-gaaattcttgcagccagctt-3', the expected PCR product being 161 bp in size. The PCR primers were designed using Primer Premier 5.0 and synthesized by Haojia Biotech. Ltd, China. The Quantum RNA 18S Internal Standards

kit (catalogue no. 1716, Ambion Inc., Austin, TX, USA), containing primers and competitors, was used to normalize variations in pipetting and amplification.

Different controls were set to monitor the possible contaminations of genomic DNA and environment DNA both at the stage of RT and RCR. The pooled samples made by mixing equal quantity of total RNA from all samples were used for optimizing the PCR condition and normalizing the intra-assay variations. PCR conditions were established as follows: for H^+-K^+-ATPase, the total volume of reaction was 25 μL, including 0.5 U Taq DNA polymerase (Promega, Shanghai), 5 mmol/L Tris-HCl (pH 9.0), 10 mmol/L NaCl, 0.1 mmol/L DDT, 0.01 mmol/L EDTA, 5% (w/v) glycerol, 0.1% (w/v) Triton X-100, 0.2 mmol/L each dNTP, 1.5 mmol/L $MgCl_2$, 0.7 μmol/L specific primers, 1.0–2.6 μL 18S rRNA. The program is set as: denaturation at 94 °C for 5 min, 20 cycles (for *in vivo* samples), 24 cycles (for *in vitro* samples) at 94 °C for 30 s, at 52 °C for 30 s, at 72 °C for 60 s, and a final extension at 72 °C for 8 min; for SS, the reaction mix contained 0.5 U Taq DNA polymerase, 5 mmol/L Tris-HCl (pH 9.0), 10 mmol/L NaCl, 0.1 mmol/L DDT, 0.01 mmol/L EDTA, 5% (w/v) glycerol, 0.1% (w/v) Triton X-100, 0.2 mmol/L each dNTP, 1.5 mmol/L $MgCl_2$, 1.6 μmol/L specific primers, 1.0-2.6 μL 18S rRNA. The program is set as: denaturation at 94 °C for 5 min, 26 cycles at 94 °C for 30 s, at 54 °C for 30 s, at 72 °C for 30 s, and a final extension at 72 °C for 8 min. All samples were included in the same run of PCR on GeneAmp PCR system 9600 (Perkin Elmer, USA) and repeated atleast thrice.

Twenty microliters of PCR products was analyzed by 2% agarose gel electrophoresis. The gels were stained with ethidium bromide and photographed with a digital camera. The net intensities of individual bands were measured using Kodak Digital Science 1D software (Eastman Kodak Company, Rochester, NY, USA). The ratio of band density for target genes to that for 18S rRNA was used to represent the abundance of H^+-K^+-ATPase and SS mRNA expression.

H^+-K^+-ATPase activity assay

H^+-K^+-ATPase activity was measured according to the method described by Hervatin *et al*.[18]. H^+-K^+-ATPase activity was evaluated as the amount of inorganic phosphate released from ATP by the method of Sanui[19]. The reaction was initiated at 37 °C by addition of 2 mmol/L ATP-Mg^{2+} salt as substrate and proceeded in a total volume of 1.0 mL containing 60 mmol/L Tris-1,4-piperzine-bis (ethanesulfonic acid) (pH 7.4), 0.1 mmol/L ouabain, 90 mmol/L sucrose, 100 μL sample and either 15 mmol/L KCl or 30 mmol/L sucrose. It was terminated after 10 min by addition of 1.5 mL of ice-cold 14% trichloroacetic acid. Ouabain was included to avoid Na^+-K^+-ATPase activity. The ATPase activity measured without K^+ was taken as the basal Mg^{2+}-ATPase activity. The difference between the activities measured with and without K^+ was defined as H^+-K^+-ATPase activity. Bradford[20] assay was employed to determine the tissue protein content and the activity of H^+-K^+-ATPase was expressed as the amount of inorganic phosphate released per milligram of protein per hour (μmol Pi/mg prot/h).

Statistical analysis

All data were expressed as mean±SE. The data were analyzed by *t*-test for independent samples or ANOVA with Statistical Packages for the Social Sciences (2000). $P<0.05$ was considered statistically significant.

RESULTS

Expression and activity of H^+-K^+-ATPase in vivo

H^+-K^+-ATPase mRNA expression and H^+-K^+-ATPase activity in control group exhibited a trend to increase from D28 to D45, reaching a peak on D45, but did not show significant age differences (Figure 1). Furthermore, neither the mRNA expression nor the activity of H^+-K^+-ATPase was affected significantly by weaning.

Effects of CS on expression and activity of H^+-K^+-ATPase in vivo

As shown in Figure 1, CS increased the level of H^+-K^+-

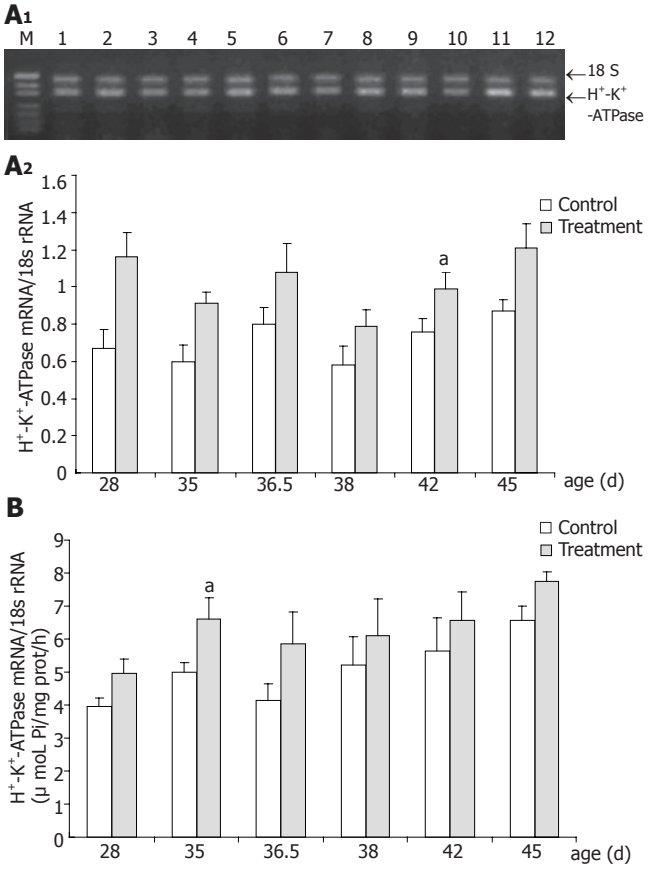

Figure 1 Expression (**A**1-2) and activity (**B**) of H+-K+-ATPase in vivo. Lane M: PUC19 marker; lanes 1-6: piglets at 28, 35, 36.5, 38, 42, 45 d of age in control group, respectively; lanes 7-12: piglets at 28, 35, 36.5, 38, 42, 45 d of age in treatment, respectively. Bars without a common superscript representing significant differences between age groups (small letters a and b for control group and capital letters A and B for treatment group); $^aP<0.05$ indicating differences between control and treatment groups at the same age.

ATPase mRNA expression and the differences were significant on D28 (P = 0.014), D35 (P = 0.017), D42 (P = 0.013) and D45 (P = 0.046), respectively. Relative abundances of H^+-K^+-ATPase mRNA expression were significantly increased by 73%, 53%, 30%, and 39% in treatment group compared with control at the same age. CS supplementation increased markedly H^+-K^+-ATPase activity by 32.3% on D35 (P = 0.043) and 18.3% on D45 (P = 0.040), respectively, compared with that of the control counterparts.

Effects of CS on expression and activity of H^+-K^+-ATPase in vitro

As shown in Figure 2, low concentration of CS exhibited no effects on both mRNA expression and activity of H^+-K^+-ATPase, while moderate and high concentrations of CS markedly increased H^+-K^+-ATPase mRNA expression by 61% (P = 0.03) and 65% (P = 0.014), and H^+-K^+-ATPase activity by 48% (P = 0.017) and 50% (P = 0.022), respectively.

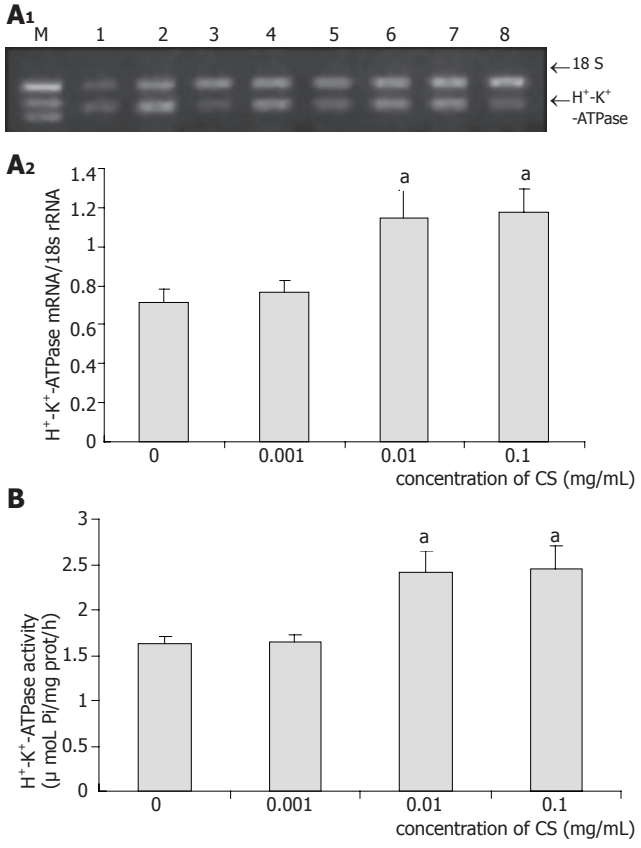

Figure 2 Effect of CS on expression (**A**$_{1\text{-}2}$) and activity (**B**) of H+-K+-ATPase in vitro. Lane M: PUC19 marker, lanes 1-2: control; lanes 3-4: low concentration group; lanes 5-6: moderate concentration group; lanes 7-8: high concentration group. [a]P<0.05 *vs* 0 mg/mL of CS.

Effects of CS on SS mRNA expression in vitro

Low concentration of CS had no influence on SS mRNA expression, whereas SS mRNA expression was markedly increased by 56% (P = 0.024) in moderate concentrations of CS and 64% (P = 0.022) in high concentrations of CS (Figure 3).

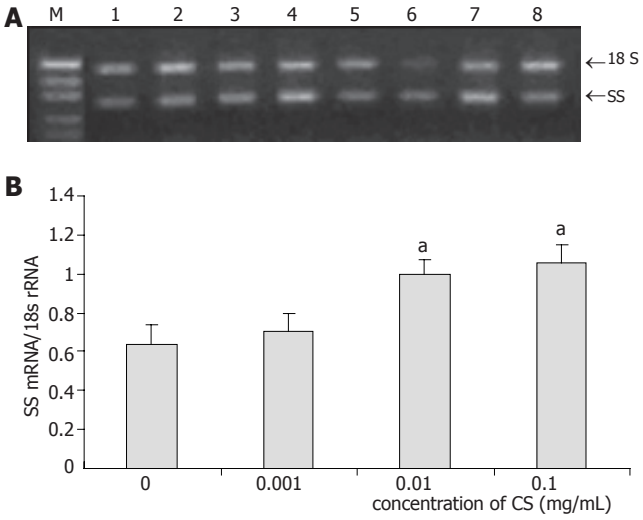

Figure 3 Effect of CS on SS mRNA expression *in vitro*. Lane M: PUC19 marker, lanes 1 and 2: control; lanes 3 and 4: low concentration group; lanes 5 and 6: moderate concentration group; lanes 7 and 8: high concentration group (**A**,**B**). [a]P<0.05 *vs* 0 mg/mL of CS.

DISCUSSION

The developmental pattern of H^+-K^+-ATPase was found to be in agreement with that of gastric acid secretion capacity, both at the level of mRNA expression and enzyme activity. Yang *et al*.[21] reported that H^+-K^+-ATPase mRNA expression and activity in fundic gland keep increasing with age from gestational day 19.5 to week 18 of postnatal age in rats. The developmental pattern of human gastric H^+-K^+-ATPase from week 25 of gestation by Western blot analysis agrees with that of gastric pH recorded in preterm infants[22]. Furthermore, the H^+-K^+-ATPase mRNA content in rat fundus increases with age from one week to six weeks of age and the change parallels the developmental change of acid secretion capacity[23]. However, the developmental pattern of H^+-K^+-ATPase expression and activity in pigs has not been reported. In contrary to the reported data, the present study failed to show significant developmental change in both the expression and the activity of H^+-K^+-ATPase in piglets around weaning throughout the period of observation. It seems that the developmental pattern of H^+-K^+-ATPase is species-specific. In addition, it is documented that gastrin is involved in the regulation of H^+-K^+-ATPase expression. In ovine fetus, developmental pattern of gastrin mRNA agrees with that of H^+-K^+-ATPase expression[24]. Gastrin can stimulate H^+-K^+-ATPase expression[25] and improve its activity by increasing the intracellular Ca^{2+} concentration to initiate the phosphorization of H^+-K^+-ATPase in parietal cells[26]. In accordance with our findings, gastrin contents in gastric tissues are stable from 4 to 6 wk of age in piglets[27].

Since the period of observation was limited to less than 3 wk from D28 to D45 in the present study, the possibility that H^+-K^+-ATPase expression and activity subjected to change during growth in a longer term cannot be excluded.

Until now no report is available describing the effect of weaning stress on expression and activity of H^+-K^+-ATPase. Our results indicated that weaning stress exhibited no effect on expression and activity of H^+-K^+-ATPase, which might be attributed to the relatively mature age of weaning on D35. This explanation is supported by the study of Efird *et al*.[28], who found that gastric acid secretion of piglets weaned after 35 d of age is not easily affected by weaning.

Our earlier publication reported that the inhibition of gastric acid secretion agrees with the upregulation of gastric SS expression in pre-weaning piglets[7]. Read *et al*.[24] reported that the developmental pattern of gastric SS mRNA is on the contrary to the patterns of gastrin mRNA and H^+-K^+-ATPase mRNA in ovine. *In vitro* studies have provided further evidence that endogenous SS plays a role as a strong inhibitory factor in gastric acid secretion, since SS antiserum significantly increases gastric acid release from perfused stomach of sheep[29].

CS possesses the ability to deplete tissue SS. Szabo and Reichlin[9] found that, in rats, CS administration brings about a prompt depletion of radioimmunoassayable SS in plasma, stomach, duodenum, pancreas, and hypothalamus. Some researches showed that gastrin plays a significant role in CS-induced hypersecretion of gastric acid. Intravenous infusion of CS in the perfused rat stomach results in a significant increase in acid secretion, which is accompanied with a marked increase in plasma gastrin concentration. The injection of anti-gastrin rabbit serum completely blocks CS-induced acid increase, and infusion of a gastrin receptor antagonist also suppresses CS-induced increase in acid secretion[13]. Van de Brug *et al*.[12] also found that intravenous bolus administration of CS induces increase in serum gastrin concentration and gastric acid outputs. However, there is no report concerning the effect of CS on expression and activity of H^+-K^+-ATPase. In the present study, we found that CS significantly increased both the expression and activity of H^+-K^+-ATPase *in vivo*. To further affirm the effect of CS on H^+-K^+-ATPase, we added CS to the culture medium of gastric mucosal epithelial cells *in vitro*. The results indicated that moderate and high concentrations of CS increased significantly both the expression and activity of H^+-K^+-ATPase, accompanied with a marked increase in the expression of SS. The upregulation of SS mRNA expression might be the consequence of SS depletion. The signal of SS depletion feeds back to the cells to boost SS synthesis in order to maintain homeostasis. Kanayama and Liddle[30] also found that the content of SS mRNA in duodenum is reduced after SS perfusion in rats. However, this upregulation might be temporal, since SS mRNA in stomach and brain significantly increases, then reduces after perfusion of CS in rats[31]. These authors presumed that SS mRNA upregulation results from SS depletion, and the subsequent SS mRNA downregulation is caused by direct effect of CS on SS expression.

In conclusion, the present experiments provide evidence that the mRNA expression and activity of H^+-K^+-ATPase in gastric mucosa remain relatively constant in piglets around weaning from D28 to D45. CS increases gastric expression and activity of H^+-K^+-ATPase both *in vivo* and *in vitro*. In addition, SS is involved in mediating the effect of CS on gastric H^+-K^+-ATPase expression and activity in weaning piglets, although the complex effect of CS on SS mRNA expression awaits further investigation.

Abstract

AIM: To construct the plasmid pcHEV23 containing fragments of HEV ORF2 and ORF3 chimeric gene and to assess its ability to elicit specific immunologic response in mice.

METHODS: The gene encoding the structural protein of HEV ORF2 fragment and full-length ORF3 was amplified by PCR. The PCR products were cloned into an eucaryotic expression plasmid pcDNA3. The resulting plasmid pcHEV23 was used as a DNA vaccine to inoculate BALB/c mice intramuscularly thrice at a dose of 100 or 200 μg. Mice injected with empty pcDNA3 DNA or saline served as control and then specific immune responses in the mice were detected.

RESULTS: After 2-3 times of inoculation, all mice injected with pcHEV23 had anti-HEV IgG seroconversion and specific T lymphocyte proliferation. The lymphocyte stimulation index in the group immunized with pcHEV23 (3.1±0.49) was higher than that in the control group (0.787±0.12, $P<0.01$). None in the control group had a detectable level of anti-HEV IgG.

CONCLUSION: DNA vaccine containing HEV ORF2 and ORF3 chimeric gene can successfully induce specific humoral and cellular immune response in mice.

INTRODUCTION

Hepatitis E virus (HEV) is an unclassified, non-enveloped RNA virus, a causative agent of acute hepatitis E transmitted principally via the fecal-oral route. The virus can cause large water-borne epidemics of the disease and sporadic cases as well. Hepatitis E occurs predominantly in developing countries usually affecting young adults with a fatality rate of 15-20% in pregnant women[1]. However, no effective treatment is currently available for hepatitis E and there are no commercial vaccines for hepatitis E in the world. Although at least four major genotypes of HEV have been identified, only one serotype of HEV is recognized. DNA vaccine can synthesize viral proteins within the host cells and induce humoral and cellular immune responses[2,3]. In this study, we constructed eucaryotic expression plasmid containing HEV ORF2 fragment and full-length ORF3 (DNA vaccine) chimeric gene and inoculated it to BALB/c mice to detect the specific humoral and cellular immune responses in mice.

MATERIALS AND METHODS

Construction of plasmid

All PCR primers were designed according to the nucleotide sequence of a Chinese HEV isolate (DDBJ accession number D11092)[4]. HEV mRNA was extracted from the feces of a patient with hepatitis E in Hangzhou, Zhejiang Province. The HEV ORF2 fragment and full-length ORF3 chimeric gene were amplified by RT-PCR. The PCR product was inserted into an eucaryotic expression plasmid pcDNA3 to form a recombinant plasmid pcHEV23 (DNA vaccine) (Figure 1).

DNA inoculation protocol

Thirty-two female BALB/c mice (18-20 g) provided by Zhejiang Experimental Animal Center were used for immunization and divided into four groups: Group 1 was injected with 100 μL saline solution as control. Group 2 was injected with 100 μg/100 μL vector pcDNA3 as control. Group 3 was injected with 100 μg/100 μL pcHEV23 plasmid. Group 4 was injected with 200 μg/100 μL pcHEV23 plasmid. Three weeks after the first injection, mice were bled and then boosted by same method. After another 3 wk, mice were boosted again for the second time (Table 1).

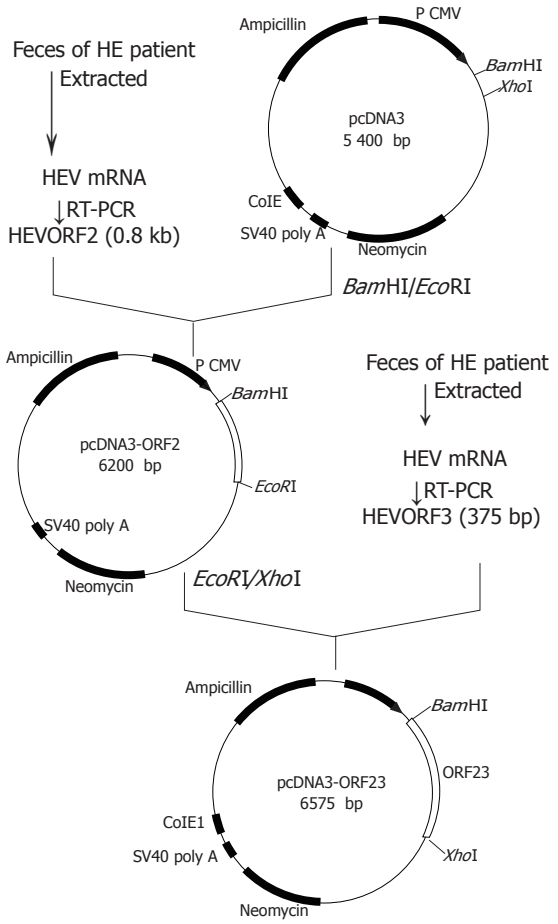

Figure 1 Construction of pcHEV23 plasmid (pcDNA3-ORF23).

Table 1 Protocol of DNA injection

Group	Mice (*n*)	Immunogen	Time of injection (wk)		
1	8	Saline	0	3	6
2	8	pcDNA3(100 μg/100 μL)	0	3	6
3	8	pcHEV23(100 μg/100 μL)	0	3	6
4	8	pcHEV23(200 μg/100 μL)	0	3	6

Serological test

Two weeks after the first three injections, blood samples were collected. All serum specimens were tested for anti-HEV IgG by EIA. In brief, microwell plates (Nunc, Roskilde, Denmark) were coated overnight at 4 °C with purified HEV ORF23 proteins (expressed *in E coli*) at 1 μg/mL in carbonate–bicarbonate buffer (pH 9.6). The wells were washed thrice with 0.05% Tween 20 in PBS (PBS-T) and then blocked with 2% BSA in PBS-T at 37 °C for 1 h. Following three washes with PBS-T, serum samples diluted in 2% BSA were added to the plates and incubated at 37 °C for 1 h. Following five washes, HRP-conjugated anti-human IgG (Sigma) diluted 2 000-fold in PBS-T was added to detect the bound antibodies. Following incubation at 37 °C for 1 h, the plates were washed as above and the substrate tetramethylbenzidine solution (Sigma) was added to the wells. After incubation at room temperature for 15 min, color development was stopped by adding 2 mol/L H_2SO_4. Optical density (OD) at 450 nm was determined with an ELISA reader. The cut-off values were set for each test as 2.1 times the mean value of negative control samples.

Table 2 Anti-HEV IgG titers after the third injection (mean±SD)

Group	1	2	3	4
Mean±SD	0.116±0.009[b]	0.210±0.028[b]	0.353±0.085[b]	0.336±0.066[b]

[b]$P<0.01$ *vs* control.

Table 3 Result of assay of T-cell proliferation (mean±SD)

Group	1	2	3	4
	0.787±0.12[b]	1.54±0.25[b]	3.1±0.49[b]	2.85±0.59[b]

[b]$P<0.01$ *vs* control.

T-lymphocyte proliferation

All the animals were killed 14 d after the last injection to analyze cellular immune responses. Single cell suspension of splenocytes was prepared for each individual animal. Splenocytes were immediately cultured in the presence of HEV ORF23 (20 μg/mL, expressed in *E coli*). Sixty-eighth day after culture, MTT was then added to the cells to measure antigen-specific proliferation. Lymphocyte stimulation index (SI) was measured according to formula: SI = A_{570} (antigen stimulation)/A_{570} (control).

RESULTS

Construction of pcHEV23 plasmid

The sequencing data indicated that the pcHEV23 construct (Figure 1) contained the correct orientation of the HEV ORF2 and ORF3 fragments (sequencing data not shown).

Analysis of anti-HEV response in pcHEV23-inoculated mice

None of the mice had seroconversion after the initial injection of pcHEV23. Following the third dose of pcHEV23, anti-HEV IgG titers in groups 3 and 4 was higher than those in groups 1 and 2 ($P<0.01$, Table 2).

T-lymphocyte proliferation assay

The lymphocyte SI in the group immunized with pcHEV23 was higher than that in saline group and pcDNA3 in control DNA group ($P<0.01$). Results are shown in Table 3.

DISCUSSION

DNA vaccines represent a new and potentially powerful approach for the development of subunit vaccines. DNA vaccines induce a broad range of immune responses due to efficient priming of T lymphocytes[5]. This novel approach to vaccination is attractive as it offers several

desirable features. First, DNA is not infectious and does not replicate and encodes only the protein or proteins of interest. Second, DNA is stable and can be made inexpensively in large quantities at a high level of purity. Third, plasmid DNA does not contain any heterologous protein components compared to a recombinant virus vaccine. Fourth, DNA vaccine can induce both cell-mediated and humoral immunity. Finally, antigen expression persists after DNA vaccination, promoting the induction of long-lived memory immune cells[6]. DNA immunization can be defined as a physical delivery of nucleic acids *in vivo* to express antigenic proteins and elicit specific immune responses. Direct naked DNA inoculation obviates the requirement of purified antigens. Pathogenic antigens synthesized inside the inoculated host cells can be processed in a natural form to develop classes I and II-regulated immune responses, mimicking the aspects of live attenuated virus.

Epitope mapping demonstrates that there are at least 7 immunodominant epitopes in HEV ORF2 region and four epitopes in HEV ORF3 region[7,8]. In this study, the full length of HEV ORF3 cDNA and partial HEV ORF2 cDNA were combined and used as an antigen-coding sequence for construction of HEV DNA vaccine.

In conclusion, direct injection of pcHEV23 is able to induce specific anti-HEV IgG and T-lymphocyte proliferation. HEV DNA vaccine constructed by us can successfully induce both humoral and cellular immune responses and appears to be a viable alternative to the recombinant protein subunit vaccine candidate.

Abstract

AIM: To investigate the significance of S phase kinase-associated protein 2 (Skp2) expression in human gastric carcinoma and the relation between expressions of Skp2, p27 and PTEN.

METHODS: Immunohistochemical analysis was performed on 138 gastric carcinoma specimens, their paired adjacent mucosa specimens, 102 paired lymphatic metastatic carcinoma tissue specimens, 30 dysplasia specimens, 30 intestinal metaplasia specimens, 10 chronic superficial gastritis specimens and 5 normal gastric mucosa specimens for Skp2 expression and on 138 gastric carcinoma specimens for p27 and PTEN expression.

RESULTS: Skp2 labeling frequency was significantly higher in intestinal metaplasia (12.68±0.86) and adjacent mucosa (19.32±1.22) than in normal gastric mucosa (0.53±0.13) and chronic superficial gastritis (0.47±0.19) (P = 0.000); in dysplasia (16.74±0.82) than in intestinal metaplasia (P = 0.000); in gastric primary carcinoma (31.34±2.17) than in dysplasia and adjacent mucosa (P = 0.000); in metastasis gastric carcinoma in lymph nodes (39.76±2.00) than in primary gastric carcinoma (P = 0.037), respectively. Skp2 labeling frequency was positively associated with differentiation degree (*rho* = 0.315, P = 0.000), vessel invasion (*rho* = 0.303, P = 0.000) and lymph node metastasis (*rho* = 0.254, P = 0.000) of gastric cancer. Expression of Skp2 was negatively associated with p27 (*rho* = -0.451, P = 0.000) and PTEN (*rho* = -0.480, P = 0.000) expression in gastric carcinoma. p27 expression was positively associated with PTEN expression in gastric carcinoma (*rho* = 0.642, P = 0.000).

CONCLUSION: Skp2 overexpression may be involved in carcinogenesis and progression of human gastric carcinoma *in vivo*, possibly via p27 proteolysis. PTEN may regulate the expression of p27 by negatively regulating Skp2 expression.

Key words: Gastric carcinoma; Skp2; p27; PTEN

INTRODUCTION

Dysregulation of the cell cycle is required for the formation of most malignant tumors. Progression of the cell cycle is controlled by interactions between cell cycle control proteins (cyclins) and their catalytically active cyclin-dependent kinase (CDKs). The activity of each cyclin-CDK complex is in turn regulated by several different mechanisms; the most important being negative regulation by CDK inhibitors[1]. p27 is an inhibitor of cyclinE-CDK2 and cyclinA-CDK2, which drive cells from G_1 to S phase of the cell division cycle[2,3]. Loss of p27 function therefore accelerates cell cycle progression and predisposes cells to malignant transformation, as is well illustrated by the observation of increased tumor incidence in hemizygous and homozygous p27-deleted mutant mice after carcinogen exposure[4,5]. Many clinical studies also indicate that low levels of p27 are associated with high aggressiveness and poor prognosis in a large variety of malignant tumors[2,3], including breast carcinoma[6,7], colorectal carcinoma[8], lung cancer[9], prostate cancer[10] and gastric carcinoma[11].

The amount of p27 is mainly regulated by post-translational ubiquitin-proteasome-mediated proteolysis[12]. Cell cycle-dependent degradation of p27 is dependent on phosphorylation at Thr^{187} in late G_1 phase by CDK2 under positive regulation by cyclinE. Thr^{187} phosphorylation is a necessary prerequisite for the sequential addition of ubiquitin molecules by an ubiquitin ligase complex, SCF^{skp2} composed of Skp1, Cull, Rbx1 and the F-box protein Skp2[3]. Polyubiquitination of p27 then targets p27 for degradation in proteasome, thus removing the p27 cell

cycle "brake" and allowing cells to transition from G_1 to S phase[13].

Some investigations have shown that Skp2 is a specific substrate-recognition subunit of SCF^{skp2}, expression of Skp2 is required for the ubiquitination and subsequent degradation of p27 *in vitro*[20-22], and Skp2 knock-out cells show high levels of p27[16]. The level of p27 has also been reported to be inversely related to that of Skp2 in lymphoma[24], oral squamous cell carcinoma[18,19] and colorectal carcinoma[20].

Recently, Mamillapalli *et al*.[21] reported that PTEN, a tumor suppressor, regulates the ubiquitin-dependent degradation of p27 through SCF^{Skp2}. Yang *et al*.[22] suggested that induction of Skp2 may be causally linked with decreased levels of p27 in prostate cancer and implicate PTEN in the regulation of Skp2 expression *in vivo*.

Recent studies have shown that Skp2 has oncogenic potential in breast epithelial cells and is overexpressed in a subset of breast carcinomas (ER- and Her-2 negative)[23] and Skp2 can mediate transformation and is upregulated during oral epithelial carcinogenesis[18]. Recently, a line of evidence also indicates a possible relationship between Skp2 expression and the malignancy of tumors. Skp2 expression has been shown to be greatly increased in malignantly transformed cell lines including oral squamous cell carcinoma[18] and correlates directly with the grade of malignancy of lymphoma[17] and oral squamous cell carcinoma[18]. Kudo *et al*.[19] reported that high Skp2 expression is also correlated with poor prognosis in oral squamous cell carcinoma. Thus, Skp2 may have a great significance in human carcinogenesis. However, few studies are available regarding the significance of Skp2 expression in human gastric carcinomas *in vivo* and there are no studies regarding the relationship between Skp2, p27 and PTEN expression. We therefore investigated the significance of Skp2 expression in human gastric carcinomas and the relationship between Skp2, p27 and PTEN expression *in vivo*.

MATERIALS AND METHODS

Patients and gastric specimens

One hundred and thirty-eight surgically resected gastric carcinoma specimens, paired adjacent mucosa specimens and paired 102 lymphatic gastric carcinoma tissue specimens metastatically selected from the Fourth Affiliated Hospital of Hebei Medical University were used in this study. All gastric carcinoma patients underwent total or subtotal gastrectomy and no patient received any treatment for cancer before surgery. All regional lymph nodes were removed. The patients comprised 111 males and 27 females with a mean age of 58.5 years and a median age of 60 years (from 36 to 78 years). After surgery, gastric specimens were fixed in 40 g/L neutral-buffered formaldehyde and embedded in paraffin. Additionally, 75 biopsy cases (5 cases of normal gastric mucosa, 10 cases of chronic superficial gastritis, 30 cases of intestinal metaplasia and 30 cases of dysplasia) were included in this study as well. To avoid evaluator variability, all pathological diagnoses were done by two pathologists. Clinical stage was done according to the International Union Contrele Cancer criteria published in 1997.

Immunohistochemistry

A standard Non-Biotin HRP two-step immunohistochemical method (Zymed) was used. Four-micrometer-thick sections were deparaffinized and rehydrated. Endogenous peroxidase in sections was inactivated in 30 mL/L hydrogen peroxide (H_2O_2) in ethanol for 15 min at room temperature. The sections were washed thrice for 5 min with 0.01 mol/L phosphate-buffered saline (PBS) and then heated in a citrate buffer (0.01 mol/L, pH 6.4) for PTEN and p27 or in a EDTA buffer (1 mmol/L, pH 8.0) for Skp2 in an 800-W microwave oven for 12 min for antigen retrieval. The sections were incubated with mouse monoclonal antibody to Skp2 (1:50 dilution, Zymed), p27 (1:50 dilution, Santa Cruz) and PTEN (1:50 dilution, Zymed) overnight at 4 °C, washed thrice for 5 min with 0.01 mol/L PBS 3 and then incubated with common IgG (Fab fraction)-HRP complex for 30 min at room temperature. Immunoreactive products were visualized using 3,3'-diaminobenzidine/H_2O_2, and finally the sections were counterstained with hematoxylin. Some sections were incubated with PBS instead of primary antibody as negative control to verify the specificity of the immunoreactions. Vascular endothelial cells showed strong PTEN expression with a nuclear predominance and served as an internal positive control for PTEN in this study. The positive breast adenocarcinoma served as a positive control for Skp2 and p27.

Immunohistochemical quantitation

Immunostaining of nuclear Skp2, p27 and PTEN in each specimen was evaluated microscopically and recorded as the percentage of Skp2, p27, and PTEN-positive cells (labeling frequency), after at least 1 000 nuclei at the lesion site were calculated in at least five high-power fields (×400). All specimens were evaluated without any knowledge of the patients' clinical information.

Statistical analysis

The differences in Skp2 labeling frequencies among specimens of normal gastric mucosa, chronic superficial gastritis, intestinal metaplasia, dysplasia, gastric adenocarcinoma, adjacent mucosa and lymphatic metastatic gastric carcinoma were compared by Mann-Whitney *U* test. The relation between Skp2 expression and the clinical and pathological variables was evaluated using the Spearman correlation coefficient. The Spearman's correlation coefficient testing was also used to determine the relation between Skp2, PTEN and p27 as well as between PTEN and p27. $P<0.05$ was considered statistically significant. All analyses were performed using SPSS 11.0 statistical software.

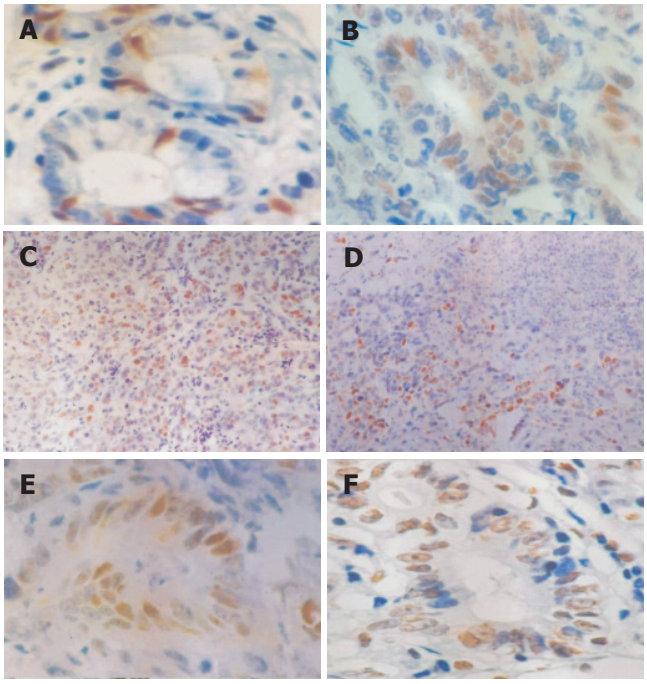

Figure 1 Skp2, p27 and PTEN expression in different gastric tissues (DAB and hematoxylin stain). **A:** Positive Skp2 in nuclei of intestinal metaplasia and dysplasia cells (original magnification ×400); **B:** Positive Skp2 in nuclei of well-differentiated gastric carcinoma cells (original magnification ×400); **C:** Positive Skp2 in nuclei of poorly differentiated gastric carcinoma cells (original magnification ×100); **D:** Positive Skp2 in lymphatic metastatic gastric carcinoma cells (original magnification ×100); **E:** Positive p27 in nuclei of well-differentiated gastric carcinoma cells (original magnification ×400); **F:** Positive PTEN in nuclei of well-differentiated gastric carcinoma cells (original magnification ×400).

RESULTS

Expression of Skp2 in human gastric specimen

The Skp2 immunoreactivity was predominantly localized in the nuclei of gastric cells (Figure 1). In 5% of the cancer specimens examined, a weak or moderate cytoplasmic immunoreactivity could be seen in addition to the predominant nuclear reactivity in cancer cells. Skp2 labeling frequency in normal gastric mucosa, intestinal metaplasia, dysplasia, primary gastric carcinoma and lymphatic metastatic gastric carcinoma was significantly higher than in normal gastric mucosa and chronic superficial gastritis ($P = 0.000$); it was in dysplasia than in intestinal metaplasia ($P = 0.000$); in primary gastric carcinoma than in dysplasia ($P = 0.000$); in lymphatic metastatic gastric carcinoma than in primary gastric carcinoma ($P = 0.037$, Table 1).

Relation between Skp2 labeling frequency and clinicopathological features in gastric carcinoma

Relation between Skp2 labeling frequency and clinicopathological variables including age, gender, histological differentiation, depth of invasion, vessel invasion, lymphatic metastasis, distant metastasis as well as clinical stage is summarized in Table 2. Skp2 labeling frequency was negatively associated with age, gender, depth of invasion, distant metastasis as well as clinical stage. A significant correlation was found between the

Table 1 Skp2 protein expression in human gastric tissues

Tissue	Specimens (*n*)	Skp2 labeling frequency(%) Median	Mean±SE
Normal gastric mucosa	5	0.00	0.47±0.19
Chronic superficial gastritis	10	0.00	0.53±0.13

[1,2,3]Skp2 labeling frequency was positively correlated with differentiated degree (rho = 0.315, $P = 0.000$), vessel invasion (rho = 0.303, $P = 0.000$), and lymph node metastasis (rho = 0.254, $P = 0.000$) in gastric carcinoma, respectively. [4]Because clinical staging could not be performed due to the lack of accurate records about lymph node in operation, data of 12 cases were cancelled in statistical analysis.

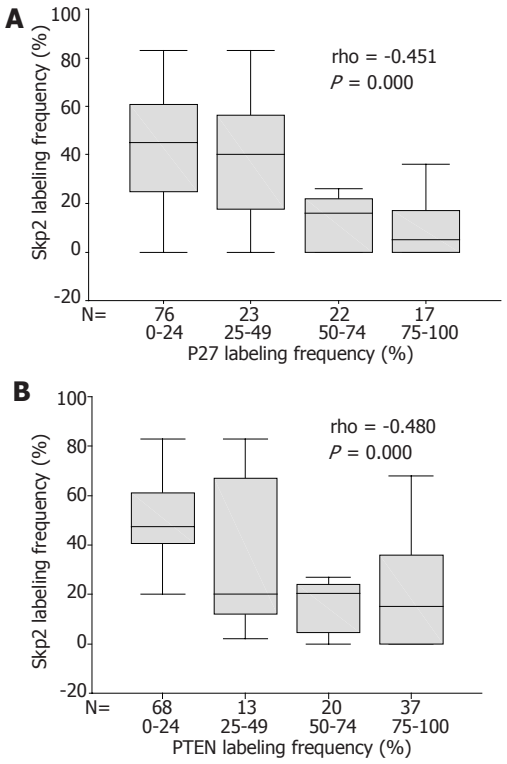

Figure 2 Correlation of Skp2 with p27 (**A**) and PTEN (**B**) protein levels. Each box and the associated bars represent the values of middle 50% and the range of the data respectively. The dark line within a box denotes the median.

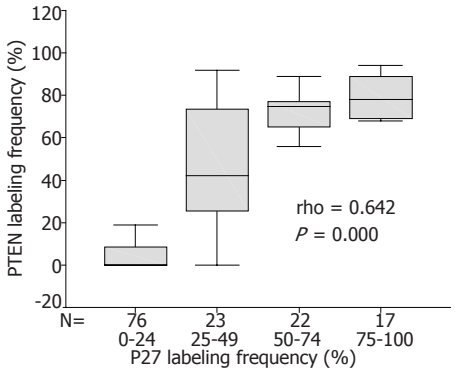

Figure 3 Correlation of p27 and PTEN expression in human gastric carcinoma. Each box and the associated bars represent the values of middle 50% and the range of the data respectively. The dark line within a box denotes the median.

Skp2 labeling frequency and differentiation degree (*rho* = 0.315, *P* = 0.000), vessel invasion (*rho* = 0.303, *P* = 0.000) and lymphatic metastasis (*rho* = 0.254, *P* = 0.000). Poorly differentiated gastric carcinoma, gastric carcinoma with vessel invasion and gastric carcinoma with lymphatic metastasis tended to have a higher Skp2 labeling frequency.

Relation between Skp2, p27 and PTEN expression in gastric carcinoma

Given the biochemical link between Skp2 and p27, we asked whether there was a correlation between Skp2 and p27 levels in gastric carcinoma using the same set of gastric carcinoma specimens used for the Skp2 analysis. A statistically significant inverse relation between p27 and Skp2 labeling frequency was evident (*rho* = -0.451, *P* = 0.000; Figure 2A). *In vitro* study linking loss of PTEN with increased Skp2 levels led us[29] to also compare the expression of PTEN and Skp2 using the same set of gastric carcinoma specimens. Interestingly, we found that increased Skp2 expression was significantly correlated with loss and decrease of PTEN expression in gastric carcinoma (*rho* = -0.480, *P* = 0.000; Figure 2B). Additionally, a positive relation between p27 and PTEN expression was observed in gastric carcinoma (*rho* = 0.642, *P* = 0.000; Figure 3).

DISCUSSION

Protein degradation by the ubiquitin–proteasome pathway plays a fundamental role in the regulation of eukaryotic cell cycle. Proteolysis of G_1 regulatory proteins is mediated by SCF ubiquitin ligase complex (SCF^{Skps}) composed of four major subunits, Skp1, Cul1, Rbx1/Roc1 and one of the F-box proteins (Fbps)[24]. There are 11 Fbps in budding yeast, 22 in Drosophila[25] and 38 in human beings[26,27]. Skp2 is a Fbp first identified together with Skp1 as an interactor of the cyclinA-Cdk2 complex which drives cells from G_1 to S phase, hence it is named as S phase kinase-associated protein 2 (Skp2)[24].

In this study, we found that Skp2 immunoreactivity was rare in normal gastric mucosa and chronic superficial gastritis, but Skp2 labeling frequency was significantly increased during the course of intestinal metaplasia, dysplasia and primary gastric carcinoma. From pathological point of view, development of gastric adenocarcinoma involves progression through a well-defined series of histological steps initiated by the change of normal mucosa to chronic superficial gastritis, followed by the appearance of atrophic gastritis and intestinal metaplasia, then dysplasia and finally adenocarcinoma[28]. These results suggest that Skp2 may have oncogenic potential in gastric carcinoma and is involved in gastric carcinogenesis. It may become a new biomarker in gastric carcinogenesis. Additionally, we found that Skp2 labeling frequency in adjacent mucosa of gastric carcinoma was significantly higher than that in normal gastric mucosa, suggesting that some adjacent mucosae of gastric carcinoma have normal histological structure, but the expression of some proteins is changed.

In this study, we found that Skp2 labeling frequency was positively correlated with differentiation degree, lymphatic metastasis and vessel invasion of gastric carcinoma. Poorly differentiated gastric carcinoma and gastric carcinoma with lymphatic metastasis and vessel invasion tended to have a higher Skp2 labeling frequency. Skp2 labeling frequency was higher in lymphatic metastatic gastric carcinoma than in primary gastric carcinoma. The overexpression of Skp2 could modulate the malignant phenotype of gastric carcinoma cells, suggesting that overexpression of Skp2 may be associated with metastasis

potential of gastric carcinoma cells. Further studies need to be done to clarify their mechanism.

In the present study, we also found that Skp2 expression was inversely correlated with the expression of p27, which is consistent with the results reported in other studies[18,19,21]. These results suggest that Skp2 overexpression is associated with p27 protein degradation in cancer tissue, which may be a reason why Skp2 overexpression is involved in carcinogenesis and progression of cancer. Furthermore, Skp2 expression was also inversely correlated with PTEN expression and p27 expression was positively related with PTEN expression in gastric carcinoma. PTEN tumor suppressor acts as a phosphatase of phosphatidylinositol-3,4,5-trisphosphate (PIP3) and negatively controls the G_1/S cell cycle transition and regulates the levels of p27[29]. Mamillapalli *et al*.[21] showed that PTEN deficiency in mouse embryonic stem cells decreases p27 level while increases Skp2 level. Conversely, in human glioblastoma cells, ectopic PTEN expression leads to p27 accumulation accompanied with a reduction of Skp2 and ectopic expression of Skp2 alone is sufficient to reverse PTEN-induced p27 accumulation, restore the kinase activity of cyclin E/CDK2 and partially overcome the PTEN-induced G_1 cell cycle arrest. Recombinant SCF^{Skp2} complex or Skp2 protein alone can rescue the defect in p27 ubiquitination in extracts from cells treated with a PI 3-kinase inhibitor. Yang *et al*.[30] showed that loss of expression or reduced expression of PTEN protein contributes to carcinogenesis and progression of gastric carcinoma. Myung *et al*.[31] reported that reduced expression of cyclin-dependent kinase inhibitor p27 is associated with advanced stage and invasiveness of gastric carcinoma. Additionally, Yang *et al*.[22] also found that elevated Skp2 protein expression in human prostate cancer is associated with loss of p27 and PTEN expression. Thus, all these findings suggest that PTEN functions as a negative regulator of the Skp2 pathway that is normally used to control S-phase entry through the regulation of p27 in gastric carcinoma and the effects of Skp2, p27 and PTEN together play an important role in carcinogenesis and progression of gastric carcinoma. These results also suggest that Skp2 functions as a critical component in the PTEN/PI3-kinase pathway for the regulation of p27.

In conclusion, alterations in the levels of proteins controlled by the ubiquitin–proteasome pathway during transformation are likely to be common. Further studies that define how such posttranscriptional control pathways are altered during transformation may provide additional biomarkers or facilitate the identification of novel therapeutic targets. The finding that Skp2 is induced in a number of different cancers suggests that drugs directed at this molecule may provide a more selective target for therapeutic development.

Abstract

An 85-year-old man with HCV infection and diabetes mellitus was diagnosed as having hepatocellular carcinoma (HCC, 13 cm in diameter) based on high serum alpha-fetoprotein (AFP), AFP-L3, and des-γ-carboxy prothrombin levels as well as typical enhancement pattern on contrast-enhanced CT. The patient did not receive any interventional treatments because of advanced age and the advanced stage of HCC. He chose to take vitamin K, which was reported to suppress the growth of HCC *in vitro*. Three months after starting vitamin K, all three tumor markers were normalized and HCC was markedly regressed, showing no enhancement in the early arterial phase on CT. Here we present the report describing the regression of HCC during the administration of vitamin K.

Key words: Hepatocellular carcinoma; Vitamin K; Regression

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common cancers worldwide[1]. HCC is developed mainly in patients with chronic hepatitis C or B virus infections and the screening of this high risk group makes it possible to detect HCC at the early stage. However, many patients are still diagnosed at the advanced stage and the prognosis is poor. Transcatheter chemoembolization or chemotherapies are performed in cases of advance HCC[1-3]. These treatments are sometimes very effective, but are harmful to the background liver and accelerate the progression of pre-existing chronic liver injury. Therefore, these therapies cannot be performed in patients with severe liver cirrhosis. In addition, severe side effects often impair the quality of life. Thus, the development of new low-invasive therapies is needed.

Vitamin K is a factor in blood coagulation and is used for the treatment of osteoporosis[4]. Vitamin K is also known to inhibit the growth of cancer cell lines, but its clinical usefulness in the treatment of human cancer remains controversial[5-7]. In this report, we present a case of advanced HCC in which marked regression during the administration of vitamin K has been documented.

CASE REPORT

In July 2003, an 85-year-old man with liver cirrhosis due to HCV and diabetes mellitus was admitted to our hospital because of giant liver tumors. The patient had no history of alcohol drinking or blood transfusion. He did not smoke and was not taking any medicine, but was under intermediate-acting insulin (12 U/d) injection. He had undergone surgery for prostate hypertrophy 3 years before the present admission. Routine laboratory studies showed Hb 13.8 g/L, platelet count 101 000/mm^3, albumin 3.2 g/L, total bilirubin 0.6 mg/dL, aspartate aminotransferase and alanine aminotransferase 232 U/L and 102 U/L respectively, γ-glutamyl transpeptidase 93 IU/L, fasting blood glucose 126 mg/dL, HbA1c 11.1%. Serum alpha-fetoprotein (AFP), lentil lectin-A-reactive AFP (AFP-L3), and des-γ-carboxy prothrombin (DCP) were 1 212 ng/mL, 76.9%, and 51 300 mAU/mL, respectively. The patient was positive for HCV antibody and hepatitis B virus core antigen but negative for hepatitis B virus surface antibody. There were no esophageal or gastric varices observed during gastro-intestinal endoscopy. Although the patient did not complain of abdominal pain, gastric ulcer was detected by endoscopy and administration of the proton pump inhibitor was started.

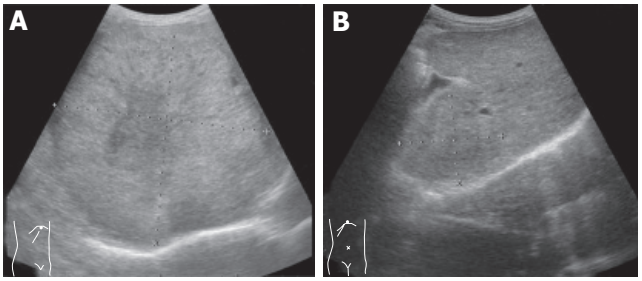

Figure 1 Giant tumor with central hypoechoic area dominated the right lobe of the liver (**A**) and remarkable regression of tumor with obscure margin after administration of vitamin K (**B**).

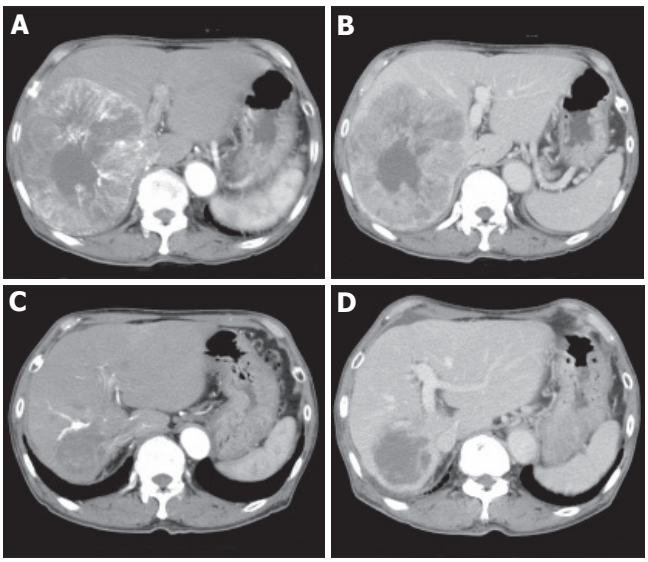

Figure 2 Enhancement of peripheral portion of tumor during early arterial phase (**A**) and hypoattenuation during portal phase (**B**) as well as remarkable tumor regression and no enhancement during early arterial phase (**C**) and portal phase (**D**) 5 mo after administration of vitamin K.

Abdominal ultrasonography (US) demonstrated that a large hyperechoic mass (13 cm in diameter) with central hypoechoic area dominated the right lobe of the liver (Figure 1A). At least four nodules about 2 cm in diameter surrounded the main nodule and another nodule (5 cm in diameter) existed at segment 4. Portal vein (PV) in the right lobe was replaced by tumor except for the PV in segments 5 and 8 in which faint blood flow was observed. Right hepatic vein was replaced and the middle hepatic vein was stretched by the tumor. Enhancement during the early arterial phase and defect during portal phase were observed by contrast enhanced-computed tomography (CE-CT, Figures 2A and B). Based on typical imaging features and elevated HCC tumor markers, the liver tumors were diagnosed as HCC. There was no distant metastasis observed by chest X-ray or abdominal CT.

Because of the patient's advanced age and advanced stage of HCC, the patient declined interventional therapies or angiography. Thereafter, we prescribed oral vitamin K_2 (45 mg daily), which was reported to inhibit cancer growth

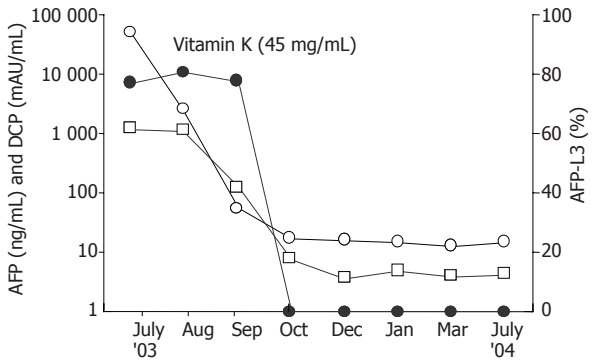

Figure 3 Clinical course of the patient.

in vitro[4,5]. The recommended dose for osteoporosis therapy was used. Informed consent for the administration of vitamin K was obtained from the patient and his family. Soon after the administration of vitamin K, AFP as well as DCP decreased and finally normalized in the 3rd month. AFP-L3 also decreased to below the detectable level from 76.9% to 0% (Figure 3). CE-CT, 5 months after starting vitamin K, demonstrated that the tumor sizes were remarkably decreased and the diameter of the main tumor was 5.5 cm (Figures 2C and D). Enhancement during the early arterial phase had disappeared in all nodules. US demonstrated that the tumor regressed and the margin of the tumor became obscure (Figure 1B). Twenty-two months have passed and there are no signs of recurrence observed to date. All three tumor markers have remained within the normal limits.

DISCUSSION

Vitamin K is known to inhibit the growth of many cancer cell lines including HCC[5–7]. The mechanisms of the anticancer action of vitamin K are not precisely understood, but several candidates including the induction of apoptosis, differentiation, and cell cycle inhibition have been proposed[4]. Recent research has demonstrated that the anticancer action of vitamin K may occur at the level of tyrosine kinases and phosphatase, modulating various transcription factors. In addition to the *in vitro* analysis, there are several case reports that described the usefulness of vitamin K for the treatment of human cancers including myelodysplastic syndrome (MDS)[6,7]. In a clinical trial of vitamin K for MDS and post-MDS acute myeloid leukemia, hematological improvement is reported in four of nine patients[8]. Recently, Koike *et al.* demonstrated that the development of PV tumor thrombus is inhibited and patient's survival is improved in patients with HCC following administration of vitamin K (unpublished data). These reports suggest that vitamin K is an anticancer agent for HCC.

Spontaneous regression of cancer is rare and estimated to occur once in 60 000-100 000 patients with cancer[9]. At least 27 cases of spontaneous regression of HCC have been reported[10-14]. There were no apparent clinical

characteristics discriminating the patient with spontaneous regression of HCC from others and various causes of regression have been documented (e.g. lack of blood supply due to arterial infarction or rapid growth of HCC, withdrawal from steroids, abstinence of alcohol consumption, administration of herbal medicines, and immunological activation due to high fever or sepsis)[10,15]. Hepatic angiography was performed in some cases and blood shortage due to the intimal damage induced by micro catheters could also be the cause of regression. In this report, the speed of tumor growth was uncertain because the patient was not followed up before admission. Other than that, he did not have any of the background factors reported previously. Therefore, possible reasons for regression are limited in this case; spontaneous regression due to blood shortage induced by rapid tumor growth or regression due to vitamin K administration, which was reported to inhibit tumor growth.

Although we could not conclude that administration of vitamin K was the cause of the regression in this case, this is a case report documenting regression of HCC during the administration of vitamin K. Further prospective study is needed to confirm the efficacy of vitamin K for the treatment of HCC.

Abstract

Unicentric Castleman's disease of the pancreas is extremely rare, with only six cases described in the worldwide literature. An asymptomatic case of unicentric, hyaline, vascular-type Castleman's disease (UCD) localized to the tail of the pancreas with central calcification imitating a primary neoplasm of the pancreas is presented. This is the first description of endosonographic and endoscopic retrograde pancreatographic findings of pancreatic UCD. Additionally, computed tomography, histological and serologic findings are reported.

Key words: Unicentric Castleman's disease; Calcification; Pancreas; Endoscopic ultrasound

INTRODUCTION

Unicentric Castleman's disease (UCD), also called giant lymph node hyperplasia, follicular lymphoreticuloma or angiofollicular mediastinal lymph node hyperplasia, is a rare lymphoproliferative disorder of unknown aetiology. UCD was first described and defined by Benjamin Castleman in 1956 in tumors of the thymus with asymptomatic mediastinal lymph node hyperplasia, which could be separated histologically from thymomas and other neoplastic lymph node disorders[1]. Flendrig and Schillings distinguished two basic pathologic types and one mixed variant[2], while Keller *et al.* designated hyaline-vascular, plasma cell, and hyaline-vascular plasma cell type[3]. UCD typically presents as indolent benign disease in young adults with a median age of approximately 35 years and is equally distributed between males and females[2,3]. A subset of patients with plasma cell variant may have systemic symptoms. UCD in the abdomen and pelvis has been only described in the radiology literature as a focal enhancing mass of varying locations, including the retroperitoneum, mesentery, and hepatic porta[4].

CASE REPORT

A 53-year-old man was well until one week before admission with renal colic with an onset of pain strongest at the right paravertebral region and radiating in the right iliac crest. Excretion urography performed in another hospital showed a slight pyelectasis of the right kidney and a left renal duplication with ureter bifidus, while, incidentally, abdominal ultrasound showed a calcified mass (3.4 cm × 3.4 cm) in the left hilar region of the kidney. Then the patient was subsequently referred to our tertiary care centre for further evaluation and treatment .

On physical examination the patient was afebrile and appeared well. The pulse was 80 bpm and the blood pressure 130/70 mm Hg. No lymphadenopathy was found. A non-tender liver edge descended 2 to 3 cm below the right costal margin; the spleen was not felt. Peripheral blood counts, liver function tests, cancer antigen (CA 19-9), carcinoembryonic antigen (CEA) and β-2 microglobulin were within normal levels. Immunologic tests for hepatitis A, B, C were negative. An ELISA for human immunodeficiency virus antibodies was negative. A postoperative ELISA (assay against viral latency-associated nuclear antigen) and a polymerase-chain-reaction test for herpes simplex virus 8 was negative and the serum interleukin 6 level was normal.

The patient had undergone a thorough systematic investigation, which included abdominal ultrasonography, computed tomography (CT), endoscopic ultrasound with fine-needle aspiration and endoscopic retrograde pancreatography (ERP). A spiral abdominal CT examination showed a well-circumscribed (5.5 cm × 4.5 cm × 4.5 cm) hypervascularized mass of soft tissue density with focal calcification in the tail of the pancreas without evidence of invasion of surrounding structures or vessels (Figure 1A). A thoracic and neck CT was normal. Endoscopic ultrasound revealed a solid, well defined, slightly heterogeneous, hypoechogenic soft-tissue mass with central calcification. Local lymph nodes were not enlarged (Figure 1B). The cytological evaluation of

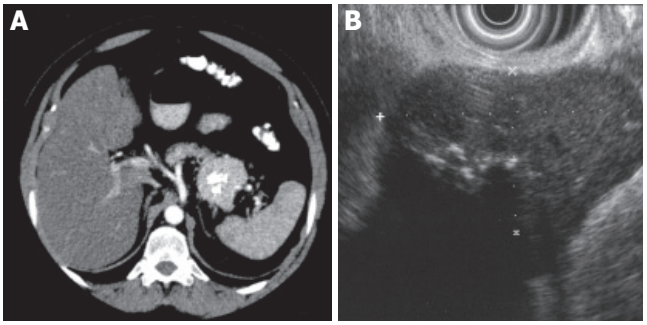

Figure 1 A: Enhanced CT shows a well-circumscribed hypervascular mass of soft tissue density with focal calcification in the tail of pancreas; **B:** 7.5 MHz endosonography shows a well-circumscribed hypoechogenic mass (2.8 x 4.9 cm) with focal hyperechogenicity and without signs of infiltration.

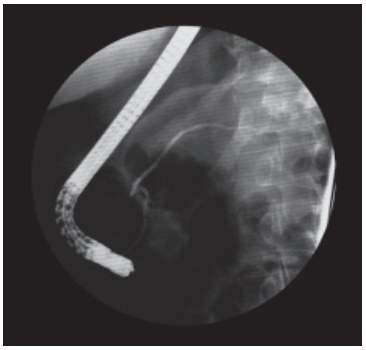

Figure 2 Endoscopic retrograde pancreatography (ERP) shows no malignant stricture of the pancreatic duct and a slight parenchymography in the tail of the pancreas.

endosonography controlled fine-needle aspiration biopsy disclosed lymphatic tissue with focal sclerosis. In ERP (Figure 2) a malignant stricture of the pancreatic duct could be ruled out and a slight parenchymography in the tail of the pancreas with circular calcification of the tumor projecting around the pancreatic duct was shown. Postoperative microscopical examination of a specimen of bone marrow obtained by needle aspiration biopsy disclosed only slight hypercellularity.

Then the patient subsequently underwent left hemipancreatectomy with splenectomy. The specimen of hemipancreatectomy had a spheroidal tumor mass measuring up to 4.6 cm, which was demarcated by a fibrous pseudocapsule (partially with tumor infiltration) from normal tumor-free pancreas tail tissue (12 cm × 7 cm × 4 cm, 367 g). Remarkably, there was a central calcification 3.2 cm in diameter (Figures 1A and 3B). Microscopic examination of the mass revealed germinal centres *with hyalinized venules* originating from a hypervascular mantle zone surrounded by small lymphocytes in a concentric onionskin pattern with focal hyaline deposits, which is characteristic for hyaline-vascular type of Castleman's disease (Figures 3A and 3B). The interfollicular stroma showed few plasma cells expressing light chains and IgM. The patient's

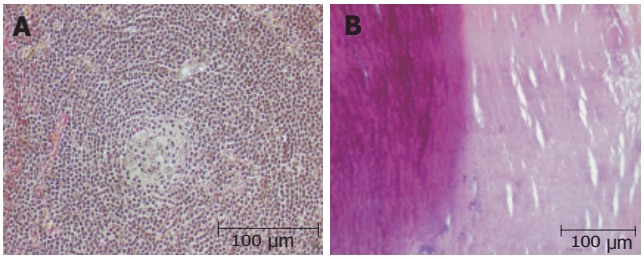

Figure 3 A: Germinal centers with hyalinized venules originating from a hypervascular mantle zone surrounded by small lymphocytes in a concentric onionskin pattern (hematoxylin and eosin); **B:** Areas of heterotopic calcification of the central part of the tumor (left panel) and hyaline deposits (right panel) (hematoxylin and eosin).

postoperative course was without complications and no recurrence has occurred after a two year follow up period in our patient.

DISCUSSION

Unicentric Castleman's disease commonly occurs in the mediastinum (over 50 %), but has also been identified in multiple anatomic locations, including the neck, the pelvis and the axilla[5]. So far, UCD in the abdomen and pelvis has been described in the radiology literature as a focal enhancing mass of varying location, whereas UCD in the pancreas constitutes an extremely rare entity, which can imitate a tumor originating from pancreatic tissue[4]. Prior to this report, endoscopic retrograde cholangiopancreatography and endoscopic ultrasound findings of pancreatic Castleman's are not available. The patient had no systemic symptoms, the pancreatic mass was well defined and hypoechogenic on endoscopic ultrasonography and showed no contact between the main pancreatic duct with circular calcification projecting around the pancreatic tail at ERP. On abdominal CT homogeneous enhancement with central pattern of calcification was found, as described in the literature[4,6,7]. Hence, possible differential diagnoses of this indeterminate tumor of the pancreatic tail containing central calcifications were acinar cell carcinoma, solid and papillary epithelial neoplasm, solid cystic tumor, serous cystadenoma or cystic teratomas of the pancreas, which are all known as well defined tumors with calcification patterns[8,9]. Castleman's disease in the abdomen and pelvis displays a variety of calcification patterns, including punctuate, coarse, peripheral, and "arborizing". In a recently published retrospective review of 16 cases of abdominal and pelvic manifestations, 31% showed calcification, one with an arborizing pattern and the remaining lesions with punctuate calcification[4]. Calcification with a diameter of 3.2 cm in a case of monocentric or multicentric disease has as yet not been observed.

Patients with the hyaline-vascular subtype are usually clinical asymptomatic, as was our patient. Only 3% of the patients present with systemic complaints[3] and less

than 10% (usually patients with plasma cell variant) have disease associated syndromes like myasthenia gravis, erythema nodosum, Horton's arteritis or Moschcowitz' s disease[5,10-13]. In contrast, the multicentric type of Castleman disease (MCD) is accompanied by a general lymphadenopathy, systemic symptoms, laboratory abnormalities, organomegaly and progressive clinical course with potential for malignancy and was not recognized until 1978[14]. Understanding of MCD has greatly expanded since the identification of its association with HIV and HHV-8 infection[15-17]. However, the sources of the immune activation in the unicentric form and the HHV-8 and HIV negative multicentric form are still unidentified. In retrospective studies, complete surgical resection for patients with unicentric hyaline vascular Castleman's disease has been associated with the best chance of cure [18].

Abstract

Generalized biliary peritonitis is a serious intra-abdominal emergency. Most of them occur due to duodenal ulcer perforation and rapidly evolve into bacterial peritonitis due to contamination by gut organisms and food. In this situation, recognition of the pathology and its treatment is straightforward and is usually associated with a good outcome. There are a few unusual causes of biliary peritonitis, of which rupture of the biliary tree is one. We describe a rare case of biliary peritonitis due to rupture of an intra-hepatic biliary radical. Unusual causes of peritonitis do interrupt our daily routine emergency surgical experience. Rapid recognition of the presence of peritonitis, adequate resuscitation, recognition of operative findings, establishment of biliary anatomy, and performance of a meticulous surgical procedure resulted in a good outcome.

Key words: Biliary peritonitis; Intra-hepatic biliary radicle; Rupture

Lochan R, Joypaul BV. Bile peritonitis due to intra-hepatic bile duct rupture. *World J Gastroenterol* 2005; 11(42): 6728-6729

INTRODUCTION

Rupture of an intra-hepatic biliary duct leading to biliary peritonitis is a rare occurrence, with only few cases reported in the literature[1-4]. This case report reinforces the necessity of complete and meticulous operative assessment of the biliary system in every case of bile peritonitis.

CASE REPORT

A 78-year-old male with severe spondyloarthropathy presented with a 12-h history of upper abdominal pain, nausea and vomiting. He was shocked (BP 80/40, pulse 120/min) and clinical examination revealed guarding, tenderness with rebound in the upper abdomen and absence of bowel sounds. A diagnosis of peritonitis was made and he was appropriately resuscitated. He responded well to the treatment and became hemodynamically stable. His hematological blood profile as well as his urea and electrolytes were unremarkable. He had conjugated hyperbilirubinemia with raised alkaline phosphatase and alanine transaminase. Plain radiology (erect CXR and abdominal films) did not demonstrate any pneumoperitoneum.

When the patient was optimized, he underwent surgery. At laparotomy, there was no evidence of gastrointestinal perforation; however, free intra-peritoneal bile was found. The extra hepatic biliary system was grossly dilated due to obvious obstruction at the distal common bile duct by an impacted calculus. The gall bladder contained calculi and was thick walled. There was a perforated superficial biliary radicle in the left lobe of the liver, which was the source of the free bile in the peritoneal cavity.

A cholecystectomy was performed and the CBD was explored. The calculus in the distal CBD needed to be extracted through a trans-duodenal sphincterotomy. Post exploratory choledochoscopy and on-table cholangiography confirmed clearance of the bile ducts. The common bile duct was drained with a T-tube and at the end of the operation the ruptured biliary radicle stopped leaking bile. It was however reinforced with two interrupted 3/0 prolene sutures. The right sub-hepatic space was drained and the abdomen was closed as per standard.

The patient was transferred to the high dependency unit for immediate care. He made a slow, but steady post-operative recovery. T-tube cholangiogram performed on day 14 (post-op) confirmed free passage of contrast into the duodenum and absence of residual CBD stones; thus allowing its removal. The patient was discharged 34 days following surgery and he is still healthy with normal liver function tests when last reviewed 2 years following surgery.

DISCUSSION

Peritonitis requiring surgical intervention is caused by perforated peptic ulcer in about 40% cases (duodenum: gastric: 3:1), appendicitis in 20%, gangrene of the small bowel or gall bladder in 15%, post-operative complications in 10% and miscellaneous causes in 15% cases[5]. Most commonly, peritonitis in the clinical setting is due to microorganisms, though the initial insult is usually chemical as in peptic ulcer perforation where bile, pancreatic

enzymes, blood, etc., gain access into the peritoneal cavity.

The peritoneum can be contaminated with bile through a number of routes. The commonest is post-cholecystectomy. This is usually due to the division of small bile channels between the gall bladder and liver, imperfect clipping of the cystic duct, residual CBD stones causing raised intrabiliary pressure and inadvertent division of an accessory hepatic duct. The latter is potentially serious usually requiring biliary reconstruction. Other causes include post liver transplant biliary peritonitis, spontaneous hepatic rupture in pregnancy and trauma to the extra-hepatic biliary system such as that following minimal access renal surgery[6].

Perforation of the biliary tract secondary to rupture of the gall bladder (empyema/gangrene) is well documented. However, spontaneous rupture of the CBD is exceedingly rare and here the etiologies are increased intra-ductal pressure, calculus erosion and necrosis of the duct wall secondary to thrombosis[7]. Spontaneous perforation of extra hepatic ducts is also a very rare cause of jaundice in infancy[8]. The commonest site is the confluence of the cystic and common hepatic ducts[9]. Biliary peritonitis secondary to intra-hepatic duct rupture is rarely reported in the literature; the causes are calculus disease of the biliary ducts (as in this case), stenosis of the papilla and Caroli's disease[10].

The clinical picture associated with biliary peritonitis varies and the correct pre-operative diagnosis is difficult. This combined with the associated comorbidity of the patient population (mainly elderly) significantly contributes to a mortality rate of 30–50%[11]. Though the initial insult by bile is chemical, secondary bacterial infection is the usual sequelae. Furthermore, it has been clearly shown that, in the presence of bacteria, bile further impairs local host defense mechanism through its detergent lytic effects[12]. Paralytic ileus is also a frequent complication. Laboratory findings are usually non-contributory but biliary peritonitis should always be suspected in any patient with unexplained abdominal symptoms.

The aim of treatment is to prevent sepsis in the abdominal cavity and thus prompt recognition of the condition and control of source of the contamination with appropriate drainage/reconstruction of the biliary system is of paramount importance. The type of surgery is dependent upon the general condition of the patient as well as on biliary anatomy. Regardless, biliary peritonitis requires some form of drainage, either externally via the percutaneous route or internally via the endoscopic/open surgery route. In our patient, the intra-hepatic duct rupture was presumably due to a very high pressure in the biliary system secondary to calculus obstruction in the distal common bile duct. Transduodenal sphincterotomy and extraction of the impacted calculus along with 'T' tube drainage resulted in an uneventful resolution. Prompt recognition of this condition before biliary/systemic sepsis supervened played a major role in the positive outcome for this patient. In conclusion, prompt laparotomy in a well-resuscitated patient and an adequately tailored operation depending on the operative findings are the mainstay to avoid local and systemic sepsis and long-term morbidity in these cases of peritonitis.

Abstract
Primary biliary cirrhosis (PBC) is usually diagnosed by the presence of characteristic histopathological features of the liver and/or antimitochondrial antibodies (AMA) in the serum traditionally detected by immunofluorescence. Recently, new and more accurate serological assays for the detection of AMA, such as enzyme-linked immunosorbent assay (ELISA), immunoblotting, and enzyme inhibition assay, have been developed. Of these, the enzyme inhibition assay for the detection of anti-pyruvate dehydrogenase complex (PDC) antibodies offers certain advantages such as objectivity, rapidity, simplicity, and low cost. Since this assay has almost 100% specificity, it may have particular applicability in screening the at-risk segment of the population in developing countries. Moreover, this assay could be also used for monitoring the disease course in PBC. Almost all sera of PBC-suspected patients can be confirmed for PBC or non-PBC by the combination results of immunoblotting and enzyme inhibition assay without histopathological examination. For the development of a "complete" or "gold standard" diagnostic assay for PBC, similar assays of the enzyme inhibition for anti-2-oxoglutarate dehydrogenase complex (OGDC) and anti-branched chain oxo-acid dehydrogenase complex (BCOADC) antibodies will be needed in future.

Key words: Primary biliary cirrhosis; Enzyme inhibition assay; Antimitochondrial antibody; 2-oxo-acid dehydrogenase complex

INTRODUCTION
Primary biliary cirrhosis (PBC) is a chronic autoimmune cholestatic liver disease characterized by the destruction of small and medium-sized bile ducts and the presence of antimitochondrial antibodies (AMA) in the serum traditionally detected by immunofluorescence[1,2]. The "gold standard" procedure for the diagnosis of PBC is histopathological examination of liver tissue. However, the characteristic histopathological changes of PBC are not always evident in biopsy specimens. Therefore, serological examination such as AMA is useful for the diagnosis of PBC because this is non-invasive and therefore can be repeated throughout the course of the disease. The major mitochondrial autoantigens recognized in the sera of PBC patients are members of 2-oxo-acid dehydrogenase complex (2-OADC) family, including E2 subunit of pyruvate dehydrogenase complex (PDC-E2), E2 subunit of branched chain oxo-acid dehydrogenase complex (BCOADC-E2), and E2 subunit of 2-oxoglutarate dehydrogenase complex (OGDC-E2)[1,3]. Unfortunately, however, there is so far no "gold standard" assay (i.e., with 100% sensitivity and 100% specificity) for the detection of AMA in PBC.

PBC is present among various ethnic and racial populations, but its incidence and prevalence varies quite widely, from the highest among Northern European populations to vanishingly low in certain parts of Asia[3]. This difference may be due, at least in part, to the diagnostic awareness of physicians for asymptomatic cases. Therefore, reliable and easy-to-use tool for screening PBC in general population is needed.

Serological assays for the detection of AMA
AMA is one of the most diagnostically useful of all autoimmune markers, since both the sensitivity and specificity for the diagnosis of PBC are acceptably high[1]. Indirect immunofluorescence assay using either Hep-2 cells or mouse kidney/stomach sections as the substrate and enzyme-linked immunosorbent assay (ELISA) using semipurified PDC as the antigen source are now widely used in clinical laboratories. Traditional indirect immunofluorescence assay has high sensitivity, and can detect reactivity to all 2-OADC enzymes. However, this assay is non-automated and labor-intensive, and the "readout" is subjective. The reactivity of serum with mitochondrial antigens other than PBC specific 2-OADC enzymes and nonspecific staining or high background could influence its specificity and sensitivity[3]. The

sensitivity, specificity, positive predictive value, negative predictive value, and accuracy determined in our previous study were 89%, 99%, 98%, 94%, and 95%, respectively[4].

Recently, new and more accurate serological assays for the detection of anti-2-OADC, such as ELISA, immunoblotting, and enzyme inhibition assay, has been developed. ELISA can detect more precisely the reactivity to a single 2-OADC enzyme in each run, and is non-subjective readout. Recently, more sensitive ELISAs using PDC-E2, BCOADC-E2 and OGDC-E2 as coating antigens have been developed[5-8]. In ELISA using commercially available MESACUP-2 Test Mitochondria M2 kit (Medical & Biological Laboratories Co., Nagoya, Japan), the sensitivity, specificity, positive predictive value, negative predictive value, and accuracy are 90%, 98%, 95%, 96%, and 94%, respectively[9]. Immunoblotting has been reported to have almost 100% sensitivity, and can detect individual reactivity to 2-OADC enzymes[10,11]. In our immunoblotting assay condition, the sensitivity, specificity, positive predictive value, negative predictive value, and accuracy were 99%, 86%, 89%, 99%, and 93%, respectively[11]. However, this assay is labor intensive, and can only be performed in specialized laboratories. Moreover, its specificity has not been well established[12]. The enzyme inhibition assay, which measures the capacity of PBC sera to inhibit the catalytic activity of PDC, is non-subjective compared to immunofluorescence, is more rapid and technically simpler than immunoblotting and ELISA. This assay has almost 100% specificity[6,13-16], but the sensitivity has been reported to be around 80%[6,15,16]. This lower sensitivity can be explained by the fact that this assay does not detect the inhibitory activity of sera to 2-OADC enzymes other than PDC, such as BCOADC or OGDC.

Enzyme inhibition assay

A striking property of AMA in PBC sera is their capacity to rapidly inactivate the catalytic function of 2-OADC *in vitro*[17]. Enzyme inhibition assay has been utilized to demonstrate a population of autoantibodies in PBC sera that inhibit enzyme function, and a miniaturized semiautomated enzyme inhibition assay was developed for the detection of anti-PDC antibodies in PBC in 1991[18] (Figure 1). Several subsequent studies have assessed its objectivity, rapidity, simplicity, and costeffectiveness, by comparing these parameters to other assays such as immunofluorescence, ELISA, and immunoblotting[13,15]. Immunoblotting might be the most expensive, and enzyme inhibition assay might have most cost-effectiveness in many countries. Recently, an automated enzyme inhibition assay kit, TRACE enzymatic mitochondrial Antibody (M2) assay (EMA) kit (Thermo Trace, Victoria, australia), became available commercially. In principle, the "Substrate reagent" (250 μL) containing sodium pyruvate, magnesium acetate, cocarboxylase, coenzyme A, and nicotinamide adenine dinucleotide (NAD), is placed in flat-bottomed microtiter wells. Thereafter, 4 μL of undiluted test serum is added to each well and incubated for 1 min at 37 °C before adding 50 μL of the "Enzyme reagent" containing

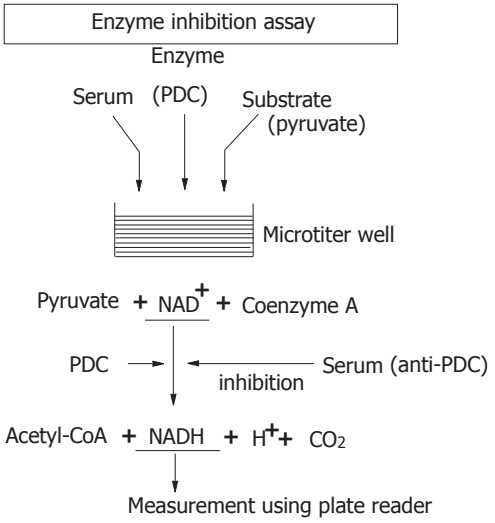

Figure 1 Principle of enzyme inhibition assay.

pyruvate dehydrogenase and dithiothreitol. After 30 s of lag time, the rate of reaction is monitored by measuring the rate of increase in absorbance at 340 nm in a microplate reader. The reaction rate (RR) is calculated using the absorbance values at 0 and 2 min based on the following formula: (final absorbance - initial absorbance)/time. The units of activity (%) are derived from the formula: (test RR/standard RR) x 100. The standard RR is derived from the "Calibrator" wells that contain anti-PDC antibody-free serum (100% activity). The unit of PDC activity of less than 70% is considered as anti-PDC positive with sensitivity and specificity of 82% and 100%, respectively, based on the information provided by the manufacturer[16] (Figure 2). By using this kit, Schmit *et al.*[14] tested the enzyme inhibition assay for 23 sera from patients with AMA-positive PBC and 92 sera from non-PBC including healthy controls, and compared the results to those of immunofluorescence and in-house ELISA. They reported that the sensitivity and specificity of EMA were quite sufficient compared to other assays. Our previous

study of EMA indicated sensitivity, specificity, positive predictive value, negative predictive value, and accuracy of 72%, 100%, 100%, 87%, and 90%, respectively. We also concluded that EMA is useful for the diagnosis of AMA-positive PBC and could be used to monitor the disease course of PBC, particularly due to the small amount of serum requested, objective read-out, and rapid turnaround time[16,19]. Jensen *et al.*[6] also reported that the sensitivity and specificity of EMA were 83% and 100%, respectively, and the EMA compared favorably against commercial ELISA methods.

Clinical utility of enzyme inhibition assay in PBC

Enzyme inhibition assay including commercially available EMA kit has the advantages of few procedural steps, small amount of test serum requested (only 4 μL of undiluted test serum), rapid turnaround time (approximately 6 min for 10 serum samples), and non-subjective readout[14,19]. Moreover, this assay has almost 100% specificity (Table 1). This means that if the serum is positive for enzymatic inhibitory antibody to PDC by enzyme inhibition assay, the diagnosis of PBC is almost confirmed. The result from our laboratory is in line with this finding because none of 245 non-PBC sera was positive for enzymatic inhibitory antibody to PDC by enzyme inhibition assay, whereas 96 (76%) of 127 PBC sera were positive (detailed data are not shown). Therefore, enzyme inhibition assay may have particular applicability in screening the at-risk segment of the population, middle-aged to elderly females[15]. This assay is also applicable in developing countries due to its objectivity, rapidity, simplicity, and low cost. However, this assay may not be suitable for screening in a particular country or area such as Japan. This assay has relatively low sensitivity compared with that of immunofluorescence and immunoblotting due to the lower frequency of autoantibodies to PDC-E2 among the Japanese compared with Caucasian patients with PBC, and a correspondingly higher frequency of antibodies to E2 subunits of the other 2-OADC enzymes[20].

This assay could also be used for monitoring the disease course in PBC. In our previous study, we determined the serial changes in enzymatic inhibitory antibody to PDC by enzyme inhibition assay using EMA kit in Japanese patients with PBC[19]. The units of PDC activity by EMA correlated significantly and inversely with AMA titers by immunofluorescence, and serum reactivity to PDC-E2 by immunoblotting, respectively. Indeed, in three patients who showed a decrease in AMA titers by immunofluorescence, AMA titers correlated more with EMA results than immunoblotting. Moreover, in a patient with fluctuating AMA titers by immunofluorescence, the units of PDC activity by EMA paralleled AMA titers[19] (Figure 3). These data suggested that PBC disease course might influence the EMA results.

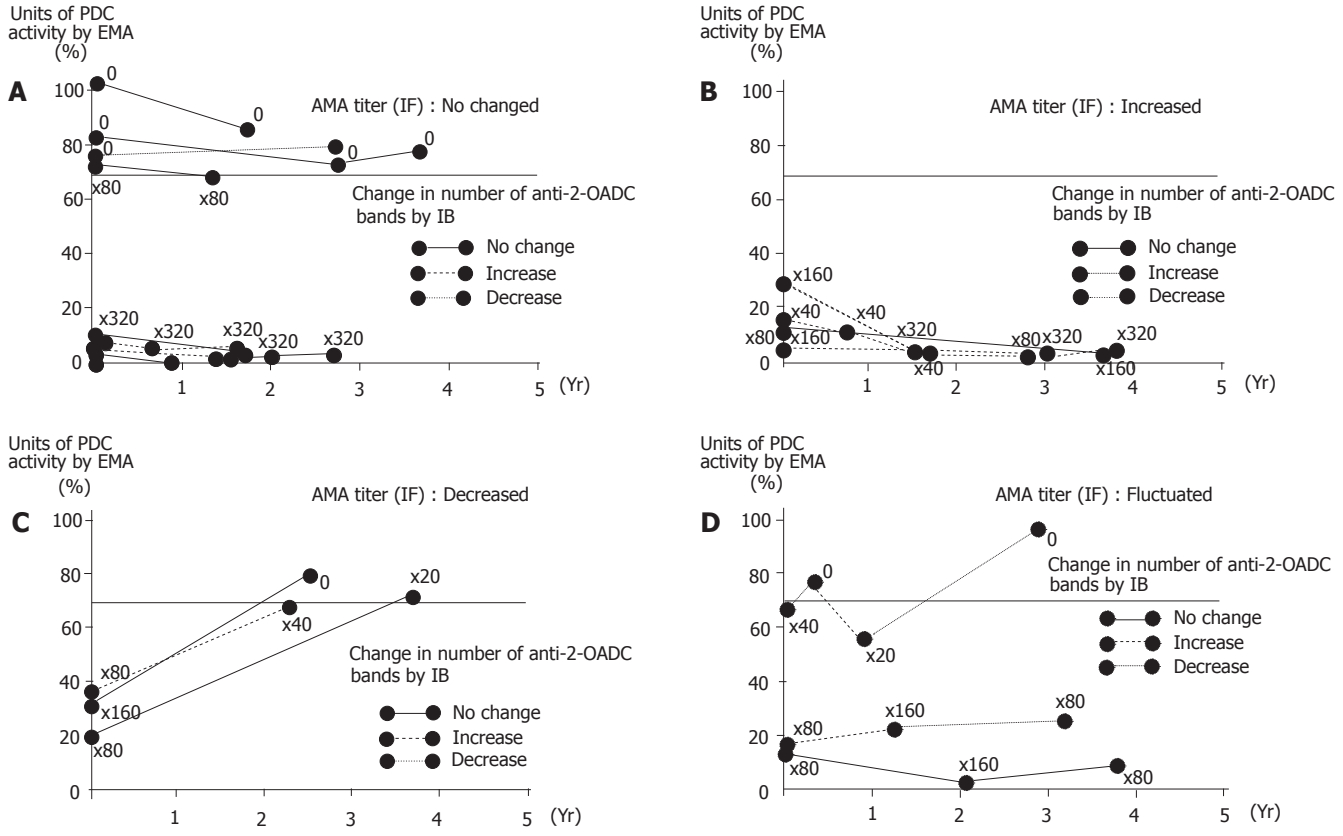

Figure 3 The units of pyruvate dehydrogenase complex (PDC) activity by enzymatic mitochondrial antibody (M2) assay (EMA) did not significantly vary in all the 9 patients in whom the titer of antimitochondrial antibodies (AMA) by immunofluorescence (IF) did not change during the course of follow-up. However, the number of anti-2-oxo-acid dehydrogenase complex (anti-2-OADC) bands by immunoblotting (IB) changed in 4 of these patients (2 increased and 2 decreased) (**A**). The units of PDC activity by EMA decreased in all 4 patients whose AMA titers by IF had increased, but the number of anti-2-OADC bands by IB did not change in 1 patient (**B**). The units of PDC activity by EMA increased in all 3 patients in whom AMA titers by IF had decreased, but the number of anti-2-OADC bands by IB in these patients did not decrease (**C**). Of the 3 patients in whom AMA titers by IF showed some fluctuation, one showed fluctuation in the units of PDC activity by EMA and two showed fluctuation in the number of anti-2-OADC bands by IB (**D**).

Table 2 Interpretation of detection of anti-2-OADC by immunoblotting and enzyme inhibition assay

Immunoblotting (IgG/IgM/IgA)	Enzyme inhibition assay	Interpretation	Estimated percentage (%)
Positive	Positive	PBC	72 - 83
Positive	Negative	Non-anti-PDC positive PBC	10 - 25
		Immunoblotting false positive?	10 - 15
Negative	Positive	Enzyme inhibition assay false positive?	Very rare
Negative	Negative	Non-PBC	Very rare

These data are based on our results that the sensitivity of immunoblotting for PBC is almost 100%, and the specificity of enzyme inhibition assay for PBC is nearly 100%, i.e., when the result by immunoblotting is negative, the serum is not from PBC, and when the result of enzyme inhibition assay is positive, the serum should be from the patient with PBC. 2-OADC, 2-oxo-acid dehydrogenase complex; PBC, primary biliary cirrhosis; PDC, pyruvate dehydrogenase complex.

Interpretation of detection of anti-2-OADC by immunoblotting and enzyme inhibition assay in PBC

Clinically, the serological diagnosis of PBC is in most instances based on the detection of AMA by indirect immunofluorescence and/or ELISA. As mentioned above, however, these two assays are not yet the "gold standard" (i.e., with 100% sensitivity and 100% specificity) for the detection of AMA in PBC, although both the sensitivity and specificity of these two assays are acceptably high. Based on the fact that immunoblotting has almost 100% sensitivity, and enzyme inhibition assay has almost 100% specificity, interpretation of anti-2-OADC results by combination of these two assays in PBC sera can be established. For example, since the negative predictive value of immunoblotting is 99%, a negative result by immunoblotting means that the serum is not from a patient with PBC. Since a positive predictive value of enzyme inhibition assay is 100%, a positive result by enzyme inhibition assay means that the serum should be from a patient with PBC. When the serum sample is positive for anti-2-OADC by immunoblotting but negative for anti-PDC by enzyme inhibition assay, it can be from non-anti-PDC positive PBC or the result of immunoblotting may be false positive. Conversely, when the serum is negative for anti-2-OADC by immunoblotting but positive for anti-PDC by enzyme inhibition assay, the result of enzyme inhibition assay may be false positive (Table 2). Thus, almost all sera from PBC-suspected patients can be confirmed for PBC or non-PBC by the combination results of immunoblotting and enzyme

inhibition assay without histopathological examination. For the development of a "complete" or "gold standard" (100% sensitivity and 100% specificity) diagnostic assay for PBC, similar assays of the enzyme inhibition for anti-OGDC and anti-BCOADC antibodies (or one-step assay for anti-PDC, OGDC, and BCOADC antibodies) will be needed in the future.

Conclusions

For the diagnosis of PBC, enzyme inhibition assay may have particular applicability in screening the at-risk segment of the population since this assay has almost 100% specificity. This assay is also applicable in developing countries due to its objectivity, rapidity, simplicity, and low cost.

Abstract
Neoplastic progression is generally characterized by the accumulation of multiple genetic alterations including loss of tumor suppression gene function. Loss of heterozygosity (LOH) has been used to identify genomic regions that harbor tumor suppressor genes and to characterize different tumor types, pathological stages and progression. LOH pattern has been detected by allelotyping using restriction fragment length polymorphism, and later by simple sequence length polymorphisms (SSLPs or microsatellite) for 10 years. This paper reviews the detection of LOH by recently developed single nucleotide polymorphism (SNP) arrays (all analyzed by Affymetrix array); furthermore, its advantage and disadvantage were analyzed in several kinds of cancer.

Key words: Loss of heterozygosity; Single nucleotide polymorphism; Array; Cancer

INTRODUCTION
Cancer arises from the accumulation of inherited polymorphism (i.e. SNPs) and mutation and/or sporadic somatic polymorphism (i.e. non-germline polymorphism) in cell cycle, DNA repair, and growth signaling genes[1]. Neoplastic progression is generally characterized by the accumulation of multiple somatic-cell genetic alterations as the tumor progresses to advanced stages[2-6]. The classic mechanism of tumor suppressor gene inactivation is described by the two-hit mode in which one allele is mutated (or promoter hypermethylation or a small intragenic deletion) and the other allele is lost through a number of possible mechanisms, resulting in the loss of heterozygosity (LOH) at multiple loci[7-11]. Loss of heterozygosity is the most common molecular genetic alteration observed in human cancers. In the model of colorectal tumorigenesis, mutational inactivation of tumor suppressor genes predominates[12].

Loss of heterozygosity and studying methods
LOH is caused by a variety of genetic mechanisms, including physical deletion of chromosome nondisjunction, mitotic nondisjunction followed by republication of the remaining chromosomes, mitotic recombination, and gene conversion. The mechanisms of LOH are remarkably chromosome-specific. Some chromosomes display complete loss. However, more than half of the losses are associated with the loss of only a part of the chromosome rather than the whole chromosome[13]. LOH is also a common form of allelic imbalance and the detection of LOH has been used to identify genomic regions that harbor tumor suppressor genes and to characterize different tumor types, pathological stages, and progression[14,15].

In addition to the inherited and sporadic polymorphisms, many tumors exhibit aneuploidy and chromosomal instability in which the diploid structure of the genome is corrupted. A modest increase in copy number (such as trisomy for a region) would not give rise to allelic imbalance in the SNP assay. Allelic imbalance in the SNP assay should thus usually indicate true LOH, except in the case of extreme amplification[16].

Global patterns of LOH can be analyzed through allelotyping of tumors with polymorphic genetic markers from each chromosomal arm[17]. Most investigations have concentrated on defining the minimal regions of loss of specific chromosomes in various cancers in an effort to identify the putative tumor suppressor genes targeted by the losses. Two allele RFLPs and Southern analysis give way to simple sequence length polymorphisms such as PCR-based microsatellite, and both have been proved to be reliable genetic markers for studying LOH[18]. RFLP markers have low heterozygosity rates and are available in small number, gel-based microsatellite assay is difficult to automate and not readily scalable[19]. Microsatellite markers are reliable genetic markers for studying LOH, but only

a modest number of SSLPs are used in LOH studies because the genotyping procedure is rather tedious and difficult to automate and are not readily scalable.

As a result, most genome-wide scans for LOH have been conducted at low resolution with a relatively small number of polymorphic markers. Previous allelotyping analysis of cancer by many groups was restricted to particular chromosomal regions or arms, or else used a relatively low density of markers. For example, an average of 120 microsatellites has been used to determine the allelotype of multiple different human neoplasms in a series of studies since 1995, and the highest density microsatellite allelotype is ~280 polymorphic markers before the year 2000[20-24].

We conducted a genome-wide LOH study of 83 tumor samples obtained from Chinese patients in sporadic colorectal cancer. We employed 400 fluorescence-labeled microsatellite marker primers to amplify the corresponding loci of genomic DNA and then electrophoresed the polymerase chain reaction products and analyzed the fluorescent signals. The LOH frequencies were high (>35%) but not associated with the tumor stage and progression in 20 loci. Loss of other loci, including two narrow regions on chromosome 2, was related to the tumor stage[25,26]. In some loci, we performed detailed deletion mapping to narrow the loss region.

SNPs are the most common form of sequence variation in human genome, occurring approximately in every 1 200 bp[27]. SNPs may occur at more than 2 million sites in the genome, thus making it possible to place SNPs at high density along the genome[28].

High-throughput polymorphism detection technologies hold great promise for the characterization of complex diseases including cancer. High-density mapping of genetic losses reveals potential tumor suppressor loci and might be useful in the clinical classification of individual tumors. SNP array has been introduced recently for genome-wide screening of chromosome imbalance.

Higher density SNP array can be used effectively to detect small regions of chromosomal changes and provide more information regarding the boundaries of loss regions. In addition, more markers increase confidence in a detected event. If multiple adjacent SNPs show a consistent change, the confidence in the call is much higher than when it is based on a single SNP[15].

HuSNP chip (the first generation of SNP chip), an array of oligonucleotide probes for 1494 SNP loci, is distributed in all human chromosomes with an average of 2.57 cm between each SNP markers. A recent study using microarray has demonstrated a 97% accuracy on 65% of the SNPs surveyed[29]. The Affymetrix 10K SNP array (the second generation) contains 11 560 SNP alleles with high frequency of heterozygosity (average 36% based on Affymetrix in-house data). The Affymetrix 100K SNP array, a new SNP array platform, provides a high accuracy (99.5%), a reproducibility (91.1%) and a high call (heterozygous or homozygous) rate (95%)[30]. The average accuracy is calculated as 81% at 95% significance with a median inter-SNP distance of 105 kb in osteosarcoma using 10K array[30].

The HuSNP chip call rate does not differ between normal and tumor samples[16]. The genotyping accuracy of the chip calls is estimated at 95.4% on the basis of validation of random SNPs in normal and tumor samples by gel-based length multiplex single-base extension (LM-SBE)[16].

Tumor sample purity mixing experiment

LOH involves complete loss of one of the two alleles at a locus, but normal cell contamination can confound the distinction between true LOH and other mechanisms of allelic imbalance[31]. However, studies using flow-cytometrically purified samples have shown that complete LOH can be detected in tissue samples[32,33].

Tumor sample purity mixing experiment showed that samples with 90% tumor purity give essentially identical results than those with 100% tumor purity, when the purity decreases to 80%; it results in an increase in "uncertain" calls and a few false positive "retention". Accuracy decreases steeply when the purity is 70% or lower, because the lost allele contains 15% or more of contaminated samples. Although tumor purity is dependent on tumor type, a purity of 80% can often be achieved using gross dissection or microdissection[16,34]. With the SNP arrays, Mei *et al*.[15] found that chromosomal changes are detectable in heterogeneous samples with a background of up to 50% normal DNA.

The DNA fragment that occurs with formalin fixation does not seem to affect HuSNP array analysis result[35]. However, it is believed that formalin reduces the size of PCR segments that may be amplified from a sample[36]. There is significant agreement between the LOH result obtained from formalin-fixed paraffin embedded prostate tumor sections and those for freshly cultured cancer cells[34].

SNP array principle and methods

DNA sample is subjected to 24 multiplex PCR reactions, the resulting products are pooled, hybridized to the SNP array, stained with streptavidin-phycoerythrin, and assayed by fluorescence detection.

Briefly, the detector for each SNP locus contains four rows of 25-mer oligonucleotides, two of which contain oligonucleotides that perfectly match either SNP allele A or SNP allele B, whereas the other two contain single-base mismatches at various positions. The allelotype at a locus is determined by fluorescence intensity ratios in an automated fashion. Affymetrix HuSNP mapping system is used to determine tumor and normal allelotypes.

A general scanner scans chips and genotyped "call" is made from the collected hybridization signals using Affymetrix HuSNP 3.1 software. Tumor and normal samples are allelotyped on separate chips. For each patient's tumor, each SNP locus is scored as LOH, retention of heterozygosity, uninformative, or uncertain by comparing the genotype calls for tumor and normal (autologous) pairs. The possible SNP calls made by Affymetrix genotyping software are A, B, AB, AB_A (i.e,

AB or A), AB_B (i.e, AB or B), and "no call". "no call", AB_A, AB_B calls are considered to be noninformative[15].

Both amplified and unamplified DNA give similar results in terms of SNP call and LOH[30]. LOH can be established or inferred from 10K SNP array data using only amplified tumor DNA with the Affymetrix Genechip chromosome copy number tool.

SNP array application in LOH detection

Using SNP detection array, Wang *et al*.[37] found that breast cancer is highly heterogeneous, with the proportion of LOH ranging widely from 0.3% to >60% of heterozygous markers.

The call rate is 74.9-83.2% over all samples, yielding 1 120–1 205 SNPs scored per sample using HuSNP array[8,14,34,37,38]. The median of heterozygous loci is 341-349 with an average coverage of one SNP per 7.9-8.7cm[14,37]. Using 10K SNP array, the call rate is 91.1% over all samples[39]. In lung and breast cancer, the average call rate does not vary significantly between the lymphoblastoid and tumor cell lines[8,37].

LOH result comparison between SNP array and microsatellite

Very few reports have presented allelotyping data on multiple sites in the same tumor using two different methods, LOH between SNP array and microsatellite is concordant in the majority of analyzed kinds of cancer samples[16,34,37]. Most affected LOH regions are consistent with those in previous LOH studies, lending validity to both the method and results[34].

The range of consistency between two methods in different loci varies from 50% to 100% in bladder cancer[14]. Moreover, when the two methods are compared by chromosome arms, the concordance is very robust[14]. In osteosarcoma assay, 14 of 18 microsatellite markers have associated SNPs with LOH[30].

By comparing the microsatellite results in selected areas of several chromosomes with SNP array-based detection of allelic imbalance, in 69 sites, 60 microsatellite markers correlate, but nine microsatellite markers do not correlate with adjacent HuSNP markers[35].

Janne *et al*.[8] found that neither HuSNP nor SSLP is perfect. Using two methods together, the combined informative rate is 84%, and both methods provide calls for loci that were not informative by the other methods. However, a combined analysis is unlikely to be practical for future studies.

The comparison shows that, given a sufficient number of polymorphic markers, the SNP array can be used to screen both small and large chromosomal losses. But neither technique is currently infallible in identifying LOH[14].

LOH conflict between SNP array and microsatellite

Lindblad-Toh *et al*.[16] examined a number of instances of apparent conflict between SSLPs and SNP-based analysis by repeating the analysis and found that discordance is slightly more often due to the errors in SSLP rather than in SNP genotyping. SNP genotyping thus appears to be at least as accurate as the SSLP approach.

SNPs associated with the remaining four microsatellite markers do not show any LOH[30]. Allelic imbalance has been detected in microsatellite analysis but not detected by the SNP, which is probably caused by a no-signal genotype call either in the tumor or in normal DNA or in both. This problem can be solved by increasing the number of SNPs for the specific loci and by developing a more sensitive method for the generation of calls[14].

Possible reason of discrepancy

Because of the lower average heterozygosity rate of SNPs (0.33) compared to microsatellite, approximately a threefold SNPs is required for an equivalent resolution.

It is difficult to determine whether the apparent discordance is due to the technical limitation or if the microsatellite markers recognize a smaller region with a different allelic loss pattern compared to the adjacent regions scored by SNP[35].

The possible reasons are as follows: limitation of mapping data; differences in resolution, amplification efficiency, and differential sensitivity between microsatellite and SNP, technical limitations such as a genotype call by the Affymetrix softwares, the presence of bad SNPs in the array[14,30].

Cancer classification by LOH pattern using SNP array

Finding unique LOH pattern by SNP array in different groups of breast cancer, in part defined by expression signature, adds confidence to newer schemes of molecular classification. Furthermore, exclusive association between biological subclasses and restricted LOH event provide rationale to search for targeted genes[37]. Janne *et al*.[8] demonstrate that clustering of LOH data can distinguish SCLC from NSCLC with reasonable accuracy.

Advantage of SNP array

SNP array assay is accurate, automatic, and readily adaptable to the clinical setting and high-density mapping. Analysis of genetic alterations with HuSNP assay saves considerable time over microsatellite analysis. The assay involves multiplex amplification and other methods that can be completed in one day. The SNP array method is also a molecular technique that allows the detection of chromosomal imbalance in tumor DNA. A minimal quantity (120-135 ng) of sample DNA is needed for each SNP assay. The amplification step makes it possible to use only a small amount of genomic DNA, which is often essential when working with limited clinical materials[14,15].

The 10K array also provides calls (either LOH or retention) for 71.7% and 22.3% of the loci identified as non-informative by HuSNP and SSLP, respectively. The proximal and distal ends of the deletion are clearly identified and single LOH events identified using SSLP fall within these regions. The mapping 10K array can identify more than twice the number of LOH regions compared to SSLP or HuSNP. The minimum, mean, and median sizes of these regions are substantially smaller by the mapping 10K array than by the other two methods. The maximum

size of the LOH regions is similar by the three methods[8]. Disadvantage of SNP array is.

SNP array is difficult to distinguish all polymorphisms and to detect low level polymorphism and requires PCR amplification.

The average proportion of LOH informative markers out of callable markers is 31–33%, which is a considerably lower heterozygosity rate than that of SSLPs (typically 70%), but can readily increase to about 50% by selecting SNP with higher heterozygosity[14,16].

High false positive rate (11-21%) and false negative rates (19.9%) have been observed with this technology, limiting its utility in both SNP and tumor analysis[30,41].

Array-based methods of SNP detection may have a certain degree of inaccuracy ("noise"), and moreover, the precise genomic mapping of each SNP is still not completely stable. Thus, "true" regions of LOH can be interrupted by apparently false positively "retained" SNP alleles. Conversely, true regions of retention of heterozygosity may be interrupted by false LOH calls[42].

In summary, with the increasing number of SNPs available and technical progression[43], it is possible to probe the entire genome, and specific regions at much higher resolution. SNP array hybridization is an accurate and efficient method for evaluating genome-wide tumor LOH at present.

Abstract

AIM: To assess the sICAM-1, sVCAM-1, and sP-selectin levels in children with *Helicobacter pylori* (*H pylori*) infection and to evaluate their significance for the morphological changes found in gastric mucosa.

METHODS: The study included 106 children: 59 children (55.7%) with chronic gastritis and positive IgG against *H pylori*, 29 children (27.3%) after previous *H pylori* infection without the bacterium colonization but with positive IgG against *H pylori*, and 18 children (17%) with functional disorders of the gastrointestinal system but with normal IgG against *H pylori*. Endoscopic and histopathological evaluation of gastric mucosa was performed based on the Sydney System classification. The evaluation of sP-selectin, sICAM-1, sVCAM-1 levels in the sera of children was carried out using ELISA test.

RESULTS: The assessment of gastritis activity degrees indicated statistically significant values in the antrum and corpus ($P<0.001$) of children examined. Serum sVCAM-1 levels were higher in group with gastritis due to *H pylori* infection than in group without infection and differed statistically ($P<0.05$). Serum sVCAM-1 levels proved to be the highest among other adhesive molecules in infected children and decreased after eradication of *H pylori*. Serum sICAM-1 levels were similar in all examined groups. Serum sP-selectin levels were similar in children with and without *H pylori* infection.

CONCLUSION: Assessment of adhesive molecules (sP-selectin, sICAM-1, sVCAM-1) in the sera of children with active *H pylori* infection can show the participation of sVCAM-1 in the pathogenesis of gastric mucosal inflammation. sP-selectin and sICAM-1 concentrations in the sera of children with *H pylori* infection after eradication cannot reveal any significant differences as compared to healthy children.

Key words: sVCAM-1; sICAM-1; sP-selectin; *Helicobacter pylori*

INTRODUCTION

In the course of *Helicobacter pylori* (*H pylori*) infection, a selective recruitment of neutrophils, monocytes, macrophages, mast cells, T and B lymphocytes takes place[1]. Additionally, infiltrating cells synthesize and release mediating cells, which influence the recruitment and activation of further inflammatory cells and increase the triggering activity of cytokines and chemokines. For example, neutrophils are the source of IL-1, IL-8, TNF-α[2], and macrophages – MIP-1α[1]. Adhesion molecules (selectins, their ligands, integrins, immunoglobulin-like molecules) take part in a selective recruitment of leukocytes[3–8]. Selectins are transmembrane molecules with numerous extracellular domains, containing lectin domain at the N-end – hence their name, L selectin (CD62L) – leukocyte, E selectin (CD62E) – endothelial cell, P-selectin (CD62P) – platelet. Saccharic residues combined with sialic acid [blood group antigen Lewis X (CD15) and its isoforms] expressing numerous leukocytes are ligands for L, E, and P selectins.

Glycosaminoglycans, such as heparin sulfate and carbohydrate residues on platelets and neutrophils, are ligands for L- and P-selectin[9,10]. A soluble form of P-selectin binds to the same ligand on granulocytes as its membrane form. It does not inhibit intergrins of granulocytes but supports agonists stimulating polymorphonuclear leukocytes, their function of secretion, PAF synthesis and LTB4 synthesis, and secretion. Thus, a soluble form does not differ in its activity from a membrane form. Its high serum levels (1-20 μg/mL) are significantly higher in the inflammatory process than in a healthy condition (36-250 ng/mL)[11].

Soluble forms of ICAM-1 (sICAM) were described

in 1991 and are derived basically from mononuclear cells. Epithelial cells are unlikely to be their source[12]. They can be found in the serum, in molecular forms: 240 ku, 430 ku, and mainly 500 ku[13]. A functionally soluble ICAM-1 form can be regulated by cytokines and is able to bind to LFA-1 ligand. Thus, sICAM may compete with leukocytic ligands for binding and decrease leukocyte adhesion to endothelial cells and may even promote their de-adhesion. sICAM-1 may be regarded as a marker of inflammation, because its levels increase significantly in the serum in the course of inflammation, at tissue damage or during the activity of proteolytic enzymes[14]. In healthy individuals, ICAM-1 occurs in small amounts on surfaces of many cells, like leukocytes, endothelial vascular cells, fibroblasts, epithelial cells whereas in the course of inflammation correlates with chronic inflammatory phase as well as the occurrence of ulceration in the course of *H pylori* infection. ICAM-1 is considered to be a marker of chronic immunological stimulation and thus it is potentially responsible for chronic course of a disease. A vascular adhesion molecule (VCAM-1) requires about 8-96 h to be activated and expressed on cells *in vitro*. Its expression is enhanced especially by TNF-α, IL- 4, and IL-13[13]. Since VLA-4 is its ligand, it binds only to mononuclear leukocytes (lymphocytes and monocytes). Normal gastric mucosa is free of leukocytes. Abundant infiltrations of poly- and mono-nuclear cells and lymphatic follicles can be found in the course of *H pylori* infection.

The aim of the study was to evaluate the levels of adhesion molecules sICAM-1, sVCAM-1 and sP-selectin in the sera of children with *H pylori* infection and to determine their significance for morphological changes in gastric mucosa.

MATERIALS AND METHODS

Patients

The study included 106 patients, who were divided into three groups with regard to the presence and course of *H pylori* infection. Group I : 59 children (55.7%) with chronic gastritis in the course of *H pylori* infection with a positive titer of IgG antibodies against *H pylori*, including 29 girls (49.2%) and 30 boys (50.8%). The children's age ranged from 2 to 19 years, the mean age was 12.2±4.6 years.

Group II : 29 children (27.3%) after previous *H pylori* infection, without the bacterium colonization of the gastric mucosa but with a positive titer of IgG antibodies against *H pylori*, including 14 girls (14%) and 15 boys (51.7%). The children's age ranged from 3 to 19 years and the mean age was 11.0±4.1 years.

Group III : 18 children (17 %) with functional disorders of the gastrointestinal tract, without *H pylori* infection but with normal IgG level against *H pylori*, 12 girls (66.7%) and 6 boys (33.3%). The children's age ranged from 5 to 17 years, and the mean age was 10.7±3.6 years (Table 1).

Ethical approval for the research was obtained from local Ethics Committee in Medical University.

Groups	*n* (g/b)[1]	Min. value	Max. value	Mean arithmetic	Median	SD	Lower quartile	Upper quartile
Group I	46 (30/29)	2.0	19.0	12.2	13.0	4.6	9	16
Group II	17 (14/15)	3.0	19.0	11.0	11.0	4.2	8	14
Group III	18 (12/6)	5.0	17.0	10.7	10.0	3.6	8	13

[1]g/b – girls/boys.

Methods

Endoscopic examination of the upper gastrointestinal tract with gastric mucosa samples (corpus and antrum) was performed in 88 children with positive IgG against *H pylori* and 18 children with negative IgG against *H pylori*. Endoscopic and histopathological evaluation was performed based on the Sydney System[16]. Chronic stomachache indicated the need for endoscopy. The assessment of sP-selectin (sP-selectin, Bender MedSystems, Austria), sICAM-1 (sICAM, Bender MedSystem) and sVCAM-1 (sVCAM, Bender MedSystems) levels in the serum samples was performed using ELISA method. The materials for the examination and assessment of individual parameters were prepared according to the manufacturer's instructions. The results were read in a spectrophotometer at 450 nm wavelength. The minimum detection threshold in the method used equaled 1.3 ng/mL for sP-selectin, 0.5 ng/mL for sICAM-1, and 0.9 ng/mL for sVCAM-1.

Statistical analysis

The results of laboratory analysis were processed using appropriate calculating techniques and statistical tests. Descriptive statistics with central deviation measure including arithmetic mean (χ), median and mode, and measure of dispersion including standard deviation (SD), variations and values of the upper and lower quartiles were given to each variable (feature) measured and group of patients. The distribution of empirical data matching the normal distribution was checked using χ^2 test and the Kolmogorow–Smirnow test. The results enabled to determine the direction of further statistical analysis and to use parametric tests or their non-parametric equivalents in statistical analysis. Since in most cases, formal normality tests proved that variations differed significantly from assumed theoretical distribution, the Mann–Whitney *U* test was used to examine the significance of difference in the feature intensity between the groups examined. $P<0.05$ was considered statistically significant. Receiver operating characteristic (ROC) curves were applied to the estimation of the usability of individual diagnostic parameters.

RESULTS

While evaluating the activity of antrum gastritis in groups, we showed the largest changes in children with *H pylori* infection (group I). The severe degree activity was found in 69.5% of this group and the moderate degree activity in 30.5% of the infected children. In children with previous infection and after bacteria eradication (group II), no severe or moderate degree activity was found, whereas mild degree activity was revealed only in 20.7% of this group (Figure 1A).

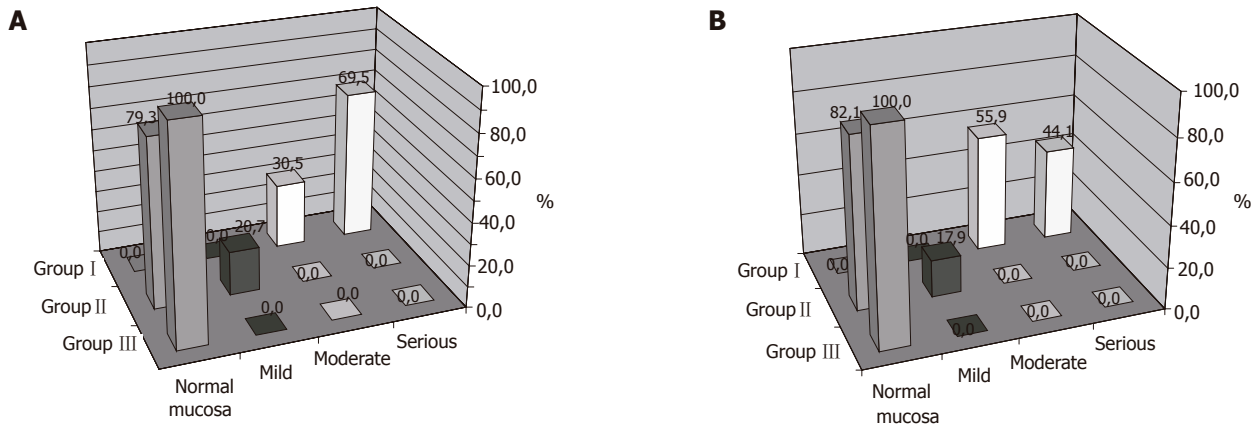

Figure 1 Gastritis activity in antrum (**A**) and corpus (**B**) of examined children (according to the Sydney System).

The analysis of antral gastritis activity by χ^2 test proved a statistical significance (P<0.001) in examined groups. While the corpus mucosa in children with *H pylori* infection (group I) was assessed, the moderate degree activity was found in 55.9% of children and the severe degree activity was revealed in 44.1% of children. In children after *H pylori* eradication (group II), the mild degree activity was established only in 17.9%. No severe or moderate degree activity was reported (Figure 1B). The histopathological evaluation of the corpus gastritis differed statistically significant in particular groups (P<0.001).

sP-selectin levels equaled 339.2±122.9 ng/mL in the sera of children with *H pylori* infection (group I). The similar levels of sP-selectin were observed in children after *H pylori* eradication (group II) and in controls. Therefore, no statistically significant differences were found between the groups examined (Table 2). Based on the results of ROC analysis of sP-selectin levels in serum, the usefulness of this parameter was not confirmed (AUC = 0.62±0.08). The highest accuracy was obtained when the level of 1 288.2 ng/mL was taken as the criterion of sP-selectin concentration. The sensitivity was 87.2% and the specificity was 52.9% for this value (Figure 2A).

Soluble ICAM level was 482.3±143.2 ng/mL in children with *H pylori* infection (group I). Similar sICAM-1 levels were observed in children after *H pylori* eradication (group II) and in controls. No statistically significant differences of sICAM levels were proved between/among the groups (Table 3). A linear correlation was proved between the age of children with *H pylori* infection (group I) and sICAM levels. A negative value of a slope of a line (b = –9.43±3.98) (according to the Sydney System) indicates that sICAM levels decreased in the serum as the age increased. The value of the line equaled 597.18±51.91 ng/mL. This correlation was statistically significant (P<0.05) (Figure 3A).

Soluble VCAM-1 levels in the sera of children with *H pylori* infection equaled 1 032.7±267.5 ng/mL. A statistically significant difference was proved between the levels of group I and group II (P<0.05) (Table 4). In children with *H pylori* infection, a statistically significant dependence (P<0.001) was revealed between the age of children examined and sVCAM-1 levels in their sera. This dependence can be described by a general formula: y =

Group II	23	176	930	490.5	487.7	–	164.7	412.0	580.0
Group III	5	367	523	422.1	400.2	–	59.7	398.3	421.2

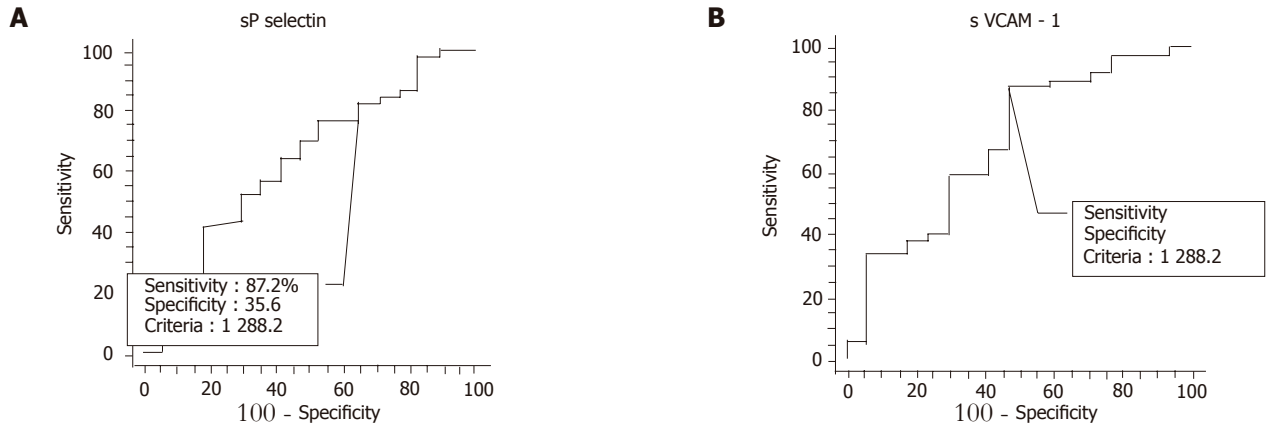

Figure 2 ROC curve for serum sP-selectin (**A**) and sVCAM-1 (**B**) levels.

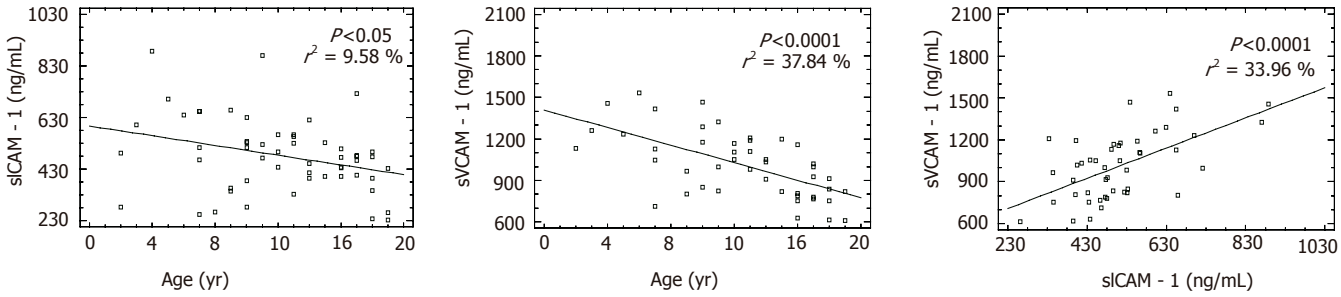

Figure 3 Correlation between age and sICAM-1 (**A**) between age and sVCAM-1 (**B**), and between sICAM-1 and sVCAM-1 (**C**) levels in serum of children with *H pylori* infection (group I).

$a+b\times x$. A negative value of a slope of a line ($b = -31.67\pm -5.18$) means that the value of sVCAM-1 levels decreased as the age of children increased (Figure 3B). Based on the results of ROC analysis of sVCAM levels in the serum, the usefulness of this parameter in *H pylori* infection and eradication was not confirmed (AUC = 0.69±0.08). In case of sVCAM-1 levels, the highest accuracy of diagnosis was obtained at the criterion of 1 288.2 ng/mL. The sensitivity was 87.2% and the specificity was 52.9% (Figure 2B).

In children with *H pylori* infection, a linear dependence ($y = a+b+x$) was proved between sICAM-1 and sVCAM-1 levels in the serum. A positive value of a slope of a line
(b = 1.08±0.23) indicates that sICAM-1 levels increased simultaneously with sVCAM-1 levels (Figure 3C).

DISCUSSION

The evaluation of soluble adhesion molecule levels in serum can confirm their presence and assess their levels quickly and therefore may be of better use in the diagnosis of *H pylori* infection or eradication than time-consuming immunohistochemical methods.

The levels of sVCAM-1 were higher in the sera of patients with gastritis of *H pylori* etiology than in patients without infection and differed significantly ($P<0.05$). The levels of sICAM in the sera were similar in all groups examined. The levels of sP-selectin were similar in the groups with or without *H pylori* infection but were twice as high as in controls. Similar results were presented in studies evaluating ICAM-1, VCAM-1 molecules on the surface of gastric epithelium[17-19].

Later studies in patients with chronic gastritis in the course of *H pylori* infection have proved that the predominant increase in ICAM-1 expression on vascular epithelial cells and inflammatory cells (lymphocytes, granulocytes) in lamina propria is connected with a massive inflammatory infiltrate and the expression of HLA-DR, LFA-1, and Mac-1 on cells presenting antigen[7,20]. No ICAM-1 expression was found on endothelial lymphocytes and epithelial cells. Similar to our study, no correlation with the degree of gastritis was proved. A decrease in the level of adhesion molecules examined was observed after effective eradication of *H pylori*.

Hatz *et al*.[21] have proved that ICAM-1 expression increases on endothelial cells. Moreover, they observed an increase in VCAM - expression in lymphatic follicles, though they neither found an increase in P-selectin expression nor any E-selectin expression. According to the authors, constant P-selectin levels (no increase) may be due to a quick metabolism of this molecule (*in vitro* it is decomposed after a few minutes after its exposition on epithelial cells) and undetectable changes of its levels in immunohistopathological examination. As stated by Hatz *et al*.[21], the increased levels of proinflammatory

cytokines such as IL-1b and TNF-α and the increased quantity of $CD4^+$ and CD45RO lymphocytes in lamina propria might contribute to the upregulated expression of ICAM-1 and VCAM-1. However, studies examining ICAM-1, VLA-4, and CD44 expressions on the surface of mononuclear cells in the serum have proved their increased quantity together with the expression of the molecules mentioned above in patients with *H pylori* infection but without ulceration and in healthy people[3,5]. Polymorphonuclear cells react similarly. The enhanced adhesion of these cells to the epithelial cells of the human navel vein exposed to *H pylori* antigens has been shown in laboratory tests evaluating ICAM-1, VCAM-1, E-selectin expression on neutrophils[6].

Innocenti *et al*.[4] found that not all *H pylori* strains are able to activate epithelial cells of gastric mucosa to the expression of adhesion molecules (ICAM-1, VCAM-1, E-selectin) and chemokines for neutrophils. But the authors failed to prove whether combination of bacterial antigens (CagPaI, Lewis, BabA, VacA) could influence *H pylori* capability of activating epithelial cells. According to these authors, bacterial proteins not described so far take part in the activation of epithelial cells.

While the interdependence was evaluated between adhesion molecules, a strong correlation was found between the serum levels of sICAM and sVCAM-1 ($P<0.001$) in children with *H pylori* infection, indicating that the increase in sICAM-1 levels is accompanied with the increase in sVCAM-1 levels. Such a correlation may point to the simultaneous and proportional contribution of both adhesion molecules in inflammation.

In our study, while the correlation of sICAM-1 and sVCAM-1 levels with the age of children examined in groups I and II was evaluated, the highest levels were found in the youngest children, whereas they decreased gradually as the age of patients increased. The correlation was statistically significant in both groups (I and II) for sICAM ($P<0.05$), whereas for sVCAM in group I ($P<0.0001$) and in group II ($P<0.05$). The variability of sICAM-1 and sVCAM levels in serum regarding the age may suggest a greater maturity of children's immunological system and its reaction to bacterial antigens.

The results of our study and other studies indicate that adhesion molecules play an important role in immuno-inflammatory response in patients with gastritis due to *H pylori* infection. The levels of adhesion molecules increase in inflammatory process. In our study, such a correlation was proved for sP-selectin.

The quantity of adhesion molecules in inflammatory infiltrating cells or the increased levels of their soluble forms in the serum correlate with the intensity of inflammatory process.

Abstract

AIM: To measure the concentrations of chosen cytokines in the antrum mucosa depending on the kind of harmful pathogenic factors and to compare the concentrations with the values of controls without allergy and coexisting *Helicobacter pylori* (*H pylori*) infection.

METHODS: The patients (97 children) were divided into three groups according to the data obtained from the case history, to the main cause of the disease and to the dominant clinical symptoms. Group I: children with food allergy (Fa); group II: children infected with *H pylori*; group III (control group): children with functional disorders of the alimentary tract (without Fa and Hp infection). *H pylori* infection was determined by the presence of anti-Hp antibodies in serum (ELISA method) and urease test performed during endoscopic examination. Cytokine concentration in homogenates of gastric mucosa was detected by ELISA method.

RESULTS: The IL-2 concentration in gastric mucosa bioptates was the highest in children with Hp infection (116.5±179.5 pg/mg of the protein) and Fa and Hp infection (98.1±101.0 pg/mg), while decreased in children with Fa (44.8±50.3 pg/mg) and controls (45.7±23.5 pg/mg). The lowest mean concentration of IFN-γ was observed in children with Hp infection (18.9±16.4 pg/mg), with Fa and Hp infection (25.5±27.7 pg/mg), with Fa (40.6±39.7 pg/mg) and controls (49.9±33.4 pg/mg). The highest IL-4 concentrations were observed in children with Hp infection (35.3±52.8 pg/mg) and in children with Fa and Hp infection (37.2±51.7 pg/mg), while lower IL-4 concentration (23.6±35.8 pg/mg) was found in children with Fa compared to the controls (22.7±13.8 pg/mg). The analysis of IL-4 concentrations in children with Hp infection regarding the intensity of gastritis showed the highest value (62.2±61.2 pg/mg) in mild and moderate gastritis. The concentrations of IL-5 in the gastric mucosa of children with or without Fa did not differ significantly and were comparable to the control group. The highest mean IL-8 value was observed in Hp-infected children with or without Fa. The highest concentration of mucosal IL-10 was detected in children with Hp infection (79.3±41.2 pg/mg) and decreased in children with Fa and Hp infection (50.1±18.8 pg/mg) and in children with Fa (39.9±35.5 pg/mg). The intensity and activity of the inflammation did not affect IL-10 concentrations in the gastric mucosa. In children with Hp infection, TNF-α concentration was the highest (45.9±49.3 pg/mg) and in children with Fa and Hp infection was low (45.3±32.6 pg/mg), whereas decreased in children with Fa (21.7±34.2 pg/mg) and in controls (31.6±14.5 pg/mg).

CONCLUSION: The morphological changes of the gastric mucosa in children with Hp infection are comparable to those in children with Fa and coexisting Hp infection. Cytokine concentration in children with Fa and Hp infection is significantly different in IFN-γ, IL-2, IL-8, and TNF-α.

Key words: Mucosal cytokines; Food allergy; *Helicobacter pylori* dehydrogenase complex

INTRODUCTION

Many medical research centers dealing with food allergy (Fa) have assessed the morphological changes of gastric mucosa in children with hypersensitivity. Endoscopic evaluation of the alimentary tract and allergical and immunological examinations of food hypersensitivity are valuable diagnostic examination and pathogenetic inquiry element[1,2]. Numerous mast cells releasing histamine and triptase as well as the phenomenon of the selective accumulation of eosinophils and neutrophils have been observed in various parts of the alimentary tract of patients sensitive to food[3-6]. Erosive gastritis and ulceration may occur periodically in the gastric and/or

duodenal mucosa, whereas chronic intestinal disorders are usually recurrent with stomachache or diarrhea with abundant mucus and sometimes bloody secretion.

Besides allergy, *Helicobacter pylori* (*H pylori)* infection is another factor triggering inflammatory changes in the gastric and duodenal mucosa of children. Czinn *et al*.[7] are the first to show the connection of inflammatory changes of the gastric pylorus mucosa with Hp in children. The presence of Hp in the stomach leads to diminishment of the mucous protective layer due to the inhibition of mucus production caused by epithelial cells. The bacteria settle in the stomach, locating in and under the layer of epithelial cells, around intercellular epithelial connections and on the surface by producing special adherence structures, the so-called "bridge attachment". The number of bacteria is the main factor conditioning the epithelial damage degree[8-10]. Inflammatory changes in the gastric mucosa dependent on Hp may persist for several years giving neutrophilic infiltrations in the acute phase and lymphoplasmatic, macrophagic, and eosinophilic infiltrations in the chronic phase of the inflammation. The size of leukocytic infiltration correlates with the degree of colonization and mucosal damage. A small amount of B lymphocytes can be observed in an inflammatory infiltrate. The inflammatory process is developed due to a smaller number of CD8+ lymphocytes when compared to helping lymphocytes CD4+[11-13].

Abnormal IgE production in response to allergens is a characteristic feature of atopy. IL-4, IL-13 and IFN-γ are the most important cytokines regulating IgE production. IL-4 and IL-13 are responsible for the change of immunoglobulins produced by B lymphocytes from IgG and IgM towards IgE and IgG4[14-16]. IFN-γ reacts adversely and inhibits IL-4 effect on B lymphocytes, which secretes specific anti-antigen antibodies. Other cytokines, IL-2, IL-5, and IL-6 have an adjunctive activity to IL-4. They increase IgE production induced by IL-4, whereas IL-12 blocks IgE production induced by IL-4[17-19].

In case of infectious factors or toxins, the first contact cells are the cells of the monocyte/macrophage system. After activation, the cells produce and secrete proinflammatory cytokines, namely IL-1, IL-6, and TNF-α. Biologically, the cell activity occurs through endocrine paths and concerns remote organs, i.e. the liver (acute phase protein production), hypothalamus (pyrogenic effect) and adrenal glands (inflammatory process eradication)[20]. In Hp infection, cytokines also play an important role in the pathogenesis of gastritis. Hp infection is connected with the upregulated production of mucosal inflammatory cytokines: TNF-α, IL-1β, IL-2, IL-6, IL-7, and IL-8[10,21–24].

The purpose of the present study was to assess the concentrations of chosen cytokines in the gastric mucosa of children with Fa and Hp infection and to compare the concentrations obtained by the group of children without Fa and coexisting Hp infection.

MATERIALS AND METHODS

Examinations were conducted in 97 patients with dyspeptic symptoms, including recurrent or chronic stomachache, disorexia, recurrent diarrhea, nausea, vomiting, and loss of body weight. The symptoms were indications for gastroscopy. The patients were divided into three groups according to the cause and clinical symptoms observed.

Group I consisted of 48 children (49.5%) with Fa including 22 girls (45.8%) and 26 boys (54.2%) aged 4.6-18.4 years (mean 10.6±3.6 years). The case history, clinical complaints and the results of the upper alimentary tract endoscopic and histopathological examinations were the qualifying criteria for the further morphologic and biochemical analysis of the patients. The children with Fa were chosen on the basis of the clinical picture, positive immunological and allergical examinations, and inflammatory changes of gastric mucosa after Hp and giardiasis exclusion.

Group II comprised 34 children (35%) with Hp infection including 17 girls (50%) and 17 boys (50%). Fa and simultaneous Hp infection (Fa+Hp) were revealed in 16 (47%) children aged 3.3-16.2 years (mean 11.0±3.8 years). The rest of the 18 patients (52.9%) suffered from Hp infection without Fa. The age of the patients ranged from 5.0 to 18 years (mean 12.8±4.1 years). Children with Fa or without Fa and Hp infection were chosen on the basis of the same criteria as in group I and the positive results urease test (CLO-test) performed during endoscopy. The presence of Hp in the gastric antrum and corpus mucosa specimens was confirmed by hematoxylin and eosin staining (H+E) and the Giemsa method. Moreover, anti-Hp antibodies were determined by ELISA method (RecomWell Helicobacter IgG, Mikrogen, Germany). The amount of the bacteria as well as gastric antrum and corpus inflammatory activities were the decisive factors defining the severity of infection[24].

Group III included 15 children (9 girls -60%, 6 boys-40%) aged 4.9-14.9 years (mean 10.1±3.2 years) with functional disorders of the alimentary tract. The patients did not complain of allergy and showed no Fa symptoms. Hp infection was also excluded and endoscopy was carried out due to clinical symptoms mentioned above. The group constituted the control group (C). During gastroscopy, three specimens were collected from the prepyloric part of the stomach. Biopsies were weighed on an analytical scale immediately after the collection and then put in 1 mL of phosphatic buffer (molality 0.05 and pH 7.4) and placed in a thermos with ice.

Biopsies were homogenized using a tissue homogenizer. The protein was determined by Lowry method (mg/100 mL). Homogenates were divided into portions of 200 mL each, then frozen and stored at -20 °C for further examinations. Determination was conducted separately for each homogenate sample after gradual warming up to the room temperature. The concentrations of tumor necrosis factor (TNF-α), IL-2, IL-4, IL-5, IL-8, IL-10, and INF-γ in homogenates of the gastric mucosa were determined by ELISA method using ENDOGEN standard kits (Cambridge, USA) according to the manufacturer's instructions. Absorbance reading was performed spectrophotometrically with the wavelength

recommended by the manufacturer. The concentrations of cytokines examined (in pg/mL) were calculated on the basis of the standard curve. The results were expressed in milligram of protein in homogenate of the tissue examined.

Statistical analysis

Statistical analysis included the arithmetic mean±SD, the minimum result (min), and the maximum result (max). The levels of parameters examined were compared using Student's *t*-test for independent or paired trials. The differences were significant at $P<0.05$. The interdependence between measurable features was evaluated with Pearson's linear correlation coefficient, of which significance was assessed using Student's *t*-test for each correlation. The interdependence between non-measurable features evaluated using an independence test χ^2 or Fisher's exact test is presented in the correlation tables.

RESULTS

The histopathological evaluation of the gastric mucosa in patients could distinguish the following categories of changes: normal mucous membrane, mucosa at the borderline of the norm (a slightly decreased number of mononuclear cells in superficial layers of the mucous membrane) and chronic inflammation. In children with Fa, normal gastric mucosa was observed in 43.7%, mucosa at the edge of the norm in 35.4% and chronic inflammation in 20.8% of children. In children with Fa and Hp infection and in those without Fa, morphological changes of the antrum mucosa resembled chronic inflammation in 100%. According to the Sydney System, three stages of gastritis could be distinguished: mild, moderate, and severe. The severe stage of antrum mucosal inflammation was observed in 55% of children with Hp infection and in 31.2% of children with Fa and Hp infection (Table 1). Moderate antrum gastritis concerned children with Fa and Hp infection (50%) and children with Hp infection (44.4%). Mild gastritis was revealed in 18.7% (group I) of children with Fa and in 18.7% of children with Fa coexisting Hp infection. Morphometric analysis regarding the severity of inflammation showed statistically significant pathological changes in the antrum ($P<0.001$). The evaluation of antral gastritis activity according to the Sydney System also presented a statistical significance ($P<0.001$). Severe antral gastritis was observed in 72.2% of children with Hp infection and in 68.7% of children with Fa and Hp infection (Table 2). The moderate activity was found in children with Fa and Hp infection (31.2%), in children with Hp infection (27.7%) and in children with Fa (6.2%). Group I showed the moderate activity in 6.2% of children. Histopathological examinations of the corpus mucosa were evaluated in the same way, i.e. in three categories of changes: normal mucosa, mucosa at the edge of the norm,and chronic inflammation.

Group I showed chronic corpus gastritis in 16.6% of children, whereas the second category of changes was observed in 37.7% and normal mucosa was reported in 45.8% of children in this group. Chronic corpus gastritis was diagnosed in 100% of children with Hp infection. In children with Fa and Hp infection, 93.7% of children had chronic inflammation and 6.2% had mucosa at the edge of the norm. Severe corpus gastritis was observed in 12.5% of children with Fa and Hp infection and in 5.5% of children without Fa but with Hp infection (Table 1). The moderate corpus gastritis occurred in 50% of children with Hp infection and in 50% of those with Fa and coexisting Hp infection. Only 2% of children with Fa had moderate corpus gastritis. Mild gastritis was observed in children with Hp infection (44.4%) and in 31.2% of children with Fa and Hp infection. Severe activity of the corpus mucosa was found in 38% of children infected with Hp and in 37.5% of allergic children infected with Hp. The moderate activity was observed in 61.1% of children with Hp infection, 56.2% of allergic children with Hp infection and 6.2% of children with Fa.

Gastric mucosal biopsies showed the highest IL-2 concentration in children infected with Hp (116.5±179.5 pg/mg of the protein) and slightly lower level in allergic children with Hp infection (98.1±101.0 pg/mg). The levels were statistically significantly different from those in the control group ($P<0.01$). The lowest IL-2 concentration was observed in children with Fa (44.8±50.3 pg/mg), which was comparable to that in the controls (45.7±23.5 pg/mg;

Table 3). The highest IL-2 concentration in the gastric mucosa with regard to the intensity of inflammation (mild+moderate) was observed in the antrum of children with Hp (184.4±227.8 pg/mg) and the allergic process with coexisting Hp infection (125.4±109.4 pg/mg). The highest IL-2 concentration in relation to gastric mucosa inflammation activity was found in children with severe Hp infection (187.6±232.6 pg/mg), being statistically significant when compared to the control group (P<0.01; Tables 4 and 5). IFN-γ concentrations in the gastric mucosa ranged from undetermined levels to 188.2 pg/mg of the protein. The lowest mean concentration of IFN-γ was observed in children infected with Hp (18.9±16.4 pg/mg of the protein) and differed significantly when compared to the controls (P<0.01). In allergic children with Hp infection, the mean concentration of IFN-γ in the gastric mucosa was slightly higher (25.5±27.7 pg/mg, P<0.01; Table 3).

The mean concentration of IFN-γ was 40.6±39.7 pg/mg of the protein in children with Fa and was close to that in the controls (49.9 ±33.4 pg/mg). In Hp infected children with mild and moderate gastric mucosal inflammation, IFN-γ concentration was the lowest (13.1±16.5 pg/mg), being significantly different from that in the controls (P<0.01; Tables 4 and 5).

The values of IL-4 ranged from undetectable to 208.4 pg/mg in biopsies of the gastric mucosa. The highest IL-4 concentration was observed in Hp infected children. IL-4 concentration was 37.2±51.7 pg/mg in allergic and Hp infected children and 35.3±52.8 pg/mg in those without Fa.

The mean concentration of IL-4 was 23.6±35.8 pg/mg in children with Fa, being comparable with the control group (22.7±13.8 pg/mg). The highest IL-4 concentration in children with Hp infection regarding the intensity of gastritis was 62.2±61.2 pg/mg in mild and moderate gastritis (P<0.01).

The IL-5 concentration ranged from 6.7 to 250.9 pg/mg in the biopsies and was 35.5±50.9 pg/mg in allergic children, being not significantly different from that in the controls. The mean concentration of IL-5 in the gastric mucosa of children with or without Fa did not differ significantly and was comparable to that in the control group.

IL-8 concentration ranged from 10.5 to 618.8 pg/mg in

Table 4 Concentrations of cytokines in gastric mucosa of children examined depending on inflammation stage according to Sydney System[25]

Cytokines (pg/mg of the protein)	Fa		Hp				Fa+Hp			
	Antrum	Corpus	Antrum		Corpus		Antrum		Corpus	
	Mild+moderate	Mild+moderate	Mild+moderate	Severe	Mild	Moderate+severe	Mild+moderate	Severe	Mild	Moderate+severe

[b]P<0.01 *vs* cytokine concentrations statistically significantly different from controls. Fa, food allergy; Hp, *H pylori*; C, control group.

gastric mucosal biopsies before the treatment. The highest mean IL-8 value was observed in Hp infected children (with or without Fa). The mean IL-8 concentration was 101.2 ±68.3 pg/mg in allergic children with Hp infection. This value was statistically significant ($P<0.005$) in comparison to that in allergic children. In children with Hp infection, the mean gastric mucosa IL-8 concentration was 88.0± 40.4 pg/mg, being statistically significant ($P<0.005$) in comparison to that in children with Fa. The evaluation of mucosa IL-8 concentration with regard to the intensity and activity of inflammatory process in the gastric mucosa did not show any statistically significant dependence (Tables 4 and 5).

In gastric mucosal biopsies, IL-10 concentration ranged from undetectable to 141.8 pg/mg. The highest mean concentration of mucosa IL-10 was detected in children with Hp infection (79.3±41.2 pg/mg) and in allergic children with Hp infection (50.1±18.8 pg/mg).

The mean IL-10 concentration was 39.9±35.5 pg/mg in children with Fa, being statistically significantly different from that in children with Hp infection ($P<0.01$, Table 3). The intensity and activity of inflammation did not affect IL-10 concentration in the gastric mucosa (Tables 4 and 5).

TNF-α concentration ranged from undetectable to 208.4 pg/mg in gastric mucosal biopsies. The mean TNF-α concentration was the highest in children with Hp infection and 45.9±49.3 pg/mg, in children without Fa compared to that in the controls ($P<0.06$). Infection revealed the mean TNF-α concentration of 45.3±32.6 pg/mg in allergic children with coexisting Hp infection, being statistically different from controls ($P<0.01$). The mean TNF-α concentration was 21.7±34.2 pg/mg in allergic children and showed statistically significant difference ($P<0.003$) in comparison to children with Hp infection or with Fa and coexisting Hp infection ($P<0.004$). The analysis of TNF-α concentration in the gastric mucosa with regard to the intensity and activity of the inflammation showed no statistically significant differences.

DISCUSSION

Our study proved that the pathogenic factors like harmful food could induce certain morphological changes of the gastric mucosa. They are smaller with regard to the percentage and "depth" than in the combined activity of allergy and Hp. It seems essential to check the intensity of the changes and their dynamics by assessing their characteristics and size as well as local properties of cytokines produced. The concentration of chosen cytokines in the antrum mucosa in children with Fa was comparable to that in the controls. However, IL-4 concentration was statistically significantly different from the control group. IL-4 is secreted by antigen- or mitogen-inactivated lymphocytes Th2 and by mast cells in the gastric mucosa infiltrates in children with Fa.

Another frequent etiological factor, Hp infection leading to gastritis, was observed besides the allergic one affecting the gastric mucosa. Histopathological changes induced by the activity of this factor were far greater than those observed in children with Fa.

It should be assumed that the intensified local production of many inflammatory cytokines, including IL-2, takes place in Hp infection where gastric mucosa is infiltrated by such cells as neutrophils, lymphocytes, monocytes/macrophages and cytoplasmic cells. The IL-2 concentration was the highest in the gastric mucosa of children with Hp infection (116.5 pg/mg) and slightly lower in children with Fa and Hp infection (98.1 pg/mg). The values were statistically significant when compared to the control group.

IL-8 is another cytokine, whose chemotactic properties are directed selectively towards neutrophils. The activity of IL-8 on neutrophils is triggered by binding to a specific receptor, which can be found on the surface of the cells (5 ku)[10,25-27]. A population of children with Fa and coexisting Hp infection was included additionally in our study. The mean concentration of IL-8 in the gastric mucosa of children with Hp infection was 88.0 pg/mg, being statistically significantly different ($P<0.01$) in comparison to 59.9 pg/mg in allergic children. The mean IL-8 concentration was even higher (101.2 pg/mg) in allergic children with Hp infection.

Another cytokine with a wide range of biological actions is IL-4 secreted by antigen-inactivated Th lymphocytes (Th2) and mast cells[28-31]. We evaluated IL-4 concentration in particular groups of children and found IL-4 levels were increased in allergic patients, though the values were not statistically different from those in the controls.

TNF-α is one of the most potent cytokines activating numerous functions of neutrophils. It stimulates directly oxygenic metabolite release by neutrophils and the effectiveness of this phenomenon depends on the doses used[32-34]. Isolauri *et al*.[35] and Majamaa *et al*.[36] showed that TNF-α is elevated in feces of allergic children, which is thought to be a delayed reaction type to food challenge. Children with immediate reaction have a significant increase in α1-antitripsin and eosinophil cationic protein (ECP) in their feces as compared to patients who do not respond to food challenge.

The relatively low TNF-α concentration in the antrum mucosa (21.7 pg/mg) of allergic children may be due to the fact that a marked percentage of the patients revealed IgE-dependent mediators engaged in allergic reactions. TNF-α assessed in biopsies of the alimentary tract mucosa or excrements feces seems to be a good factor for active immunological reactions to food allergens ingested by children who react to food without IgE participation. Isolauri *et al*.[35] showed that TNF-α can be equally used as a factor of pathogenic process activation and food hypersensitivity as cationic protein (ECP) and α1-antitripsin in case of patients whose cytokines secreted by T lymphocytes are responsible for clinical symptoms.

In conclusion, the pathogenic process is individually different with regard to morphological examinations and proinflammatory and proallergic cytokine production. Concentrations of IFN-γ, IL-2, IL-8, and TNF-α in the gastric mucosa of children with Fa and those with Hp infection (without Fa) are different.

Abstract

AIM: To investigate the effect of regulatory peptides bombesin (BBS) and neurotensin (NT) on intestinal barrier function in partially hepatectomized rats.

METHODS: Ninety male Wistar rats were randomly divided into five groups: I (*n* = 10): controls, II (*n* = 20): sham operated, III (*n* = 20): partial hepatectomy 70% (PHx), IV (*n* = 20): PHx+BBS (30 μg/kg/d), V (*n* = 20): PHx+NT (300 μg/kg/d). Groups IV and V were treated for 8 days before PHx and 48 h post surgery. At the end of the experiment, on day 10, intestinal barrier function was assessed by measuring endotoxin concentrations in portal and aortic blood. Tissue sections of the terminal ileum were examined histologically and villus density, mucosal thickness, mitotic activity and apoptosis in crypts were assessed. In addition, ileal mucosa was analyzed for DNA and protein content and microbiological analysis was performed in cecal contents. To estimate intestinal oxidative stress, lipid peroxidation was determined on tissue homogenates from terminal ileum.

RESULTS: BBS or NT administration significantly reduced portal and systemic endotoxemia observed 48 h after partial hepatectomy. In hepatectomized rats (group III), a trend towards induction of mucosal atrophy was observed, demonstrated by the reduction of villus density, mucosal thickness, protein content and significant reduction of DNA, while these alterations were reversed by regulatory peptides administration. This trophic effect of BBS and NT was accompanied by induction of mitoses above control levels and a significant reduction of apoptosis in intestinal crypts. Intestinal lipid peroxidation was found significantly lower in PHx group and regulatory peptides exerted an antioxidant action, further decreasing this parameter of oxidative stress. The bacterial population of *E. coli* and aerobic Gram (+) cocci was increased in cecal content of hepatectomized rats, while this parameter was not affected by the administration of BBS or NT.

CONCLUSION: Gut regulatory peptides BBS and NT improve intestinal barrier function and reduce endotoxemia in experimental partial hepatectomy. This effect is, at least in part, mediated by their trophic, antiapoptotic, mitogenic, and antioxidant effect on the intestinal epithelium. This observation might be of potential value in patients undergoing liver resection.

INTRODUCTION

Despite current advances in the safety of hepatic resection and perioperative care, which have led to a significant reduction of perioperative mortality, septic events remain still an important problem complicating the outcome of hepatectomized patients[1]. It has been previously shown that enteric bacteria and endotoxins passing through the intestinal barrier to extraintestinal sites and the systemic circulation result in intra-abdominal abscess formation, pulmonary infections, sepsis and multiple organ dysfunction in patients and rats after liver resection[1,2]. A

compromised gut barrier function promotes the escape of enteric bacteria and endotoxins into portal circulation, while the reduction of the functional reticuloendothelial volume after hepatectomies permits their systemic spread[3].

Bombesin (BBS), a tetradecapeptide originally isolated from the skin of the European frog *Bombina bombina* is analogous to gastrin-releasing peptide found in mammalians[4]. BBS stimulates the release of various gut hormones and peptides e.g, gastrin, cholecystokinine, insulin, glucagons, somatostatin, motilin, pancreatic polypeptide, neurotensin and exerts a trophic effect on intestinal and gastric mucosa and pancreas, while it stimulates intestinal motility[5,6]. It has been previously shown that BBS improves intestinal integrity in experimental models of gut barrier dysfunction, such as after elemental diets, methotrexate administration, chemically induced colitis and burns[5,7-9].

Neurotensin (NT), a tridecapeptide originally isolated from the bovine hypothalamus, is additionally found in the gut mucosal endocrine cells (N cells), especially in the ileum[10]. NT stimulates pancreaticobiliary secretions, intestinal blood flow and colonic motility, while it inhibits small intestinal and gastric motility. It is a potent trophic agent for small and large intestine, gastric mucosa and pancreas[11-14]. NT has been shown to prevent intestinal atrophy induced by feeding rats an elemental diet, restores mucosal ulceration after radiation therapy and enhances intestinal regeneration after small bowel resection[7,15,16].

We have recently shown that BBS and NT improve intestinal barrier function in experimental obstructive jaundice by exerting mitogenic, antiapoptotic, and antioxidant effects on the intestinal epithelium[17]. The present study was undertaken to investigate the effect of exogenous administration of BBS and NT on gut barrier function after partial hepatectomy in rats.

MATERIALS AND METHODS

Animals

Ninety male albino Wistar rats, weighing 250-320 g, were used. They were housed in stainless-steel cages, three rats per cage, under controlled temperature (23 °C) and humidity conditions, with 12-h dark/light cycles, and maintained on standard laboratory diet with tap water *ad libitum* throughout the experiment, except for an overnight fast before surgery.

The experiments were carried out according to the guidelines set forth by the Ethics Committee of Patras University Hospital, Patras, Greece.

Experimental design

Animals were divided randomly into five groups: Group I (n = 10): non-operated controls, group II (n = 20): sham operated, group III (n = 20): partial hepatectomy (70%), group IV (n = 20): partial hepatectomy and BBS administration, group V (n = 20): partial hepatectomy and NT administration.

Starting on d 0, the animals of groups IV and V were treated daily with BBS (10 μg/kg, subcutaneously, thrice a day) and NT (300 μg/kg, intraperitoneally, once a day), respectively, while the animals of groups I, II, and III were divided to receive daily either three subcutaneous or one intraperitoneal injection of 0.5 mL normal saline. Previous pilot studies showed that the way of saline administration does not affect the results. On the 8th day, animals from groups III, IV, and V underwent laparotomy and partial hepatectomy (almost 70%) as described by Higgins and Andersson[18], while animals in group II underwent laparotomy and mobilization of the liver. The abdominal incision was closed in two layers with chromic 4-0 cat gut and 4-0 silk. All surgical procedures were performed under strict sterile conditions, using light ether anesthesia. Administration of BBS, NT, and normal saline was continued for 48 h after surgery. On the 10th d, all animals were operated (group I) or reoperated (groups II, III, IV, and V), again under strict sterile conditions. Samples were obtained according to the experimental protocol, after which the rats were killed by exsanguination.

Peptides preparation

A stock solution of BBS (Sigma Chemical Co, St. Louis, MO, USA) was prepared by first dissolving the amount of peptide needed for the study in 1 mL sterile water containing 0.1% (w/v) bovine serum albumin and then diluted with normal saline containing 1% (w/v) bovine serum albumin, so that the amount of BBS needed for each injection to be contained in a volume of 0.1 mL. This solution was divided into equal aliquots of 0.1 mL that were stored in plastic tubes at -20 °C. At the time of administration, in order to prolong absorption, each aliquot was mixed with 0.4 mL of a solution of 8% (w/v) hydrolyzed gelatin (Sigma Chemical Co, St. Louis, MO, USA). A final volume of 0.5 mL, containing 10 μg BBS/kg body weight, was injected subcutaneously thrice daily.

A stock solution of NT (Sigma Chemical Co, St. Louis, MO, USA) was prepared by first dissolving the amount of peptide needed for the study in 1 mL sterile water containing 0.1% (w/v) bovine serum albumin and then diluted with normal saline containing 0.1% (w/v) bovine serum albumin, so that the dose of NT needed for each injection to be contained in a volume of 0.1 mL. This solution was divided into equal aliquots of 0.1 mL that were stored in glass vials at -20 °C. At the time of administration, each aliquot was further diluted with 0.4 mL sterile saline to a final volume of 0.5 mL and was given intraperitoneally as a bolus injection containing 300 μg NT/kg body weight.

Endotoxin measurements

For the determination of endotoxin concentrations, a laparotomy was performed in all groups, the portal vein and the abdominal aorta were punctured and samples of 1 and 2 mL of blood were obtained, respectively. Endotoxin concentration was determined by the quantitative chromogenic Limulus amebocyte lysate test according to the manufacturer's instructions (QCL-1 000, BioWhittaker, Walkersville, USA) and expressed in EU/mL.

Measurements of mucosal DNA and protein

DNA and protein content in the terminal ileal mucosa were determined in all animals. A 1-cm long sample of the terminal ileum was excised, opened by longitudinal incision and washed with cold normal saline. Using a clean glass slide the mucosa was removed and homogenized in 1 mL NaOH 1 N, by means of a polytron homogenizer. The protein was measured according to Lowry's method[19] using a commercial kit (Sigma Diagnostics, Deisenhofen, Germany) and the DNA was determined according to a modified Barton technique[20].

Histological evaluation

For histological examination, tissue samples from the terminal ileum were obtained from all animals. The ileal samples were fixed in 10% neutral buffered formalin, embedded in paraffin, sectioned at 4 μm and stained with hematoxylin and eosin. In each ileal specimen, several histologic features were evaluated and recorded. These features included architectural distortion, villous blunting, surface and crypt epithelial injury, presence and cell type of inflammation of the lamina propria, surface and cryptal intraepithelial infiltration, lamina propria fibrosis and granulation tissue formation. Ileal mucosal morphometric characteristics were studied by measurements of villus density, defined as the number of villi per centimeter (V/cm), and villus height (Vh) in micrometers (μm). Villus height was measured with a micrometer eyepiece affixed to a Reichert–Jung light microscope and at least 20 well-preserved villi were estimated in each sample. In addition, the number of mitoses and apoptotic bodies per crypt were also counted. Apoptotic bodies of the cryptal epithelium were identified and tallied using a morphometric analysis, which has been described in detail elsewhere[21]. Apoptotic bodies were defined as rounded vacuoles with fragments of karyorrhectic nuclear debris and were differentiated from small isolated fragments of nuclear chromatin and intraepithelial neutrophils. Apoptotic bodies and mitoses were counted in all architecturally successive crypts included in the specimen, regardless of crypt orientation, and their total number was divided by the number of the crypts. The number of apoptotic bodies per crypt is referred to as the apoptotic body count (ABC).

Cecal bacterial population

Collection of cecal contents for microbiological analysis, was performed by the following technique: the ascending colon was ligated below the hepatic flexure, and a 21-gauge needle mounted on a 5 mL syringe was introduced into the cecum through the ileocecal valve, after puncturing the terminal ileum. Two milliliters of sterile saline was infused in the cecum, after which the needle was withdrawn and the terminal ileum was ligated. The cecal content was manually mollified for 2 min and after a good mixture was achieved, 1 mL of colonic content was removed; serial tenfold dilutions were performed and 0.001 mL of each sample was inoculated into 5% blood and McConkey's agar plates for recovery of aerobic bacteria and Gram-negative/nonspore-forming agar plates for anaerobes. After 24 and 48 h of incubation at 37 °C, for aerobic and anaerobic cultures respectively, colonies were identified and counted. Quantitative culture results were expressed as the number of colony-forming units (CFU) per milliliter or per gram of the cecal samples, calculated from the dilutions of colonic content. *E coli* was identified by Gram stain and a standard biochemical identification system (API-20E, Biomérieux, Marcy-l'Etoile, France, according to the analytical profile index).

Intestinal lipid peroxidation

A 1-cm long tissue sample of the terminal ileum of each animal was excised, washed in 9 g/L of NaCl and was homogenized in a porcelain mortar in liquid nitrogen. Intestinal homogenates were processed for the determination of lipid peroxidation, according to a modified [2-thiobarbituric acid (TBA)]-based method, as reported previously[22]. Lipid peroxidation was expressed in pmoles malondialdehyde (MDA)/mg total protein.

Statistical analysis

The results are expressed as mean (SD). Comparisons among multiple groups were performed using the one-way ANOVA, followed by Bonferroni's *post hoc* test, when variances across groups were equal or by Dunnett's T3 *post hoc* test, when variances were not equal. Variance equality was tested by Levene statistical analysis. Differences were considered significant, when $P<0.05$.

RESULTS

Portal and aortic endotoxin concentrations

Hepatectomized animals (group III) presented significantly elevated endotoxin concentrations in portal and aortic blood compared with groups I and II ($P<0.001$, respectively). Treatment with BBS or NT led to significantly lower endotoxin values both in portal vein ($P<0.001$ *vs* group III, respectively) and aorta ($P<0.001$ and $P<0.01$ *vs* group III, respectively) (Figure 1).

Mucosal DNA and protein

DNA content of the intestinal mucosa was significantly decreased in partially hepatectomized rats as compared to controls ($P<0.01$) and increased in BBS and NT treated rats ($P<0.05$ and $P<0.01$ *vs* group III, respectively)

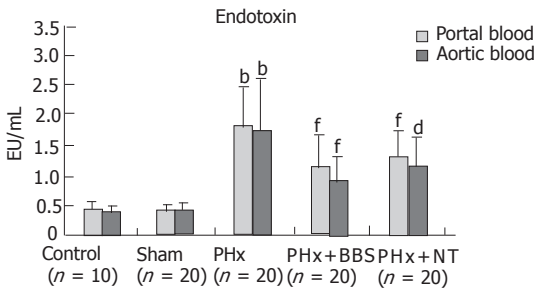

Figure 1 Portal and aortic endotoxin concentrations. Values are mean±SD. [b]$P<0.001$ *vs* sham, [d]$P<0.01$ and [f]$P<0.001$ *vs* PHx. PHx, partial hepatectomy; BBS, bombesin; NT, neurotensin.

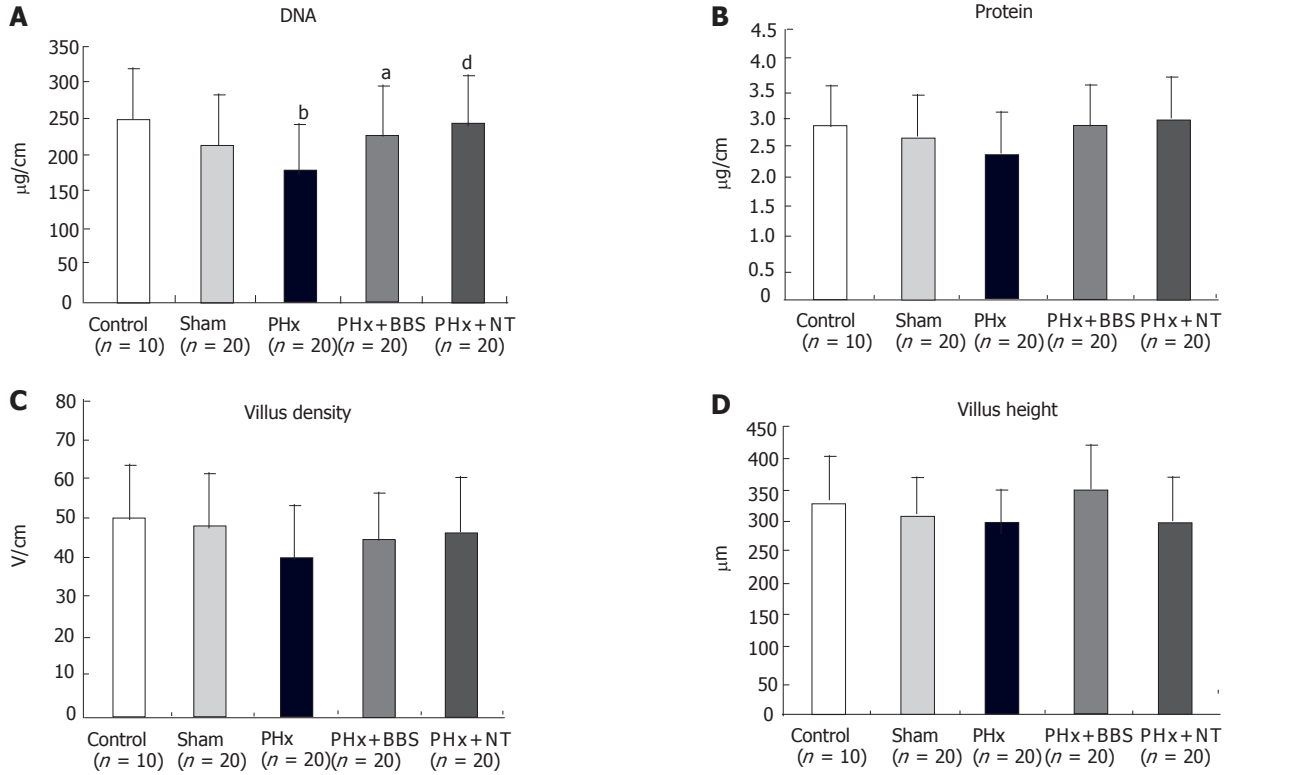

Figure 2 Indices of ileal mucosa trophic state. Values are mean±SD. [b]*P*<0.01 *vs* control, [a]*P*<0.05 and [d]*P*<0.01 *vs* PHx. PHx, partial hepatectomy; BBS, bombesin; NT, neurotensin(**A-D**).

(Figure 2A). Protein content was also decreased in hepatectomized rats and increased to normal levels after peptides administration, but these differences did not reach statistical significant levels (Figure 2B).

Intestinal morphology

Overall, the ileal architecture remained intact and epithelial continuity was retained, in all specimens studied. The ileal biopsies from group III demonstrated a reduction in the number of villi per centimeter (Figure 2C) and in villus height (Figure 2D), which were increased towards control values in rats treated with BBS or NT; however, the differences among groups were not significant. Intestinal crypt mitotic activity was reduced in hepatectomized rats, though not to significant levels, and increased above normal levels after BBS or NT administration (Figure 3A). Crypt epithelial apoptosis was present in all intestinal samples evaluated. The ABC in ileal specimens from control group was significantly lower compared with group III ($P<0.001$) (Figure 3B). After BBS or NT administration the ABC was significantly reduced ($P<0.05$ and $P<0.01$, compared to PHx, respectively).

Cecal bacterial population

Table 1 provides the quantitative culture results of the cecal contents for aerobic and anaerobic bacteria. In partially hepatectomized rats (group III) there was a significant increase in Gram (+) cocci and *E coli* cecal count as compared with group I ($P<0.05$, respectively). Neurotensin presented a trend towards reduction of aerobic and anaerobic bacterial populations, which reached significant levels for Gram (+) anaerobic bacteria ($P<0.001$ *vs* group III).

Table 1 Bacterial cecal population (CFU×10^5/mL)

Groups	*n*	Aerobic bacteria		Anaerobic bacteria	
		Gram (+) cocci	*E coli*	Gram (+)	Gram (–)
Control	10	6.70 (1.62)	1.04 (0.88)	9 (2.74)	4.64 (1.99)
Sham	20	9.45 (4.92)	1.60 (2.07)	13.34 (5.62)	6.5 (4.35)
PHx	20	11.09 (5.71)[a]	6.43 (6.38)[a]	13.17 (3.88)	5.48 (4.57)
PHx+BBS	20	11.70 (6.41)	6.31 (6.20)	10 (4.29)	4.45 (2.86)
PHx+NT	20	6.76 (4.31)	2.77 (3.92)	6.76 (5.64)[b]	3.08 (4.48)

Data expressed as mean (SD). [a]*P*<0.05 *vs* control, [b]*P*<0.001 *vs* PHx. PHx, partial hepatectomy; BBS, bombesin; NT, neurotensin.

Intestinal lipid peroxidation

Liver resection resulted in decreased intestinal lipid peroxidation ($P<0.001$ *vs* group II), while administration of BBS or NT led to further significant decrease of this index of oxidative stress ($P<0.01$ and $P<0.001$ *vs* group III, respectively, Figure 4).

DISCUSSION

An intact intestinal barrier function effectively separates potentially harmful intraluminal elements such as bacteria and endotoxins from extraintestinal tissues and the systemic circulation. Major liver resection has been shown to compromise the anatomic and functional integrity of the gut barrier resulting in the translocation of indigenous bacteria and endotoxins to remote organs and

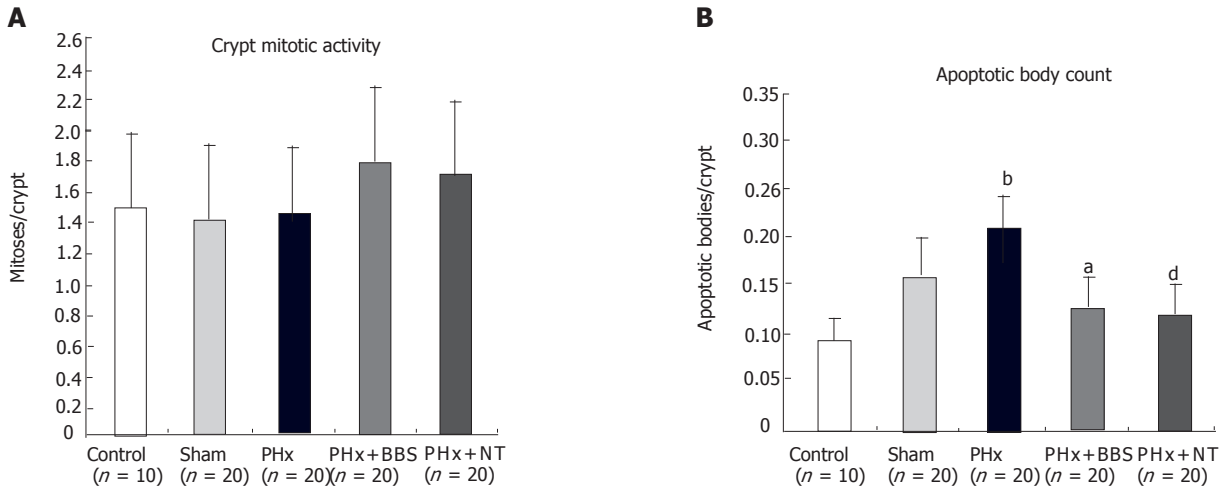

Figure 3 Crypt epithelial cell proliferation and apoptosis. Values are mean±SD. $^{b}P<0.001$ *vs* control, $^{a}P<0.05$ and $^{d}P<0.01$ *vs* PHx. PHx, partial hepatectomy; BBS, bombesin; NT, neurotensin(**A**, **B**).

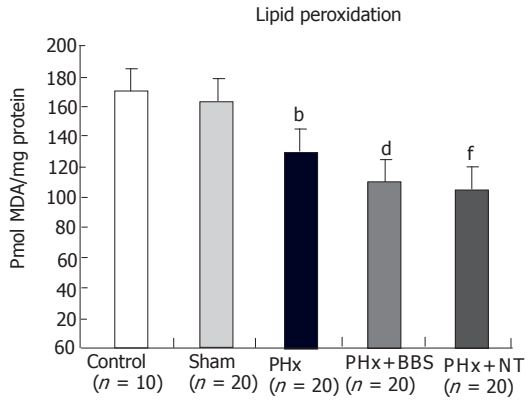

Figure 4 Lipid peroxidation in the intestine. Values are mean±SD. $^{b}P<0.001$ *vs* sham, $^{d}P<0.01$ and $^{f}P<0.001$ *vs* PHx. PHx, partial hepatectomy; BBS, bombesin; NT, neurotensin.

tissues[3,23]. Systemic endotoxemia plays a pivotal role in the development of septic complications and dysfunction of remote organs after liver resections through activation of a systemic inflammatory response, which is associated with structural and functional deleterious effects on vital organs[24]. Failure of the gut barrier leads to bacterial and endotoxin translocation and the pathogenesis of the so-called "gut-derived sepsis"[25]. However, the mechanisms implicated in intestinal barrier failure after liver resection have not been fully elucidated.

Physical injury to the intestinal mucosa is one of the mechanisms postulated to promote bacterial translocation. In our study, the ileal architecture remained intact and epithelial continuity was retained in hepatectomized rats. Previous experimental studies have shown that 70% hepatectomy induces trophic changes on the distal ileum after 30 d, causing atrophy of the ileum wall and a drop in villus thickness[26]. The present study shows that 48 h after partial liver resection there is a trend for decreased villous density and mucosal thickness that does not reach statistical significant levels. Diminished bile production and secretion to the duodenum, after partial hepatectomy, deprives partly the gut from its trophic action thus promoting mucosal atrophy. On the other hand, the plethora of enterotrophic growth factors and cytokines that are elaborated after liver resection exert the opposite effect[27]. The combinatory action of these factors seems to produce a balanced adaptive intestinal response, 48 h after partial hepatectomy.

The balance between cell proliferation and death in intestinal crypts is crucial for epithelial homeostasis because the total of epithelial cells lining villi originate from stem cells located in the proliferation zone of the crypt. Apoptosis was the only histologic parameter that altered significantly in the present study. Definite evidence of apoptosis is seen in the crypt, where apoptotic cells are seen once in every 5^{th}-10^{th} crypt section[28]. Occasional apoptotic bodies found in the rapidly proliferating epithelial cells of the normal gastrointestinal mucosa, help to maintain a steady-state in cellular populations[29]. Control animals presented this basal level of apoptotic activity known as spontaneous apoptosis, which serves to remove either occasionally overproduced stem cells or stem cells with minor DNA damage caused by external factors. Two-thirds hepatectomy resulted in a significant increase of apoptosis in the crypt, which may explain the trend for induction of mucosal atrophy without alterations in the mitotic activity of the intestinal epithelium. In addition, increase of the apoptotic process in the intestinal epithelium may partly contribute to the decrease of mucosal DNA content. Apoptotic cells have a lower DNA content than the G0/G1 value and this hypo-diploid DNA is a hallmark to show apoptosis[30].

Apoptosis is a morphologically distinct, gene-directed, form of cell death that contributes to both physiological and pathological processes[31]. Although in gastrointestinal epithelium it has been associated with several conditions[17,21,32], the biological significance of intestinal apoptosis after liver resection is not clear till

date. The responsible mechanism could reflect primary immunologic events following hepatectomy (apoptosis has been shown to be induced by a variety of triggers, including proinflammatory cytokines such as TNF, IL-1, and IL-6, or by cytotoxic T lymphocytes that act through either granzyme B or Fas receptor pathways) or a direct action of bacterial toxins[31,33,34].

Another factor associated with bacterial translocation is intestinal flora disturbances. In our study hepatectomized rats presented a significant increase of cecal aerobic bacteria [*E coli* and Gram (+) cocci]. Diminished bile production and disturbances of interdigestive motility may have led to bacterial overgrowth. Bile salts have a constraining role on the indigenous microflora, while secretory *IgA* contained in bile modulates the local immunological milieu[35]. In addition, delayed intestinal transit time in experimental liver resection seem to be implicated in intestinal bacterial overgrowth and increased bacterial translocation[36]. A correlation between cecal overgrowth of a specific organism and bacterial translocation of the same organism is well documented[37]. Overgrowth of *E coli* detected in our study and diminished biliary *IgA* may lead to increased attachment of this bacterial strain to the intestinal mucosa, predisposing to bacterial translocation and previous studies have shown that *E coli* is usually cultured from the mesenteric lymph nodes of hepatectomized rats[2].

Another parameter we have addressed in our study is intestinal oxidative stress estimated by quantification of lipid peroxidation, which is a common indicator of oxidative stress. Our data show that 48 h after partial hepatectomy decreased levels of lipid peroxidation were measured in the intestine. This may be attributed to liver regeneration and release of several growth factors and hormones that may influence intestinal oxidative stress[27]. In addition, previous studies demonstrate evidence for activation of the intestinal cytosolic antioxidant enzyme glutathione *S*-transferase after hepatectomy[38]. Another explanation might be that the removal of a large portion of the liver could result in a decrease of oxidants originating from the liver, therefore lowering lipid peroxidation. The liver and gut are considered as an anatomic and functional unit with inseparable and interdependent functions and from this point of view liver regeneration under low oxidative stress[39] may be associated with similar oxidant alterations in the intestine. A question that rose is if low oxidative stress is compatible with increased apoptosis. Whether a cell will enter or not the apoptotic process is determined by a variety of stimuli and intrinsic pathways and it seems that apoptosis of enterocytes after partial hepatectomy is not mediated by oxidative stress.

The present study has further investigated the role of gut regulatory peptides BBS and NT on gut barrier function in experimental partial hepatectomy. To the best of our knowledge, our results demonstrate for the first time that administration of BBS or NT improves gut barrier function after partial hepatectomy, leading to significantly lower portal and aortic endotoxin concentrations. Treatment with these factors reversed the decrease of intestinal morphometric characteristics and preserved mucosal DNA and protein content to control levels. Although these alterations were statistically significant only for DNA, they show a trend for induction of a trophic effect on the intestinal mucosa. This effect was accompanied by the increase of cell proliferation beyond control levels and inhibition of programmed cell death in intestinal crypts. The mitogenic effect of BBS and NT may be a direct receptor-mediated effect, since intestinal epithelial cells express receptors for both peptides[40-42] and it is known that BBS and NT are potent cellular growth factors whose binding to their receptors activates a mitogenic signal to the nucleus[43]. An indirect mechanism may be related to a further reduction of intestinal lipid peroxidation since oxidative state is involved in the modulation of cell proliferation and death[44]. The antiapoptotic effect of BBS and NT may be mediated by the reduction of endotoxemia and amelioration of the subsequent systemic inflammatory response, characterized by the release of numerous cytokines and proinflammatory mediators, such as tumor necrosis factor-alpha, which may activate the apoptotic process. Another explanation of their antiapoptotic action may be provided through induction of vasodilation[45,46], which improves intestinal microcirculation thus preventing enterocytes hypoxia, energy depletion and activation of apoptotic pathways.

Apart from their antiapoptotic action on the intestinal epithelium, BBS and NT exerted an antioxidant effect as well, further decreasing intestinal lipid peroxidation. The compromise of the intestinal barrier function, after partial hepatectomy, shows that intestinal compensatory response, which may be partly expressed by low oxidative stress, is relatively insufficient to overwhelm the noxious effect of hepatectomy on the intestinal epithelium. From this point of view, the additional decrease of intestinal oxidative stress achieved by peptides treatment may contribute to the enhancement of intestinal barrier. The results of this study are consistent with our previous work demonstrating the antioxidant effect of BBS and NT on the intestinal epithelium of bile duct ligated rats[17]. Possible explanations of their antioxidant action is the reduction of systemic endotoxemia, which is associated with generation of oxygen free radicals via a xanthine oxidase depended pathway, improvement of oxygen supply to enterocytes through vasodilation, or receptor-mediated activation of intracellular antioxidant pathways. It has been shown that binding of regulatory peptides to their specific G-protein coupled receptors is followed by a pivotal activation of protein kinase C[43]. Increased cellular PKC activity promotes the mitochondrial translocation and organization in a catalytically active form of a representative isoform of glutathione *S*-transferases, which are an important antioxidant enzyme system[47].

In conclusion, the present study shows that the gut regulatory peptides BBS and NT improve the intestinal barrier function and reduce endotoxemia, in experimental partial hepatectomy. This effect is, at least in part, mediated by their antiapoptotic, mitogenic and antioxidant effect on the intestinal epithelium. Although laboratory results

should not be easily extrapolated to the clinical situation, we feel that BBS and NT merit consideration, as potential therapeutic agents, for the improvement of gut barrier function in cases of liver resection.

ACKNOWLEDGMENT

The authors wish to express their thanks to Dr I Spiliopoulou, Department of Microbiology of Patras University Medical School, for her excellent work in microbiological analyses.

Abstract

AIM: To examine surgical specimens of pancreas with either chronic pancreatitis or pancreatic cancer in order to study whether ductal hyperplasia and dysplasia in pancreas represent precursor lesions for pancreatic cancer.

METHODS: We examined expression of Ki-67, CEA, p53, and K-*ras*, in the surgical specimens of pancreas with adenocarcinomas (n = 11) and chronic pancreatitis (n = 12). Cellular proliferation was assessed by Ki-67 proliferation index using the proliferation marker Ki-67. In specimens with pancreas cancer, we divided pancreas epithelium into normal (n = 7), ductal hyperplasia (n = 3), dysplasia (n = 4), and cancerous lesion (n = 11) after hematoxylin and eosin staining, Ki-67, and CEA immunohistochemical staining. In cases with chronic pancreatitis, the specimen was pathologically examined as in cases with pancreas cancer, and they were also determined as normal (n = 10), ductal hyperplasia (n = 4), or dysplasia (n = 5). p53 and K-*ras* expression were also studied by immunohistochemical staining.

RESULTS: In pancreatic cancer, the Ki-67 index was 3.73±3.58 in normal site, 6.62±4.39 in ductal hyperplasia, 13.47±4.02 in dysplasia and 37.03±10.05 in cancer tissue, respectively. Overall, p53 was positive in normal ducts, ductal hyperplasia, dysplasia, and carcinoma cells in 0 of 14 (0%), 0 of 7 (0%), 7 of 9 (78%), and 10 of 11 (91%), respectively, and K-*ras* was positive in 0 of 8 (0%), 1 of 3 (33%), 4 of 6 (67%), 4 of 5 (80%), respectively.

CONCLUSION: Our results favorably support the hypothesis that ductal hyperplasia and dysplasia of the pancreas might be precursor lesions for pancreas cancer. Further evaluation of oncogenes by the molecular study is needed.

Key words: Ki-67; p53; K-*ras*; Chronic pancreatitis; Pancreatic ductal adenocarcinoma

INTRODUCTION

The pancreatic cancer has the poorest prognosis among various cancers with a 5-year survival rate of 3%, making it the fourth most common cause of cancer-related mortality rate[1-3]. Although the surgical resection offers the only chance for cure, only 10-30% of patients have resectable tumor[4]. Since early diagnosis followed by complete resection is the only way to the complete recovery, understanding the pathogenesis of pancreatic cancer seems to be of great value.

The ductal hyperplasia of pancreas is defined by abnormally increased number of epithelial cells of pancreatic duct. It may be detected in both normal and chronically inflamed pancreatic tissues, and its incidence is generally increased with age[5]. However, the patients with chronic pancreatitis and ductal hyperplasia have been reported to be associated with the development of pancreas cancer[5-8]. In addition, there has been an investigation suggesting three times higher incidence of papillary hyperplasia of pancreatic duct epithelium in patients with pancreatic cancer compared with the control group[6]. There is also a report that 41% of patients with pancreatic cancer showed hyperplasia of pancreatic duct epithelium when 9% of the control group have that pathological finding[7].

In an effort to search for the pathogenesis of pancreatic cancer, mutations of K-*ras*, p53, and overexpression of HER-2/neu were found in human pancreatic ductal adenocarcinoma[9].

Currently, the hypothesis of multistep carcinogenesis

that states cumulative genetic mutations in the normal pancreas might have progressed into pancreatic cancer is mostly accepted. However, detailed explanation for each step of carcinogenesis needs further investigation. In the current study, we performed histological examination of pancreas and detected normal epithelium and that with ductal hyperplasia, dysplasia, or cancerous lesions. Then we immunohistochemically determined the expression of Ki-67, K-*ras*, and p53 to identify if ductal hyperplasia and dysplasia of pancreas might be precancerous lesion.

MATERIALS AND METHODS

Subjects

The study was performed in 11 patients with pancreatic ductal adenocarcinoma and 12 patients with chronic pancreatitis, the total 23 patients went through surgical pancreatic resection at Inha University Hospital. The mean age of patients was 67 years (range 40-74 years) for pancreatic cancer and 61 years (range 37-67 years) for chronic pancreatitis. Male to female ratio was 6:5 for pancreatic cancer and 10:2 for chronic pancreatitis.

Histologic classification

The degree of pancreatic ductal lesion was classified morphologically according to Cubilla and Fitzgerald[6], and the pancreatic carcinoma according to Kloppel[10]. Most pancreatic duct epitheliums are composed of cuboidal and low columnar cells, their cytoplasm filled with mucous components. They are surrounded by loose fibrous connective tissue. Hyperplasia of pancreatic duct epithelium is divided into either flat or papillary type. However, recent studies show that there is no difference in genetic mutations between these two forms of hyperplasia[9]. Therefore, we considered these two different forms of hyperplasia in the same tissue in this study. Dysplasia was classified according to flattening, papillary hyperplasia of ductal epithelium, increased nucleus/cytoplasm ratio as the epithelium changes into atypical form, loss of nuclear polarity, morphologic form, and aggregation. A little evidence of cellular division was also considered as dysplasia. The degree of hyperplasia was evaluated objectively by counting the numbers of hyperplasia using the method of Ki-67 (Immunotec, France) immunohistochemical staining. To see whether dysplasia develops or not, we performed CEA immunohistochemical staining in the area of hyperplasia stained with Ki-67 using double staining method and classified them into different categories, so that we can minimize the errors arising from differential classification of pancreatic tissue.

Immunohistochemical staining

After 10% of surgically resected pancreatic tissue was fixed in neutral formalin, paraffin-embedded tissue was sliced to the thickness of 4 μm continuously. One slice was stained with hematoxylin-eosin (H&E), and the others were stuck to the slide with poly-L-lysine for immunohistochemical staining. After all the slices went through autoclave (120 °C, 15 lb) for 15 min to expose the antigens fixed by formalin, we treated with H_2O_2 for 30 min to eliminate intrinsic peroxidase. For immunohistochemical staining, CEA monoclonal antibody (Ab) (DAKO, Carpenteria, CA, USA) and Ki-67 monoclonal Ab (Immunotech, Marseille, Cedex, France) were diluted to 1:150 and 1:100, respectively, then incubated at room temperature for 3 h. Labeled streptavidin biotin kit (LSAB kit, DAKO) and 3',3-diaminobenzidine (DAB) were used for staining. Also p53 monoclonal Ab (Novocastra, Newcastle, UK) was diluted to 1:150 and incubated at 4 °C for one day. Then alkaline phosphatase, anti-alkaline phosphatase kit (APAAP kit, DAKO) was used for staining and fast red (DAKO) for expression. For K-*ras* staining, $p21^{ras}$ monoclonal Ab (Oncogene Research Products, Calbiochem, Germany) was diluted to 1:50. The serially sliced tissues were examined morphologically at the same area using H&E staining for histologic diagnosis, and then were compared with the results of immunohistochemical staining in response to CEA, p53, K-*ras*, and Ki-67. The following Ki-67 proliferation index was expressed as the percent of Ki-67-positive cells of 1 000 pancreatic duct epithelial cells. The double staining was performed using Ki-67 and CEA monoclonal Ab to ascertain the presence of dysplasia. Dysplasia was classified using CEA+p53 and CEA+Ki-67 staining.

RESULTS

Histology

Hematoxylin and eosin staining Normal pancreatic duct epithelium is composed of mainly cuboidal and low columnar cells and surrounded by fibrous connective tissues (Figure 1A). We detected basally located nuclei, aggregation and intraductal papillary proliferation of pancreatic duct epithelial cells in ductal hyperplasia (Figure 1C). Dysplasia of the pancreatic duct showed an

[1]Fails to stain.

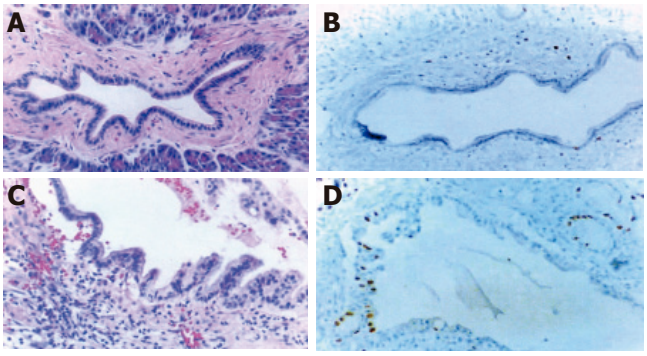

Figure 1 H&E and immunohistochemical staining of normal pancreatic and ductal hyperplasia tissues. **A:** Normal interlobular duct surrounded by fibrous tissue is illustrated. Small cuboidal cells with basally located nuclei having intact nuclear polarity are seen in the inset. H&E stain, ×100; **B:** Ki-67 monoclonal Ab does not show reaction to almost epithelial cells. DAB and hematoxylin counter stain, ×100; **C:** Pancreatic duct hyperplasia with uniformly large columnar epithelial cells, which are more than twice as long as cytoplasm of normal cells and have mucinous metaplasia of the cytoplasm. The nuclei are small and basally located without atypia. H&E stain, ×100; **D:** Ki-67 monoclonal Ab shows a few proliferating nuclei of hyperplastic ductal epithelium. DAB and hematoxylin counter stain, ×100.

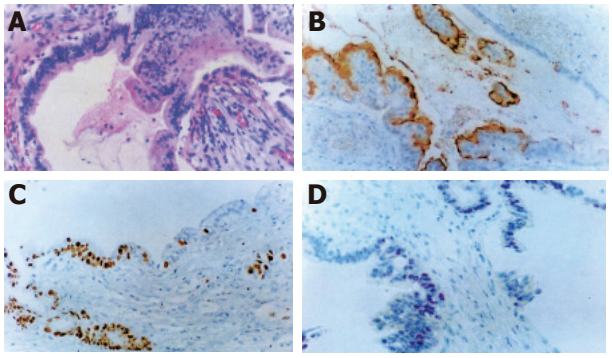

Figure 2 H&E and immunohistochemical staining of dysplastic tissues of the pancreatic duct. **A:** The nuclear enlargement, increased nuclear-to-cytoplasmic ratio, loss of nuclear polarity, pleomorphism, and nuclear overcrowding are seen. Several mitotic figures including atypical form are present. H&E stain, ×100; **B:** CEA monoclonal antibody shows positive reaction in the cytoplasmic membranes of dysplastic cells. DAB and hematoxylin counter stain, ×100; **C:** Ki-67 monoclonal antibody shows focally increased proliferating nuclei of dysplastic cells. DAB and hematoxylin counter stain, ×100; **D:** p53 monoclonal antibody shows focally positive reaction in the nuclei of dysplastic cells. AEC and hematoxylin counter stain, × 100.

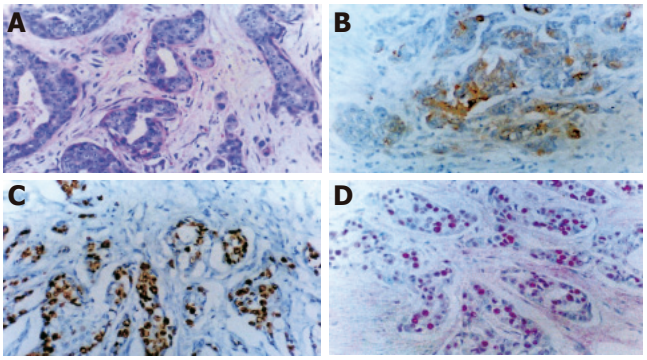

Figure 3 H&E and immunohistochemical staining of pancreatic cancer. **A**: Moderate to poorly differentiated pancreatic adenocarcinoma with desmoplastic background. H&E stain, ×200; **B**: Immunohistochemical staining using CEA monoclonal antibody shows positive reaction in the cytoplasms of tumor cells. DAB and hematoxylin counter stain, ×200; **C**: Ki-67 monoclonal antibody shows significantly increased proliferation of nuclei of tumor cells. DAB and hematoxylin counter stain, ×200; **D**: Intense nuclear immunohistochemical staining of p53 in an invasive pancreatic adenocarcinoma. AEC and hematoxylin counter stain, ×200.

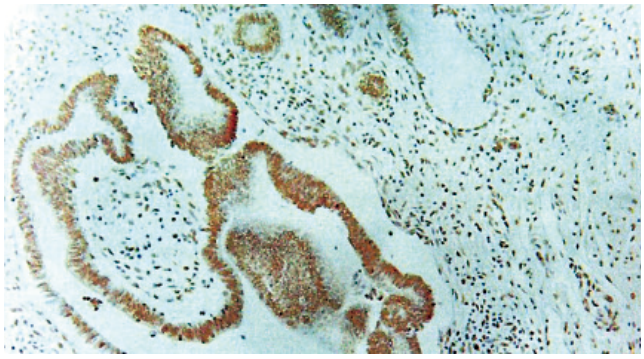

Figure 4 Cytoplasmic staining with K-*ras* is illustrated in both ductal hyperplasia and adjacent invasive adenocarcinoma. K-*ras* immunohistochemical stain, ×200.

increased nuclear to cytoplasm ratio and loss of nuclear polarity (Figure 2A). The tissue of pancreatic duct showed numerous cell divisions, an increased nuclear-to-cytoplasm ratio, and loss of cellular polarity (Figure 3A).

Immunohistochemical staining Normal pancreatic duct showed negative reaction to Ki-67, CEA, p53, K-*ras* staining (Figure 1B), whereas in hyperplasia, the nuclei were stained by Ki-67 (Figure 1D), cellular membrane by CEA and cytoplasm by K-*ras*, respectively. In dysplasia, the nuclei were stained by Ki-67, p53, and cell membrane by CEA respectively (Figures 2B-D). Focal, weak positive reaction to CEA was also detected in the cytoplasm. In pancreatic cancer, the nuclei were stained by Ki-67 and p53, whereas both cell membrane and cytoplasm showed strong positive reaction to CEA (Figures 3B-D). K-*ras* showed negative reaction to K-*ras* (Table 1, Figure 4).

Ki-67 proliferation index

Pancreatic cancer tissue Ki-67 proliferation index of pancreatic cancer tissue based on the histologic classification was 3.73±3.58, 6.62±4.39, 13.47±4.02, and 37.03±10.05 in normal, ductal hyperplasia, dysplasia, and cancer site respectively.

Chronic pancreatitis tissue Ki-67 proliferation index based on the histologic classification in chronic pancreatitis tissue was 2.35±2.79, 7.66±5.78, and 8.64±5.51 in normal, ductal hyperplasia, and dysplasia, respectively.

Results based on random histologic classification Ki-67 proliferation index based on random histologic classification was 2.35±2.79, 9.07±5.39, 10.79±5.51, and 37.03±10.05 in normal, hyperplasia, dysplasia, and cancer area, respectively.

Expression of p53 protein

In all 11 pancreatic cancer tissues, the expression of p53 protein was observed in all dysplasia (4/4), but not in all normal sites. The expression of p53 protein was also observed in 91% of cancer area that involved lesions.

In 12 samples of all chronic pancreatitis tissues, the expression of p53 protein was negative in both normal and hyperplasia sites, whereas positive in 60% of dysplasia site. Overall, the expression of p53 protein was negative in all normal sites and pancreatic epithelial hyperplasia, whereas positive in 78% of dysplasia and 91% of cancer sites.

Expression of K-ras protein

The positive reaction to K-*ras* protein seen in cytoplasm was observed in 33% of hyperplasia sites and 67% of dysplasia sites, but not in normal tissue in the pancreatic cancer patients. The positive staining to K-*ras* was in 80% of cancer tissue. The character and intensity in staining was not proportional to the differentiation of cancer. In chronic pancreatitis, K-*ras* was expressed in 67% of dysplasia, but not in normal sites. Overall, K-*ras* was expressed in 33% of pancreatic duct hyperplasia, 67% of dysplasia and 80% of cancerous sites, but no expression of K-*ras* could be detected in any normal sites.

DISCUSSION

It is generally accepted that three to seven accumulated mutations might be required for a normal cell to transform into a neoplastic cell[11]. A famous example of multistep development of malignancy has been reported in colorectal carcinoma[12], and similar multiple mutational steps seem to be associated in the development of pancreatic cancer[13]. Chronic pancreatitis is accepted as a precancerous lesion of pancreatic cancer, although a detailed mechanism regarding this is yet to be delineated. Several possible mechanisms have been proposed. There has been a study suggesting that ductal hyperplasia might play an important role[6,8]. Unfortunately, this hypothesis is hard to be tested since ductal hyperplasia could not be objectively determined on general means of pathological examination. Moreover, morphologically and functionally different kinds of pancreatic tissue tend to be mixed together which makes statistical analysis difficult. All these problems are partly due to the ambiguous pathologic terms and definitions; for example, the pancreatic duct hyperplasia, dysplasia, atypical ductal hyperplasia, intraductal tumor, carcinoma *in situ*, adenomatous hyperplasia, and atypical adenomatous hyperplasia[7,14].

In the present study, we only used the term, hyperplasia and dysplasia, since there are similar lesions, morphologically and cytologically, in other parts of the gastrointestinal tract. In order to objectively determine pancreatic duct hyperplasia, we used Ki-67 proliferation index. In evaluation of atypical hyperplasia, we used CEA immunohistochemical study.

The p53 gene is a tumor suppressor gene that involves regulation of the cell cycle and its mutation is most common in human cancers[15]. Mutated p53 in tumor cell accumulates nuclear p53 proteins and this overexpression is used as a marker for immunohistochemical staining[15,18]. It is reported that mutation of p53 has been reported to be detected in at least 50-70% of pancreatic adenocarcinoma[15-17]. In this study, p53 overexpression was most frequently shown in the cancerous lesion, rarely in the dysplastic cells and not at all in hyperplastic and normal cells. Therefore, it seems that the overexpression of p53 is implied to be the last phenomenon in the tumorigenesis. The fact that overexpression of p53 is shown more frequently in cancer tissues, regardless of the cell differentiation, suggests that it would be a useful marker in detecting activated dysplasia from well-differentiated cancer.

$P21^{K\text{-}ras}$ protein, synthesized by K-*ras* gene, accumulates in the cytoplasm[12], and found to be strongly stained in cytoplasm of most of the cancer cells[19]. The pancreas cancer originated from the exocrine gland showed 75-95% incidence of K-*ras* activation[20-24]. High incidence of K-*ras* mutation in pancreatic cancer implicates that this mutation might be a basic step of carcinogenesis. However, the earliest pancreatic lesion in which K-*ras* mutation can be found is not clearly known. As for the reports on the detection of K-*ras* mutation in the hyperplastic pancreatic duct of chronic pancreatitis patients, there have been some discrepancies. The current study immunohistochemically examined oncogene protein expressions in various pancreatic lesions. Although the presence of mutated gene needs to be confirmed at the molecular level, we found the possible continuity between pancreas diseases through protein expressions of oncogene. K-*ras* was strongly and frequently expressed in dysplastic and cancerous tissues compared with that of hyperplastic tissue. These results indicate that the overexpression of K-*ras* is associated with the pancreatic duct dysplasia in the carcinogenesis. Results in chronic pancreatitis were also similar to pancreatic cancer, suggesting that ductal dysplasia may be the precancerous lesion.

In our study, we found the possibility of the existence of stepwise mutation in the progression of advanced cancer from normal pancreatic cell. First, in the pancreatic cancer tissues, we found tissues presumed to be precancerous lesion, histologically different from normal epithelial cells. Second, this premalignant lesion was found more frequently in the tissues of pancreatic cancer compared with that of other disease states. Third, in the dysplastic and cancer tissues, the excessive expression of oncogene product was shown more frequently than in normal tissues. Fourth, K-*ras* protein overexpression developed in earlier stage of carcinogenesis, while the overexpression of p53 protein mostly occurred in advanced steps such as dysplasia or cancer. Finally, in chronic pancreatitis, some hyperplastic and dysplastic tissues showed the overexpression of oncogenic proteins similar to pancreatic cancer, although at low percentage. Therefore, chronic pancreatitis patients with protein overexpression of oncogene would have higher risk of cancer. Consequently, these results suggest that there is a correlation between the protein overexpression by genetic alteration and histological changes. Although we investigated mutation of only two important genes using low-sensitive immunohistochemical staining method, we believe that this study would be useful in the future

researches on the pathogenesis of pancreatic cancer.

Abstract

AIM: To investigate the effect of IL-4 on the altered expression of complement activation regulators in pancreas and pancreatic necrosis during experimental severe acute pancreatitis (SAP).

METHODS: SAP model of rats was established by retrograde injection of 5% sodium taurocholate (1 mL/kg) into the pancreatic duct. We immunohistochemically assayed the expression of three complement activation regulators: decay accelerating factor (DAF; CD55), 20 ku homologous restriction factor (HRF20; CD59) and membrane cofactor protein (MCP; CD46), in the pancreatic acinar cells of rats at 0, 3, 6, 12, and 24 h after the induction of SAP model. Meanwhile the levels of amylase and lipase were determined, and morphological examination was performed. Then, 61 rats were randomly divided into three groups. Group A (n = 21) received no treatment after the SAP model was established; group B (n = 20) was given IL-4 (8 μg/animal) intraperitoneally 0.5 h before the SAP model was established; group C (n = 20) was given IL-4 (8 μg/animal) intraperitoneally 0.5 h after the SAP model was established. Plasma amylase and lipase, extent of pancreatic necrosis and expression of complement activation regulators were investigated 6 h after the induction of SAP model.

RESULTS: Three complement activation regulators were all expressed in pancreatic acinar cells. MCP was not found on the basolateral surface as reported. Contrary to the gradually increasing plasma level of amylase and lipase, expression of complement activation regulators decreased after SAP model was set up. At the same time, the severity of pancreatic necrosis was enhanced. A strong negative correlation was found between the expression of MCP, DAF, CD59 in pancreatic acinar cells and the severity of pancreatic necrosis (r = –0.748, –0.827, –0.723; P<0.01). In the second series of experiments, no matter when the treatment of IL-4 was given (before or after the induction of SAP model), the serum level of amylase or lipase was decreased and the extent of pancreatic necrosis was ameliorated significantly. Compared to SAP control group, the expression of DAF and CD59 in pancreas was reinforced when IL-4 was given before the induction of SAP model (P<0.01, P<0.05), but the expression of MCP was not influenced (P>0.05). The expression of DAF was enhanced, when IL-4 was given after the induction of SAP model (P<0.05), but the expression of CD59 and MCP did not change (P>0.05).

CONCLUSION: Complement activation regulators may participate in the pathogenesis of pancreatic inflammation. Downregulation of complement activation regulators expression may be one of the causes of pancreatic necrosis. IL-4 treatment may control SAP aggravation by enhancing expression of DAF and CD59 in pancreas and decreasing pancreatic necrosis. Moreover, DAF and CD59 may play an important role in the regulation of complement activation regulators during SAP.

INTRODUCTION

During activation of complement, fragments of complement proteins may be deposited on non-target cells[1], thereby causing tissue injury. In order to prevent this, several proteins on cell membranes inhibit the activation of the complement cascade[2]. These proteins include decay accelerating factor (DAF; CD55) which inhibits the formation of C3 and C5 convertases and promotes their catabolism[3,4], 20 ku homologous restriction factor (HRF20; CD59) which inhibits the formation

of terminal complement complexes by preventing the polymerization of C9 on C5b-8[5,6], and membrane cofactor protein (MCP; CD46) which functions as a cofactor in the factor I-mediated inactivation of C3b and C4b[7]. These proteins, which are widely distributed in normal tissues[8-10], are thought to protect host tissues from autologous complement-mediated damage.

Expression of these three proteins has been described in the gastrointestinal tract of human beings[11-14]. In normal colonic and gastric mucosa, DAF and CD59 have been found only on the apical surface of epithelial cells, whereas MCP is localized on the basolateral surface of these cells[11,13-15]. In patients with ulcerative colitis (UC) and chronic gastritis, the expression of DAF in colonic and gastric epithelial cells was markedly enhanced and was proportional to the severity of mucosal inflammation[14,15]. Expression of these complement activation regulators has not been assayed in more severe types of inflammation. Being one of the main causes of pancreatic necrosis, activation of complement in the process of SAP has been proved by other authors[16,17]. We therefore examined the distribution of DAF, CD59, and MCP in pancreatic acinar cells and the relationship between the expression of these proteins and the severity of pancreatic necrosis during SAP. In addition, we investigated the therapeutic effects of IL-4 on the expression of complement activation regulators and pancreatic necrosis in order to clarify the role of IL-4 and three membrane inhibitors of complement during SAP.

MATERIALS AND METHODS

Animals and model of severe acute pancreatitis

Male Wistar rats (250-300 g) were used in this study. Animals were allowed to have free access to water before the experiment. Anesthesia was induced with an intraperitoneal injection of 6% sodium pentobarbital (Northeast Drug Manufactory, China) (0.1 mL/100 g body weight). After midline laparotomy and transduodenal cannulation of the pancreatic duct, the hepatic duct was closed by a small bulldog clamp, and then 5% sodium taurocholate (Sigma, USA) in saline was infused at a rate of 0.1 mL/min. Control animals received an infusion of 0.9% saline solution.

Experimental design

In the first series of experiments, animals were killed at 3, 6, 12, and 24 h after the induction of pancreatitis (n = 10 per group). Pancreatic tissues were removed and processed as indicated below.

In the second series of experiments, to test the effect of IL-4 on complement activation regulators, 61 rats were randomly divided into three groups. Group A (n = 21) received no treatment after the SAP model was established, group B (n = 20) was given IL-4 (Peprotech, UK) (8 μg/animal)[18-20] intraperitoneally 0.5 h before the SAP model was established, group C (n = 20) was given IL-4 (8 μg/animal) intraperitoneally 0.5 h after the SAP model was established. Animals were killed at 6 h after the induction of pancreatitis model.

Pancreatic tissue was immediately frozen in liquid N_2 and embedded in OCT embedding medium. All blood samples were centrifuged at 3 000 r/min for 5 min. Supernatant was stored at -70 ℃.

The serum levels of amylase and lipase were determined by a colorimetric kinetic method and nephelometry method respectively.

Tissue immunohistochemistry staining

Cryostat sections were serially cut at 6 μm, and fixed in acetone for 10 min. After being washed with phosphate-buffered saline (PBS), the sections were treated with 30 mL/L H_2O_2 for 15 min at room temperature to inactivate endogenous peroxidase, and then with a 1:10 dilution of non-immune goat serum for 20 min to block non-specific immunoglobulin binding sites. After the excess serum was blotted, the sections were incubated with each of the primary antibodies (dilution 1:150 in PBS) [MCP (sc-7056), DAF (sc-9156), CD59 (sc-9157), Santa Cruz, USA] for 2 h at room temperature, control sections were incubated with PBS. Unbound antibody was washed from the tissue thrice in PBS for 5 min, incubated with the secondary biotin-labeled goat anti-mouse IgG antibody for 20 min, and then washed thrice for 5 min with PBS. Subsequently, the sections were incubated with peroxidase-labeled streptavidin-biotin for 20 min (ABC kit; Boster, Wuhan, China). After being washed with PBS for four times, the sections were stained with 0.02% (w/v) 3,3'-diaminobenzidine tetrahydrochloride (Boster, Wuhan, China). The sections were counterstained with hematoxylin, washed with PBS, dehydrated in graded concentrations of ethanol, and mounted.

Vascular endothelial cells were used as a positive control for DAF, MCP, and CD59. Expression of complement activation regulators in pancreatic acinar cells was scored on a scale of (-) to (+3)[15], where (-) denotes faint or no staining; (1+) specific staining in 10-50% of cells; (2+) specific staining of 50-90% of the cells; (3+) specific staining of 90-100% of cells.

Evaluation of pancreatitis severity

The extent of pancreatic acinar cell necrosis was quantitated morphometrically by an observer who was not aware of the sample identity, as described by Kusske *et al.* [21]. For these studies, cryostat sections were stained with hematoxylin and eosin. Ten randomly chosen microscopic fields (×200) were examined for each tissue sample, and the extent of acinar cell injury/necrosis was expressed as a percentage of total acinar tissue.

Statistical analysis

Data were presented as mean±SE. Differences between groups were compared using analysis of variance followed by Student's t-test. Correlation between the expression of complement activation regulators and pancreatic necrosis was analyzed using Spearman's rank correlation test. Correlation between IL-4 intervention and the expression of complement membrane inhibitors was analyzed using

the χ^2-test. P<0.05 was considered statistically significant.

RESULTS

Serum levels of amylase and lipase

Tables 1 and 3 summarize the changes of serum amylase and lipase activities in experiments 1 and 2.

Evaluation of morphology

In the first series of experiments, the morphological changes varied with the time elapsed after sodium taurocholate injection. By gross examination, the ductal tree became hemorrhagic immediately after injection, and the whole pancreas became edematous and brownish red in color within the next 5-10 min. As time elapsed, edema, hemorrhages, acinar cell necrosis (Table 1), amount of ascitic fluid and inflammatory cell infiltration aggravated gradually. At 24 h, the color of pancreas was pale and slightly yellowish. Many animals had marked distension of the stomach.

In the second series of experiments, pancreatic necrosis was significantly reduced, when IL-4 was administered either prophylactically or therapeutically (P<0.01), (Table 3).

Expression of complement activation regulators

At the microscopic level, we observed the expression of DAF, CD59, and MCP on the luminal surface of pancreatic acinar cells. We did not find positive staining of MCP on the basolateral surface of pancreatic acinar cells, though staining for MCP was positive on the basolateral surface of gastric and colonic epithelial cells[14,15]. Although DAF, CD59, and MCP were well recognized as membrane binding proteins, immunostaining of these proteins was also detected in the cytoplasm[15]. No staining was observed when samples were treated with control PBS. Expression of complement activation regulators decreased gradually after SAP model was set up. We also examined the relationship between the expression of three complement inhibitors and the pancreatic necrosis. We found a strong negative correlation between the expression of MCP, DAF, and CD59 in pancreatic acinar cells and the severity of pancreatic necrosis (r = -0.748, -0.827, and -0.723; P<0.01), (Table 2). In the second series of experiments, compared to SAP control group, the expression of DAF and CD59 in pancreas was reinforced when IL-4 was given before the induction of SAP model (P<0.01, P<0.05), but the expression of MCP was not influenced (P>0.05). The expression of DAF was enhanced when IL-4 was given after the induction of SAP model (P<0.05), but the expression of CD59 and MCP did not change (P>0.05) (Table 4).

DISCUSSION

Severe acute pancreatitis is a common acute abdominal disorder. Since angiorrhexis and hemorrhage in pancreas are frequent during severe acute pancreatitis, and the complement system is activated by trypsin[16,17], it is possible that inflammation may result in constant exposure of pancreatic acinar cells to activated complement

fragments in the blood. Then, severe pancreatic necrosis is inevitable. Being the membrane inhibitors, complement activation regulators in the acinar cells may be important for local defense system during SAP. We investigated the role of RCA in the process of SAP and then attempted to attenuate inflammatory reaction by regulating the expression of complement activation regulators.

It has been reported that expression of DAF on gastric epithelial cells and colonic epithelial cells is strongly enhanced during gastritis and ulcerative colitis, and a strong positive correlation between DAF expression and degree of inflammation (extent of inflammatory cell infiltration) has been found[14,15]. At the same time, other researches revealed that expression of MCP and CD59 in alveolar epithelial cells is conspicuously enhanced during acute lung injury, but is greatly decreased during acute respiratory distress syndrome[22]. These results suggest that complement activation regulators play a different role in these inflammatory diseases.

We utilized immunohistochemical methods to assay the expression of DAF, CD59, and MCP in normal and pathological pancreatic specimens. We found that MCP, DAF, and CD59, which are glycosyl phosphatidylinositol (GPI) anchored membrane proteins, were present on the apical side of pancreatic acinar cells[23], whereas MCP, a transmembrane protein, was not distributed in these cells as in epithelial cells of the colonic and gastric mucosa[14,15]. While complement activation regulators were slightly or moderately expressed in the acinar cells of normal pancreatic tissue, their expression in pancreatic acinar cells decreased gradually after the model of SAP was induced. These phenomena are similar to those in ARDS[22]. Although there are differences in the inflammatory process between pancreatic and pulmonary epithelial cells, the lower expression of complement activation regulators detected in the inflammatory cells suggests that complement activation regulators play an important role in the regulation of complement activation in epithelia during severe inflammation. In this study, a strong negative correlation was observed between the expression of complement activation regulators and inflammation (pancreatic necrosis). It is not clear, which of MCP, DAF, and CD59 is the most important factor in the regulation of complement activation during SAP. Although the precise mechanism by which the repression of complement activation regulators is regulated remains to be elucidated, it is clear that these proteins are important in the regulation of the inflammatory process of the pancreas.

In general, the expression of membrane inhibitors of complement is mediated by various cytokines[24-27]. Being an anti-inflammatory mediator, IL-4 has been proven to enhance the expression of DAF in small intestine epithelial cells and vascular endothelial cells *in vitro*[24-28]. We applied IL-4 to rats with severe acute pancreatitis to testify its therapeutic effects on the expression of complement activation regulators and pancreatic necrosis *in vivo*. We found that the expression of DAF and CD59 was upregulated when IL-4 was administered prophylactically (given before the model was established), but the expression of MCP did not change significantly. When IL-4 was administered therapeutically (given after the model was established), only DAF was upregulated. Compared to control group, the serum amylase and lipase activities and the extent of pancreatic necrosis were significantly reduced when IL-4 was administered either prophylactically or therapeutically. These findings suggest that activation of complement during severe acute pancreatitis may be mediated primarily by DAF and CD59, and IL-4 treatment may be a valuable strategy for severe acute pancreatitis. Considering the therapeutic value of IL-4, some other biological activities of IL-4 should be mentioned. It has been reported that IL-4 displays its anti-inflammatory feature by inhibiting the activation and accumulation of macrophages[29], preventing the production of TNF-α and IL-1β[30], upregulating the expression of IL-1 receptor antagonist[31], stimulating 15-lipoxidase activity of macrophages[32]. These functions are important to control systemic inflammation reaction that is common during SAP.

In conclusion, complement activation regulators may play an important role in the regulation of complement activation, and downregulation of complement activation regulators may be one of the causes of pancreatic necrosis. IL-4 treatment provides a new therapeutic strategy for controlling systemic inflammatory reaction during severe acute pancreatitis.

Abstract

AIM: To detect the DNA binding activity of nuclear factor-kappaB (NF-κB) in rat hepatocyte and to investigate the effects of NF-κB on rat hepatocyte regeneration and apoptosis after 70% portal branch ligation.

METHODS: Sixty Wistar rats were randomly divided into control group and portal branch ligation group. The animals were killed 12 h, 1, 2, 3, 7, and 14 d after surgery to determine the contents of plasma ALT. Hepatocytes were isolated and nuclear protein was extracted. DNA binding activity of NF-κB was measured by EMSA. Hepatocyte regeneration and apoptosis were observed under microscope by TUNEL staining. The ultrastructural changes of liver were observed under electron microscope.

RESULTS: Seventy percent portal branch ligation produced atrophy of the ligated lobes and the perfused lobes underwent compensatory regeneration, the total liver weight and plasma ALT levels were maintained at the level of sham-operated animals throughout the experiment. After 2 d of portal branch ligation, DNA binding activity of NF-κB in hepatocyte increased and reached its peak, the number of apoptotic hepatocyte in the ligated lobes and the number of mitotic hepatocyte in the perfused lobes also reached their peak. Typical apoptotic changes and evident fibrotic changes in the ligated lobes were observed under electron microscope.

CONCLUSION: After 70% portal branch ligation, DNA binding activity of NF-κB in hepatocyte is significantly increased and NF-κB plays an important role in hepatocyte regeneration and apoptosis.

INTRODUCTION

Portal branch ligation (PBL) or embolization is widely used in the treatment of liver carcinoma, especially in the treatment of patients who have already missed the surgical opportunity[1-3]. PBL or embolization could produce atrophy of the ligated lobes and the perfused lobes undergo compensatory regeneration, while the liver structure and function maintained normal. But the mechanism is still unclear.

It is demonstrated that nuclear factor-kappaB (NF-κB) plays an important role in cell regeneration and apoptosis after partial hepatectomy[4-6]. To study its effects on hepatocyte regeneration and apoptosis, we observed the changes of DNA binding activity of NF-κB in rat liver and its relations to hepatocyte regeneration and apoptosis after 70% PBL.

MATERIALS AND METHODS

Animals

Sixty Wistar rats, weighing 200-240 g, were obtained from the Animal Center of the Third Military University and used in all experiments. All animals were kept in a temperature- and humidity-controlled environment in a 12-h light/dark cycle and allowed free access to water and standard food-pellet diet.

Surgical procedure and experimental design

All surgical procedures were carried out under sodium pentobarbital (40 mg/kg intraperitoneally) anesthesia at room air between 9:00 and 12:00 a.m. with a clean but not sterile technique. The 70% PBL model used was based on the Bilodeau method[7]. In 70% PBL, a median laparotomy was performed, and the branch of the portal vein feeding the anterior and lateral lobes was carefully dissected under

an operating microscope and completely ligated with a 7-0 suture. Care was taken not to injure the hepatic artery and the bile duct and to avoid hemorrhage. In sham-operated rats, a laparotomy followed by dissection of the relevant ligaments without ligature was performed. The animals had free access to water and food after surgery. The animals were killed 12 h, 1, 2, 3, 7, and 14 d after surgery.

Electrophoretic mobility shift assay

Nuclear extracts were prepared separately from the anterior (ligated) and posterior (nonligated) lobes as previously described[8]. Protein concentration was determined using the Bradford method. Double-stranded NF-κB consensus oligonucleotides (5'-AGT TGA GGG GAC TTT CCC AGG C-3', 3'-TCA ACT CCC CTG AAA GGG TCC G-5', Promega Co., USA) were end-labeled[5] with [γ-^{32}P] ATP (Beijing Yahui Biomed Inc., Beijing, China) using T4 polynucleotide kinase (Promega Co.). After the probe was purified, 5 μg of nuclear proteins was preincubated for 10 min at room temperature with 2 μg poly (dI-dC) (Sigma Co., USA) in the binding buffer. Double-stranded oligonucleotides were ^{32}P end-labeled with [γ-^{32}P] ATP and added to the extracts. The mixture was further incubated for 30 min at room temperature and then electrophoresed (200 V, 2 h) on a 5% polyacrylamide gel in a 0.5× TBE buffer. Then the gel was subjected to gamma autoradiography at -70 ℃ for 12 h, and analyzed with gel imaging system (Biorad Co., USA).

Liver morphologic structure

The rat liver color and quality were observed. Both ligated and nonligated lobes were weighed separately for measurement of their absolute and relative weights (the ratio of liver weight/body weight), and their percent in the whole liver was calculated.

Serum ALT level

Serum ALT level was measured with the biochemical multi-analyzer in Biochemistry Department of our hospital.

Histological studies and mitotic activity

Liver sections were derived from formaldehyde-fixed tissues embedded in paraffin and stained with hematoxylin –phloxin–saffron. Mitotic activity in stained sections was determined. Mitotic hepatocytes were sought in 100 consecutive high-power fields (×400), and mitotic index was expressed as per 1 000 hepatic nuclei. Prophases before dissolution of nuclear membrane and late telophases were excluded.

In situ determination of hepatocyte apoptosis (TUNEL stain)

Tissue sections of rat liver were dewaxed in toluene and alcohol. After rehydration with phosphate-buffered saline, they were incubated with proteinase K (25 μg/mL) for 15 min at room temperature and then with terminal deoxyribonucleotidyl transferase (1 U/mL) and digoxigenin-tagged dUTP (10 μmol/L) at 37 ℃ for 1 h in 0.2 mol/L sodium cacodylate, 30 mmol/L Tris (pH 7.2), 1 mmol/L $CoCl_2$, and 0.25 mg/mL bovine serum albumin. The sections were exposed to anti-digoxigenin antibodies labeled with alkaline phosphatase for 30 min at room temperature in 50 mmol/L Tris (pH 7.4) and 150 mmol/L NaCl. The binding of the antibody was revealed with 4-nitroblue tetrazolium chloride and 5-bromo-4-chloro-3-indolyl-phosphate reagents. Slides were counterstained with 1% eosin.

Ultrastructural study

The rat liver was cut into sections as large as 1 mm× 1 mm×1 mm, which were embedded in Epon618 resin and stained with uranyl acetate and lead citrate. H-2000 transmission electron microscope was used to study the ultrastructure.

Statistical analysis

Results were expressed as mean±SD. The statistical difference between the groups was tested using the one-way analysis of variance (ANOVA). $P<0.05$ was considered statistically significant.

RESULTS

Activation of NF-κB in hepatocyte after 70% PBL

After 12 h of 70% PBL, DNA binding activity of NF-κB both in ligated and nonligated lobes increased and reached its peak on d 2, and returned to normal on d 7. The changes of DNA binding activity of NF-κB in the ligated lobes were more obvious than those in the perfused lobes. No NF-κB binding was observed in nuclear extracts from control animals (Figure 1).

Changes in liver morphologic structure

The liver lobes deprived of portal flow were darkened, rapid and progressive atrophy occurred, with their proportion being reduced gradually in the whole liver. At the same time, the nonligated lobes were progressively enlarged, the total liver weight was maintained at the level of sham-PBL controls at each time interval (Figure 2A).

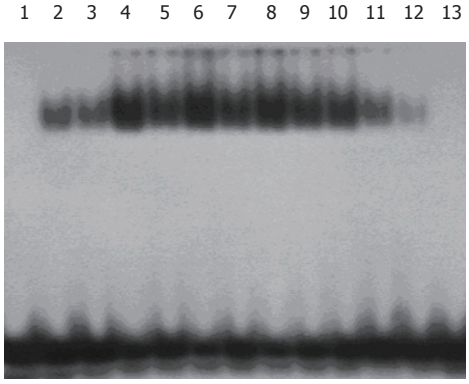

Figure 1 Changes of NF-κB binding activity in rat liver at different time points after 70% PBL by EMSA. Lane 1: control group; lanes 2, 4, 6, 8, 10, 12: 0.5, 1, 2, 3, 7, 14 d ligated liver lobes in PBL group; lanes 3, 5, 7, 9, 11, 13: 0.5, 1, 2, 3, 7, 14 d nonligated liver lobes in PBL group.

Changes in serum ALT level

There were no changes of serum ALT level in control group. After 70% PBL, the serum ALT level only increased slightly 1 d after surgery and then returned to normal (Table 1).

Table 1 Changes of serum ALT level after 70% PBL (U/L) (mean ± SD)

Group	0.5 d	1 d	2 d	3 d	7 d	14 d
Control	55.6±8.9	43.7±10.4	38.5±7.8	40.1±9.4	36.4±11.3	42.0±13.7
PBL	59.7±17.3	67.9±15.7[a]	44.6±9.8	42.6±7.8	38.9±12.1	41.3±7.9

[a]$P<0.05$ *vs* control group.

Histological studies and mitotic activity quantification

No apparent changes were found at light microscopic examination in the control liver. One day after 70% PBL, mild necrosis was found in the ligated lobes, mainly around the central vein. The cytoplasm was homogenous, and the nuclear pyknosis inside the necrosis and neutrophils was seen in some lesions. After 3 d, the necrosis was partly resorbed, and many monocytes were seen inside them. The lobules were small, with portal areas lying near each other. One to two weeks after ligation, the necrosis was completely disappeared, and the lobules became small. Fibrosis appeared around larger portal and hepatic veins, and bile ducts were collapsed with low epithelium.

Remarkable hepatocyte regeneration was observed in the nonligated lobes 12 h after 70% PBL and reached its peak 2 d later, and was still high after 7 d. The liver structure was almost normal (Figure 2B).

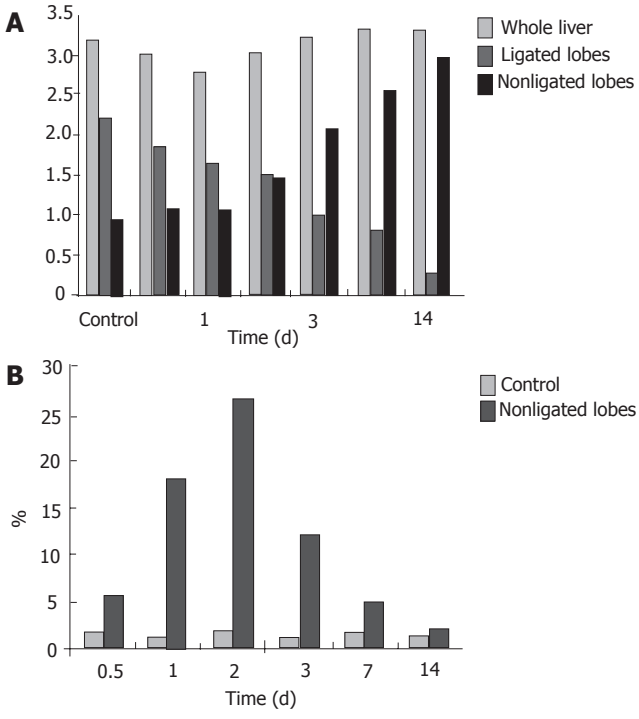

Figure 2 Changes in weight of rat liver (**A**), Changes of mitogenetic index of rat hepatocyte (**B**) after 70% PBL.

Hepatocyte apoptosis assay

There were only few apoptotic hepatocytes in the liver of control animals and in the nonligated lobes after 70% PBL. Many apoptotic hepatocytes were found in the ligated lobes 1 d after 70% portal branch ligation, and reached its peak 2 d later. These cells were mainly present around the central veins with necrosis (Figures 3A-E).

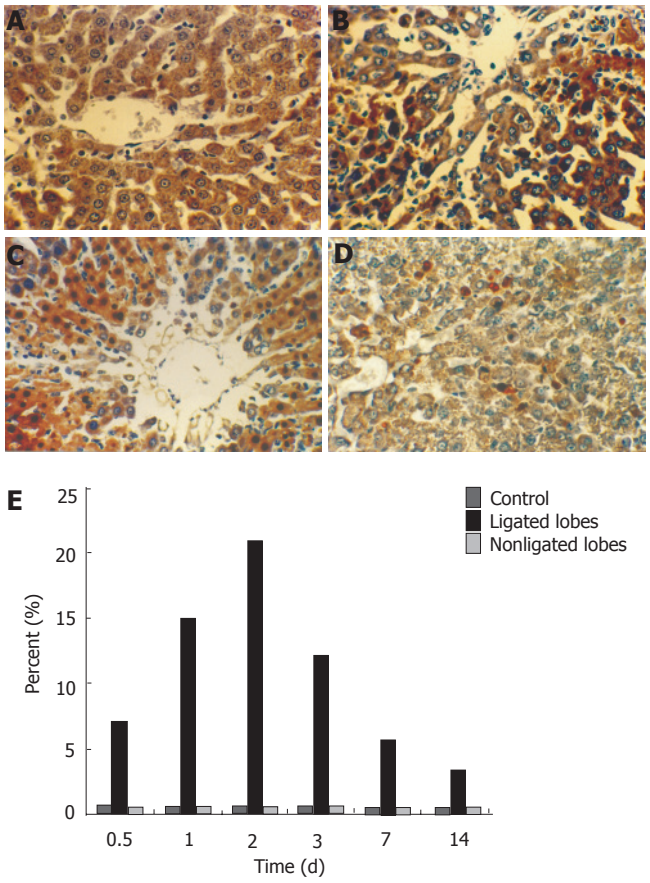

Figure 3 Apoptotic hepatocytes in control group (**A**), in rat ligated liver lobes 1 d (**B**), 2 d (**C**), 7 d (**D**), and hepatocyte apoptotic index (**E**) after 70% PBL.

Ultrastructural changes

The liver ultrastructure was normal in control animals and was almost normal in the ligated lobes early after 70% PBL, and only wild necrosis was found in some local areas. One day after 70% PBL, many apoptotic hepatocytes were found in the ligated lobes. Histological evidence for apoptosis included disappearance of the nuclear membrane, condensation, and margin of karyoplasms or chromatin, pieces of nuclei. There were no morphological changes in the mitochondriae and other intracellular structures (Figure 4). A number of apoptotic hepatocytes reached its peak 2 d later. Collagen was deposited in the Disse space and hepatic sinus became narrow 7 d after 70% PBL. Evident fibrotic changes were found in the ligated lobes 14 d after 70% PBL. A lot of collagens were deposited in the Disse space and portal areas, between hepatocytes and in hepatocytes.

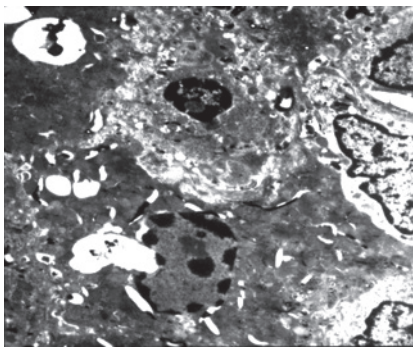

Figure 4 Ultrastructure of rat ligated liver lobes 2 d after 70% PBL (EM ×6 000)

DISCUSSION

PBL or embolization is widely used in the treatment of liver carcinoma, especially in the treatment of patients who have missed the opportunity of surgery[1-3]. It was verified in our experiment that PBL could produce atrophy of the ligated lobes, whereas the perfused lobes underwent compensatory regeneration, the liver structure and function maintained normal. Therefore, it is safe and practicable to ligate 70% portal vein branch in normal rat liver.

The 70% PBL could produce atrophy of the ligated lobes through hepatocyte apoptosis; whereas the perfused lobes undergo compensatory regeneration through hepatocyte mitosis. The total liver weight and function maintained normal. The mechanism of rat liver is still unclear. We observed the changes of DNA binding activity of NF-κB in liver through EMSA. After 70% PBL, DNA binding activity of NF-κB significantly increased both in ligated lobes and nonligated lobes, which was positively correlated with hepatocyte regeneration and apoptosis. Therefore, we could conclude that NF-κB plays an important role in hepatocyte regeneration and apoptosis after 70% PBL.

NF-κB, as a universal nuclear transcriptional factor, plays an important role in the regulation of genes relative to cell regeneration and apoptosis[9,10]. In most cells, NF-κB heterodimers are present in the cytoplasm forming an active complex by interacting with the IκB family of proteins. In response to a variety of activators, IκB-α, the prototypic member of this family of inhibitors, is phosphorylated at series 32 and 36, rendering the factor susceptible to proteolysis via the ubiquitin–proteasome pathway. This event unmasks a nuclear localization sequence of the transactivating heterodimers, allowing NF-κB translocation to nuclei. Therefore, the complex binds to κB consensus motifs in DNA, upregulating the transcription of many genes[11-14].

NF-κB plays an important role on hepatocyte regeneration in nonligated lobes by inhibiting hepatocyte apoptosis and accelerating hepatocyte regeneration. NF-κB can inhibit hepatocyte apoptosis by regulating relative cytokine transcription and expression[15-17], inducing antiapoptotic genes in Bcl-2 family[18], regulating the expression of TRAF and IAP at transcription and translation level and inhibiting the activation of caspase-8, a key enzyme in cell apoptosis[19-21], activating the apoptotic inhibitors[22,23]. NF-κB, which takes part in hepatocyte regeneration, may be mediated by regulating the transcription and expression of relative genes. NF-κB can activate the transcription and expression of TNF-α, increased TNF-α can stimulate secretion of IL-6, which can activate STAT3 through combining with IL-6R on the surface of hepatocyte, and accelerate hepatocyte regeneration[24-27].

We observed that the changes of DNA binding activity of NF-κB in the ligated lobes were more obvious than those in the perfused lobes. One reason is that compensatory response to the excessive hepatocyte apoptosis could maintain the relative weight and function of the liver. The other reason is that NF-κB plays an important role in accelerating hepatocyte apoptosis. Kuhnel *et al*.[28] reported that NF-κB mediates hepatocyte apoptosis through transcriptional activation of Fas (CD95) in adenoviral hepatitis. Recently the induction of NF-κB through the double-stranded RNA-dependent protein kinase has been suggested as a principal mechanism of virus-mediated apoptotic cell death[29].

In conclusion, NF-κB plays a completely different role in the ligated lobes and nonligated lobes through different stimulating factors and different signal transduction pathways. This may have important significance in maintaining liver structure and function after 70% PBL.

Abstract

AIM: To investigate the effects of four different ingredients of zedoary (Curcuma aromatica oil, Curcumol, β-elemence, and Curcumin) on the gene expressions of hepatic stellate cells (HSCs), and to explore the molecular mechanism of zedoary against hepatic fibrosis at gene network level.

METHODS: We detected the mRNA sequences of 50 liver fibrosis-related genes in GenBank and designed oligonucleotide probes. We synthesized oligonucleotides with PE8909 DNA synthesizing instrument, and carried out oligonucleotide microarray with OGR-04 dropping instrument and aldehyded glass chip. Cultured HSC-T6 cells were treated with different concentrations of Colchicine, Curcuma aromatica oil, Curcumol, β-elemence, and Curcumin. According to the experiment of cell toxicity, we took the appropriate concentrations of medicines that resulted in over 50% of cell survival as experiment concentrations. We collected the cells at 1, 6, 12, and 24 h, and extracted total RNA with TRIzol reagent, then labeled cDNAs with Cy3-dUTP and Cy5-dUTP. These labeled cDNAs were hybridized to an oligonucleotide microarray which was washed several times and scanned by scanner GenePix 4000B. Different gene expressions of HSC-T6 cells were analyzed by ImaGene 4.2 software.

RESULTS: After HSC-T6 cells were cultured in a medium containing 6.25 μg/mL Colchicine for 12 h, expression of TIMP-1 decreased 2.2-folds. After HSC-T6 cells were cultured in a medium containing 78.125 μg/mL of Curcuma aromatica oil for 24 h, the expression of TIMP-2 and IL-6 decreased 2.3- and 2.2-folds, respectively. Moreover, after HSC-T6 cells were cultured in a medium containing 1.5625 μg/mL of Curcumol for 12 h, the expression of TGFβ1 and P450a decreased 2.3- and 2.1-folds, respectively.

CONCLUSION: Our results may show the possible molecular mechanism of Curcuma aromatica oil and Curcumol against hepatic fibrosis.

Key words: DNA microarray; Curcuma aromatica oil; Curcumol; Hepatic stellate cells; Hepatic fibrosis

INTRODUCTION

In the past 10 years or more, great progress has been made in treating liver fibrosis with Chinese herbal medicines such as compound 861[1] and Fuzheng Huayu Decoction[2] and Tidu Hugan Decoction[3] as well as single herbal medicines as red sage root, zedoary, Chinese caterpillar fungus, hanfangchin A, extracts from peach seeds. Although many medicines can be used to treat liver fibrosis, effective medicines are still hard to find. Herbal medicines have the characteristics of multiple targets and poly-functioning routes, but genes in the organisms alone form a strict and complicated network. Therefore, study of herbal medicines should focus on the molecular mechanism at the level of genetic network based on the integral bio-system. Genetic chip technology is characterized by high communication, low consumption and miniaturization, thus providing a technological platform to study the mechanism of herbal medicines against liver fibrosis[4].

We found that zedoary could inhibit the proliferation of hepatic stellate cells (HSCs). Curcumin can be used to treat inflammation and tumors and Curcuma aromatica oil functions as an anti-inflammation, anti-virus, anti-tumor and anti-thrombus agent. Now more than 20 chemical ingredients such as Curcumol, Epicurzerenone, β-elemence, Camphene, Isoborneol, Borneol, Cineole, and 4-methyl-pyrazine have been identified from Curcuma

aromatica oil. It was reported that Curcumol and Elemence can function as anti-tumor and virus agents[5, 6]. Xi *et al*.[7] found that zedoary could protect hepatic cells against necrosis and degeneration as well as proliferation of fibrous tissues.

To study the molecular mechanism of zedoary against liver fibrosis, we used the genetic expression spectrum chips to represent 50 genes related to liver fibrosis and substituted HSC-T6 for original HSCs, and investigated the effects of four different ingredients of zedoary (Curcuma aromatica oil, Curcumol, β- elemence, Curcumin) on the gene expression of activated HSCs.

MATERIALS AND METHODS

Materials

Colchicine was purchased from American ALEXIS Co, Elemence injection and Curcumin were obtained from Jingang Pharmaceutic Corporation Ltd, Dalian, China. Curcumol and Curcuma aromatica oil were from Pharmaceutical University, Shenyang, China. HSC-T6 was provided by the Insititute of Hepatology, Shanghai University of Traditional Chinese Medicine and pharmacology. AXSys Probe Punctum-controlling software was purchased from Cartesian Technologies Co., and ImaGene 4.2 figure-analyzing softwares was from American Biodiscovery Co.

Preparatin of gene probes

Design of oligonucleotide probe Oligonucleotide probes were designed by the design software of oligonucleotide probe . The coding region near the 3 end was selected for BLAST analysis. One or two probes related to liver fibrosis whose homology was less than 70% were used as spare probes.

Synthesis of oligonucleotide Oligonucleotides were synthesized by the chemical method of standard subphosphorus imide using PE8909 DNA synthesizer. *N*-MMTr-6- ammonia-2-cyanogen-*N* and *N*-diisopropyl-subimide ammonia were modified by 5- or 3-amino-group. Dense ammonia was deprotected at 55 ℃ and incised for 15 h, and purified by ordinary portland cement column.

Preparation of probes In brief, 0.5 μg/μL oligonucleotide probe was resolved into 3×SSC solution, glass chip was aldehyded and stayed overnight, processed with 2 g/L SDS de-ion water for 10 min, and then dried for later use.

Preparation of medical culture medium Colchicine was dissolved in double-vaporing water to get the original solution (3.2 mg/mL). Curcumin was mixed with 950 mL/L alcohol to get the original solution (320 mg/L). Curcumol was mixed with 950 mL/L alcohol plus Tween-80 to get the original solution (3.2 mg/mL). Curcuma aromatica oil was mixed with Tween-80 (ratio, 1:10) plus 950 mL/L alcohol to get the original solution (2.5 mg/mL). Elemence injection (5 mg/mL) was used. All the medicines were filtrated through 0.45 micropores and stored at 4 ℃.

Culture of HSC-T6 cells

The ampoule was taken out of the liquid nitrogen jar (wearing protective glasses and gloves) and put into a porcelain enamel vessel containing 36-37 ℃ water with shaking. The pocket was cut and the ampoule was taken out, sterilized with 700 mL/L alcohol. The cell suspension was aspirated and put into centrifuge tube, then 10 mL culture medium was added, centrifuged for 5 min at 500-1 000 r/min and rinsed . The culture medium was changed on the next day.

Test of cytotoxicity (MTT assay[8])

The 96-well plates were incubated at 37 °C until HSC-T6 cells were grown in a single layer. The culture medium was incubated for 48 h, and then 5 mg/mL MTT was added and incubated for 48 h. The A value of the solution was tested in enzymatic marking instrument (wave length on the light-filtrating slice is 492 nm). According to the experiment of cell toxicity, we took the appropriate concentrations of medicines that resulted in over 50% of cell survival. The formula of cell survival rate: cell survival rate (%) = (medicine group/control group)×100%.

Incubation of HSC-T6 cells with medicines at different times

HSC-T6 cells were incubated with different concentrations of Colchicine, Curcuma aromatica oil, Curcumol, β-elemence, and Curcumin, followed by collecting them at 1, 6, 12, and 24 h, respectively.

Extraction and evaluation of cellular tRNA

Extraction of cellular tRNA HSC-T6 cells were washed softly with germ-free PBS. One-milliliter of TRIzol reagent was used to blow the cells and to make them dissolve completely. Then 0.2 mL of methylene trichloride was added, followed by centrifugation at 12 000 *g* for 15 min at 4 ℃. The supernatant was aspirated with 200 μL tip (dealt with DEPC) and moved to another EP tube. Then 0.5 mL of isopropylalcohol was added and put aside for 15 min, and centrifuged at 12 000 *g* for 10 min at 4 ℃. The RNA was washed with 750 mL/L alcohol (dealt with DEPC), and then 1 mL of 750 mL/L alcohol (dealt with DEPC) was added, centrifuged at 7 500 r/min for 5 min at 4 ℃, and stored at -20 ℃.

Evaluation of purity DEPC water was added to 2 μL of RNA to make a total volume of 100 μL. Ultraviolet spectrophotometer was used to measure the value of A_{260} and A_{280} as well as A_{260}/A_{280}. The formula of concentration of RNA: RNA (μg/μL) = A_{260}×40× dilution multiple/1 000.

Evaluation of integrity Five-microliter of RNA samples were put into 10 mL/L formaldehyde degeneration sepharose for cataphoresis, followed by painting with EB and examination under ultraviolet light.

Reverse transcription system and the labeling and purification of cDNA

Reverse transcription system and conditions Ten-microliter of TRNA (10 μg/μL), 0.3 μL of positive control, 4.0 μL of oligo (dT)16 (0.5 μg/μL) and 0.5 μL of

RNase inhibitor (40 U/μL) were mixed together, incubated for 10 min and then put into ice bath. Then 5.0 μL of 5× first chain buffer, 2.0 μL of DTT (0.1 mol/L), 1.0 μL of Cy3-dUTP or Cy5-dUTP (1 mmol/L), 0.5 μL of dTTP (10 mmol/L, and 0.1 μL of each dATP, dCTP and dGTP (100 mmol/L) were mixed together and incubated for 2 min at 42 ℃. Then 1.0 μL of SuperScript II RNase H-transcriptase (10 U/μL) was added and incubated for 2 h. Then 1.0 μL of RNaseH was added and incubated for 0.5 h at 30 ℃, followed by inactivation of anti-transcriptase at 70 ℃ for 15 min. Then 5.0 μL of NaOH (1 mol/L) was added and incubated at 65 ℃ for 1 h, followed by addition of 5.0 μL of 1 mol/L HCl (pH 6.8) and 6.0 μL of 5 mol/L NaCl. The sediment was stayed overnight at –20 ℃, centrifuged at 12 000 *g* for 10 min at 4 ℃. The supernatant was abandoned, the sedimentation was washed once with 750 mL/L alcohol and then dried, followed by resolving in 2 μL of aseptic water and stored at -20 ℃.

Evaluation of cDNA One-microliter of the above product of reverse transcription was put into 10 mL/L formaldehyde degeneration sepharose for cataphoresis, and then the quality of probes was evaluated.

Hybridization and wash

Two microliters of probes labeled by fluorescence were diluted to 8 μL for hybridization, and the hybridization liquor was moved onto the cover glass chip with the density of 2 μL/cm^2. The solution was put onto the carry sheet glass chip equally by the capillarity between cover glass chip and carry sheet glass chip. Then the glass chips were put into a hybridization box and 5 μL of 3× SSC was added to keep the humidity. The probe washing temperatures varied according to the different probes, usually under room temperature. The order of washing liquor was lotion A–C.

Analysis of data from fluorescence

After hybridization, the genetic chips were scanned by Scanner Genepix 4 000B, ImaGene4.2 was used to analyze the ratio of Cy3, Cy5 and the intensity of two kinds of fluorescence signals.Housekeeping gene and positive control were taken to balance the data of fluorescence of Cy3 and Cy5. Ratio of Cy3, Cy5>2 or <0.5 was used to evaluate the differences of genetic expression.

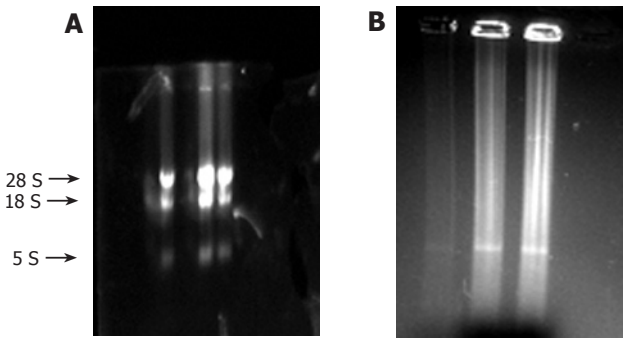

Figure 1 Influence of ingredients of zedoary on genetic expression of HSCs. **A:** tRNA formaldehyde degeneration; **B:** products of reverse transcription.

RESULTS

Effects of different medicines on the growth of HSCs

After treatment of HSC-T6 cells with different concentrations of Colchicine, Curcuma aromatica oil, Curcumol, β-elemence, and Curcumin for 48 h, along with deduction of the concentrations, the survival ratio of HSC-T6 increased.

Influence of four different ingredients of zedoary on the genetic expression of HSCs

RNA was put on 10 mL/L formaldehyde agarose gels for cataphoresis, and the results were recorded with gel photography. Three strips (28S, 18S, and 5S) can be seen in Figure 1A. After the analysis by software, the ratio of 28S and 18S was found to be between 1.5 and 2.0, showing that the RNA was integral and without degradation. Using ultraviolet spectrophotometer, the value of A_{260}/A_{280} was found to be between 1.7 and 2.0, showing that the RNA was pure and without protein pollution or phenol.

In addition, most of the cDNAs were observed between 0.5 and 2 kb (Figure 1B). Distribution of probes is shown in Table 1.

Hybridization

In the hybridization scanning figures of probes (Figures 2A, 3A, and 4A), the green spots represent the locations of downregulated genetic expression. ImaGene 4.2 software was used to analyze the intensity and ratio of Cy3 and Cy5. After correction of housekeeping gene and positive

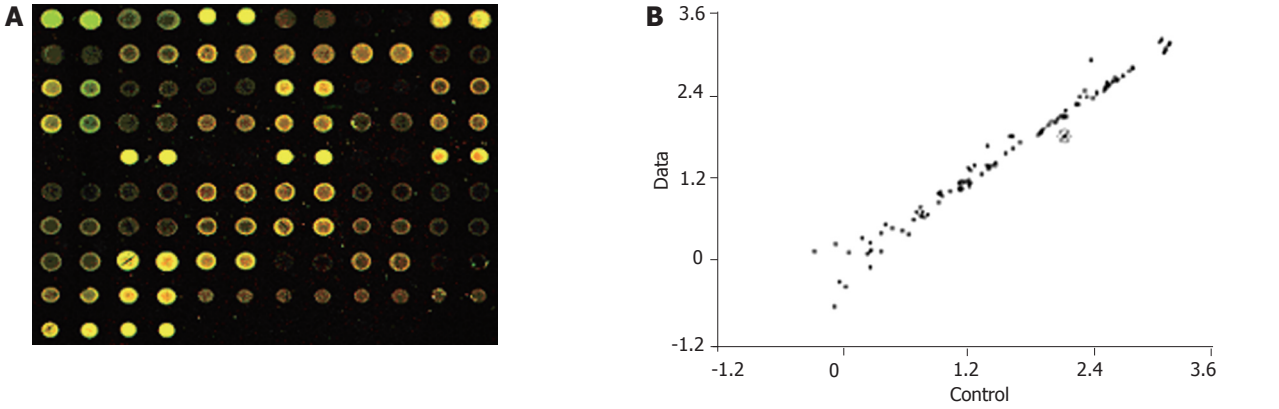

Figure 2 Effects of 6.25 μg/mL Colchicines on genetic expression of HSC-T6 cells after 12 h. **A:** Scanning diagram; **B:** scattering diagram.

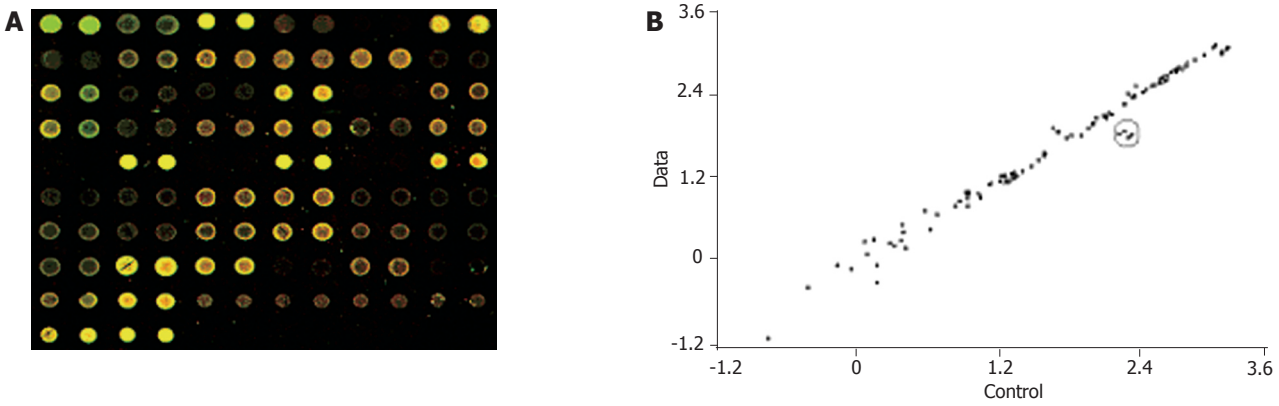

Figure 3 Effects of 78.125 μg/mL Curcuma aromatica oil on genetic expression of HSC-T6 cells after 24 h. **A:** Scanning diagram; **B:** scattering diagram.

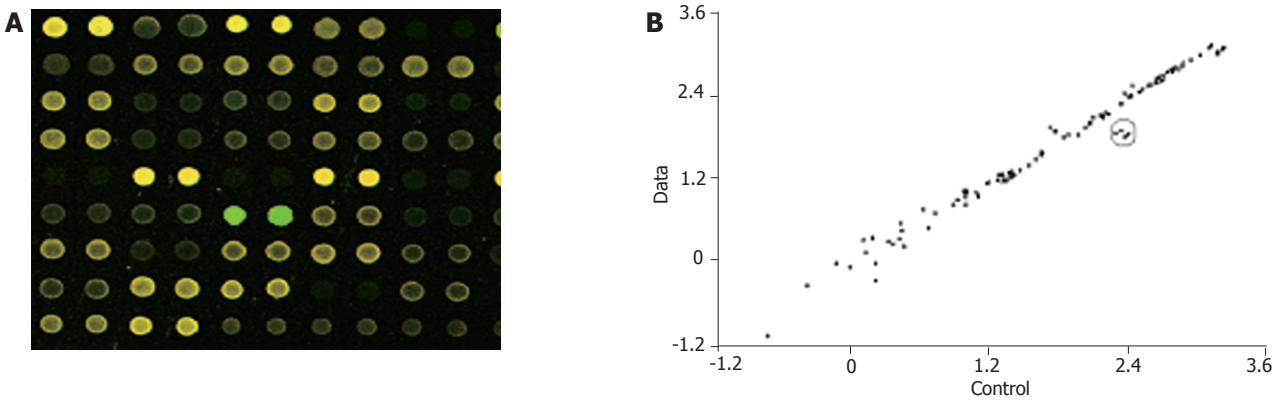

Figure 4 Effects of 1.5625 μg/mL Curcumol on genetic expression of HSC-T6 cells after12 h. **A:** Scanning diagram; **B:** scattering diagram.

control, the two conditions were taken to evaluate the difference of genetic expression as follows: (1) the ratio of Cy3 and Cy5 >2 or <0.5; and (2) one of Cy3 and Cy5 >1 000. In the scattering diagram (Figures 2B, 3B, and 4B), the spots on the opposite angles show that the intensity of two groups (treatment group and control group) was the same. The farther they depart from the opposite angles, the bigger the difference of genetic expression would be. The different effects of medicines on genetic expression are shown in Tables 2-4. After culture of HSC-T6 cells in a medium containing 6.25 μg/mL of Colchicine for 12 h, the expression of TIMP-1 decreased 2.2-folds, which was in agreement with a previous report[9], suggesting that the genetic probe testing system in the experiment was dependable. Furthermore, Figures 3 and 4 stand for the scattering diagram and the scattering diagram of Curcuma aromatica oil group and Curcumol group, respectively, and the data of analysis are shown in Tables 3 and 4.

Table 2 Genetic expression difference of HSC-T6 cells treated with Colchicines (6.25μg/mL) for 12 h

Gene	GenBank	Ratio
TIMP-1	U06179	2.20

Table 3 Genetic expression difference of HSC-T6 cells treated with Curcuma aromatica oil (78.125 μg/mL) for 24 h

Gene	GenBank	Ratio
TIMP-2	NM-021989	2.30
IL-6	M26744	2.20

Table 4 Gene expression difference of HSC-T6 cells treated with Curcumol (1.5625 μg/mL) for12 h

Gene	GenBank	Ratio
TGFβ1	NM-021578	2.30
P-450a	J02669	2.10

These results showed that after HSC-T6 cells were cultured in a medium containing 6.25 μg/mL Colchicine for 12 h, the expression of TIMP-1 decreased 2.2-folds. The expression of TIMP-2 and IL-6 decreased 2.3- and 2.2-folds, respectively, after HSC-T6 cells were cultured in a medium containing 78.125 μg/mL of Curcuma aromatica oil for 24 h. Moreover, the expression of TGFβ1 and p450a decreased 2.3- and 2.1-folds, respectively, after HSC-T6 cells were cultured in a medium containing 1.5625 μg/mL Curcumol for 12 h. Other concentrations of neither Curcuma aromatica oil nor Curcumol could bring forth gene expression differences, nor did β-elemence and Curcumin.

DISCUSSION

Genetic chip technology is characterized by high communication, low consumption and miniaturization[10-13], providing a technological platform to study the mechanism of herbal medicines against liver fibrosis. Genetic expression spectrum chips can be categorized into two kinds, namely cDNA chips and oligonucleotide chips, the probe of the former is cDNA, the probe of the latter is fragment of oligonucleotide. To study medicines with genetic expression spectrum chips can help us acknowledge the target genes of herbal medicines, western medicine and some foods with medical functions. It is also an effective way to study the toxicity of medicines, and the mechanism of causing deformity and genetic mutation of medicines.

According to the key role of HSCs in hepatic fibrosis, 50 genes related to liver fibrosis are chosen. They can be categorized into five groups as follows: (1) expressing cytokines and receptors of cytokines, such as transforming growth factor β1 (TGF β1), platelet-derived growth factor A (PDGFA), platelet-derived growth factor C (PDGFC), interleukin-1, interleukin-6, interleukin-10, hepatocyte growth factor 1 (HGF1), hepatocyte growth factor 2 (HGF2), vascular endothelial growth factor A (VEGFA), vascular endothelial growth factor B (VEGFB), vascular endothelial growth factor C (VEGFC), vascular endothelial growth factor D (VEGFD), fibroblast growth factor 1 (FGF1), fibroblast growth factor 2 (FGF2), platelet-activating factor (PAF), tumor necrosis factor α (TNFα), insulin-like growth factor 1 (IGF1), insulin-like growth factor 2 (IGF2), endothelin 1 (ET-1), intercellular adhesion molecule 1 (ICAM-1), vascular cell adhesion molecule 1 (VCAM-1), murine macrophage inflammatory protein 2 (MIP-2), monocyte chemotactic protein 1 (MCP-1), transforming growth factor β receptor I (TGFβRI), transforming growth factor β receptor II (TGFβRII), platelet-derived growth factor receptor α (PDGFRα), platelet-derived growth factor receptor β (PDGFRβ), tumor necrosis factor α receptor 1 (TNFαR1), platelet-activating factor receptor (PAFR), and endothelin receptor A (ETRA). TGFβ1 is the strongest factor which promotes the synthesis of extracellular matrix (ECM). PDGF can accelerate the proliferation of HSCs; (2) expressing MMPs (matrix metalloproteinases) and TIMPs (tissue inhibitor of metalloproteinases), such as MMP2, MMP3, MMP8, TIMP-1, TIMP-2, and TIMP-3, which take part in the degradation of ECM; (3) gene expression related to the preliminary activation of HSCs, such as c-myc, Ets-1, STAT1, c-jun B, c-jun D; (4) involving in gene expression related to the biological oxidation[14], such as cytochrome P450d, cytochrome P450a, cytochrome P450e, cytochrome P450-LA, and cytochrome P450 (4A3), CYP1B1, CYP2D4; and (5) house keeping gene, such as β-actin and GAPDH.

How to choose the genes related to liver fibrosis is the key of the design of oligonucleotide probes. The mRNA sequences which contain 40 amino acids are selected and then oligonucleotide probes are designed using the design software of oligonucleotide probe. By and large, the length of oligonucleotide probe is 15-80 nt, the content of GC is 45-55%. Probes of the coding region approaching end 3 are chosen for BLAST analysis. One to two probes whose homology of sequences was less than 70% are chosen as gene distinctive oligonucleotide probes.

Because some sequences of mRNA related to collagen I, III, IV are so short, the probes designed through software are easy to cause cross reactions which may result in false positive results, and such genes, therefore, cannot be chosen. However, the aforementioned 50 genes, in general, can represent approximately the changes which take place in the process of preliminary and persistent activation of HSCs in liver fibrosis.

HSC-T6 cells are SV40 transfected HSCs of Sprague-Dawley rats. The cells can be steadily cultured and their phenotype is activated HSCs which can express high-level collagen I and TIMP-1 mRNA, etc. In our study, HSC-T6 was substituted for the original HSC. Yin *et al.*[15,16] took HSC-T6 as model cells to investigate the influence of compound 861 on the gene expression of MMP-3 and TIMP-1 and they found that 0.25, 0.5, and 1.0 mg/mL of compound 861 could increase the expression of MMP3 and inhibit the expression of TIMP1.

TIMPs can prevent MMPs from degrading ECM[17-21]. Using genetic chip technology, we found that after HSC-T6 cells were cultured in a medium containing 6.25 μg/mL

Colchicine for 12 h, the expression of TIMP-1 decreased 2.2-folds. Expression of TIMP-2 decreased 2.3-folds after HSC-T6 cells were cultured in a medium containing 78.125 μg/mL Curcuma aromatica oil for 24 h. These results showed that Curcuma aromatica oil, like Colchicines, can also inhibit the expression of TIMPs and reduce the inhibition of MMPs which, in turn, help MMPs to degrade ECM. This may be one of the mechanisms for zedoary against liver fibrosis.

IL-6 is also called hepatic cell stimulating factor which can directly stimulate hepatic cells proliferation, induce the expression of IL-6 receptors in liver, and stimulate fibroblastic cells to synthesize collagens[22–26]. In our study, 78.125 μg/mL Curcuma aromatica oil could decrease the expressions of IL-6, TIMP1 and other genes related to hepatic fibrosis, thereby enhancing MMPs to degrade ECM. It might be another mechanism of zedoary against hepatic fibrosis.

TGFβ1 plays an important role in hepatic fibrosis which can activate HSCs and, as a transcription factor of collagen, accelerate its expression[27]. In our study, the expression of TGFβ1 decreased 2.3-folds after culture of HSC-T6 cells in a medium containing 1.5625 μg/L Curcumol for 12 h, suggesting that Curcumol can inhibit the synthesis of ECM through the inhibition of TGFβ1 which might be an another important mechanism of zedoary against hepatic fibrosis.

Cytochrome P450 (or Cyt P450) involves in the synthesis of steroid hormone, bile acid and bile pigments as well as the process of the bio-transformation of medicine and poison[14]. Yang *et al*.[28] have shown that lipid peroxidation takes part in the activation of HSCs. Svegliati Baroni *et al*.[29] have indicated that HCM/Fe might induce a significant increase in collagen type I accumulation in HSC culture media, and HSCs proliferation may be associated with changes in the Na^+/H^+ exchanger activity. Nieto *et al*.[30] transfected CYP2E1 to HSC-T6 cells, and found that there was an increase in the level of reactive oxygen species and type I collagen mRNA. It has been reported that when HSCs were cultured with HepG2 cells which overexpress CYP2E1 together, the level of collagen markedly increased, suggesting that the solved oxidants can activate HSCs[31]. In our study, we found that after culture of HSC-T6 cells in a medium containing 1.5625 μg/mL Curcumol for 12 h, the expression of P450a decreased 2.1-folds, suggesting that the metabolism of Curcumol in HSC-T6 cells might bring forth oxidation-conjugation reaction through the P450 enzyme system, induce a decline of oxidative stress and lipid peroxidation, and thus inhibit the activation of HSCs. This may be one of the mechanisms of zedoary against hepatic fibrosis.

In conclusion, two different ingredients of zedoary (Curcuma aromatica oil, Curcumol), when treated with HSC-T6 cells for 24 and 12 h, can decrease the expression of TIMP-2, IL-6, TGFβ1 and P450a by different degrees, indicating the molecular mechanisms of zedoary against hepatic fibrosis at gene network level. But the changes of genes and the expression of proteins might not be the same events. Along with the development of protein histology, further research needs to testify the proteins related to liver fibrosis, for example, to examine the content of type I collagen using ELISA or investigate the influence of Curcuma aromatica oil and Curcumol on protein expression of HSC-T6 cells by protein chip technology.

Abstract

AIM: To assess the changes of portal and arterial velocities, resistance index, spleen and liver size during a long observation period (13.7 years) after orthotopic liver transplantation (OLT).

METHODS: Two hundred and sixty patients were recruited retrospectively for this study and divided into groups with defined time intervals after OLT. The cross-sectional changes of portal and arterial velocities, resistance index, spleen and liver size between the defined time intervals were studied. The complications detected by ultrasound were compared to gold standard methods.

RESULTS: The mean values for liver size were all within the normal range. The splenic size decreased between the time intervals 100 and 1 000 d after OLT (*t*; $P<0.01$). While portal and arterial flow velocities decreased up to 5.5 years (*t*; portal velocity $P<0.01$, maximal systolic velocity $P = 0.05$, maximal end diastolic velocity $P<0.01$), RI increased during this interval (*t*: $P<0.01$). Higher RI values were found in older patients ($r = 0.24$, $P<0.001$).

CONCLUSION: The arterial and portal velocities show adaptation processes continuing over the course of many years after OLT and are reported for the first time. The vascular complications detected by ultrasound occur mostly up to 100 d after OLT.

Key words: Ultrasound; Color Doppler; Liver transplantation; Monitoring

INTRODUCTION

Since the 1980s, OLT has become a standard therapy for patients with end-stage liver disease[1] and till date, the outcome of this therapy depends on the early diagnosis and appropriate treatment of complications[2]. Vascular complications are a frequent cause of early graft failure[3]. Graft damage can be either directly caused by hypoxemia or indirectly by biliary ischemia during graft handling which equally leads to chronic biliary damage[4,5]. Time-dependent changes of splanchnic hemodynamics in liver graft recipients have been reported[6]. Based on these data, it is likely that an understanding and interpretation of splanchnic hemodynamics may lead to the prevention and diagnosis of vascular complications[6].

Apart from physical examination and biochemical work-up, routine and diagnostic imaging procedures are recommended to detect post-OLT vascular complications[7-9]. B-mode and especially color Doppler sonography have played a central role in the monitoring of post-transplantation patients. The use of ultrasound allows for the early diagnosis of hepatic arterial as well as biliary complications[3,9,10] and contributes to a better understanding of splanchnic hemodynamic changes[6].

Long-term follow-up studies of splanchnic hemodynamic changes after OLT are time consuming and therefore not applicable. The aim of this study was to assess the post-transplantation changes of duplex parameter as well as liver and splenic size in liver graft recipients for a long period of observation. This study was performed retrospectively as a cross-sectional analysis in a large cohort of OLT patients. The secondary objective of this study was to assess the post-transplantation complications detected by ultrasound during this observation time.

MATERIALS AND METHODS

All the liver graft recipients received routine ultrasound

examinations in our sonography department. For this study, we chose a sample of all OLT patients (with or without clinical problems) who received ultrasound examinations between February 2000 and December 2001. Five hundred and eighteen ultrasound examinations on 282 patients were performed during this period. Patients who received at least one ultrasound examination after liver transplantation were included in this study. In the case of multiple ultrasound examinations, one examination was chosen randomly in order to prevent dependencies, due to multiple measurements of a single case. Patients who had acute cardiac or renal failure were excluded (n = 2). Two hundred and sixty consecutive patients were included, and their clinical characteristics are shown in Tables 1 and 2.

All patients were examined with high-end ultrasound equipment Power Vision 8000 (Toshiba, Japan) and Elegra Sonoline Advanced (Siemens, Germany) using convex arrays 3.5C40H (Siemens, Germany) and C 3-6 MHz (Toshiba, Japan) as well as sector array 3-6 MHz (Toshiba, Japan). The patients were examined by two gastroenterologists with more than 20 years of experience in the field of ultrasound.

Systematic B-mode examination of all abdominal organs including the retroperitoneum was performed following the recommendations of the German Association of Ultrasound in Medicine (DEGUM). Liver size was measured by the diameter of the right lobe in the mid clavicular line (MCL). The spleen length was measured from upper to lower pole in an oblique intercostal array position. The normal liver size was defined as 13±0.5 cm[11]. The normal spleen size was defined as 11±0.5 cm[11]. In addition, the portal vein and the bile duct anastomosis were examined in the proximal and distal portion.

The maximum velocity of the portal vein [(P)V_{max}], the maximum systolic velocity [(A)V_{max}], the maximum end diastolic velocity [(A)V_{min}] and the resistance index of the hepatic artery (RI) were measured before and after the anastomosis in each case after an overnight fasting. Settings such as gain, filter, and pulse-repetition frequencies were adjusted as needed for optimal signal detection to prevent artifacts. Segmental arterial stenosis was considered to be present when circumscript aliasing was visualized by color Doppler sonography using the maximal pulse repetition frequency (PRF) as well as the presence of a V_{max} exceeding 170 cm/s. Alternatively, in case of the absence of a segmental stenosis, the detection of a tardus-parvus duplex spectrum with a cut off RI below 0.5 in addition to a V_{max}>170 cm/s was required for the definition of a stenosis. Stenosis of the portal vein required a two-fold increase of flow velocity in the stenosis. Dilated intrahepatic and extrahepatic bile ducts were defined as exceeding 3 and 10 mm in diameter (DEGUM guidelines), respectively.

The complications detected by ultrasound were confirmed by following the gold standard methods. In all patients with suspected stenosis or thrombosis of the hepatic artery by ultrasound examination, a CT-angiography was performed to confirm the diagnosis. Most of the biliary complications such as bile duct dilatation, thickening, stricture, and calculi in the bile duct system were confirmed by endoscopic retrograde cholangiopancreatic ography (ERCP) in patients with chocholedochostomy[12] and by percutaneous transhepatic cholangiography (PTC) in patients with status after hepaticojejunostomy. The occurrence of intrahepatic abscesses was confirmed by biopsy. Liver biopsies after OLT were available from 94 patients (n = 45 acute rejections, n = 2 chronic rejections, n = 2 ischemia, n = 21 viral re-infection, n = 21 fibrosis, n = 7 cirrhosis, n = 33 cholangitis).

Statistical evaluation was performed using the SPSS 11.5 software package for Windows™. Mean values and standard errors of the means (mean±SE) as well as frequencies were calculated. Correlations were done using Spearman's (S) rank correlation coefficient. We also analyzed the changes of the velocity values as well as organ sizes in the course of time. Due to different time points of ultrasound examinations after OLT, we divided the patients in groups with defined time intervals after OLT. The time points were days 100 (1), 1 000 (2), 2 000 (3), 3 000 (4), 4 000 (5) and 5 000 (6) after OLT. The number of patients at the defined time intervals was as follows: n = 20 (1), n = 120 (2), n = 81 (3), n = 48 (4), n = 25 (5), n = 11 (6). At these time points, the data of patients before the defined

time point (days after transplantation) were compared with the data of patients after this time point. Mean values of the parameters were calculated and compared for significance using the *t*-test. Therefore, our data reflected only the changes of the studied parameters at these time points. The changes of the parameters in the group of patients before the defined time points were graphically demonstrated. The graphs were assembled using the Prism 3.0 software package.

Correlations as well as the mean values were calculated with and without extremes. The extremes were defined as stenosis or thrombosis of the portal vein and/or the hepatic artery ($n = 8$).

RESULTS

Frequencies of ultrasound-detected B-mode findings/ complications after OLT

Vascular complications over a 13.7-year observation period were detected in one case (0.4%) of thrombosis and five cases (1.9%) of stenosis of the hepatic artery and in seven cases (2.7%) of stenosis of the portal vein by ultrasound (Table 3). All cases were confirmed by CT angiography.

In a 13.7-year observation period by ultrasound examination, 58 (22.3%) patients showed biliary complications, of them 33 (56.9%) had either ERCP or PTC. In 29 patients (87.9%), ultrasound diagnosis was confirmed either by ERCP or PTC. Nine patients (3.5%) had extrahepatic dilatation and 37 cases (14.2%) had intrahepatic dilatation of the bile ducts. One patient (0.4%) had calculi, 14 (5.4%) patients had sludge in the intra- and extra-hepatic bile ducts. Eighteen patients (6.9%) showed a thickening of intra- and extra-hepatic bile duct walls, two cases (0.8%) had intrahepatic abscesses, one patient (0.4%) had stricture of the main hepatic bile duct, 114 patients (43.8%) had splenomegaly after OLT, and 14 patients (5.4%) had detectable ascites (Table 3).

Changes in organ size after liver transplantation

The mean liver size after OLT was 12.2±0.2 cm in MCL. The mean splenic size after liver transplantation was 12.9 ±0.2 cm (Table 4). Women had a smaller spleen than men (12.2±0.3 cm *vs* 13.4±0.2 cm, *t*; $P<0.01$).

Table 3 Ultrasound findings and complications in liver graft recipients

US findings	US frequency in this study (%)	Reported frequency (%)
Thrombosis of the hepatic artery	0.4	12 [21]
Stenosis of the hepatic artery	1.9	3–5 [8]
Stenosis of the portal vein	2.7	1–6.2 [3,17]

Table 4 Ultrasound data (mean±SE)

Parameter	Value	Unit
(P) V_{max}	30.0±1.5	cm/s
(A) V_{max}	67.1±4.2	cm/s
(A) V_{min}	20.4±1.6	cm/s
RI	0.69±0.01	
Spleen size	12.9±0.2	cm
Liver size in MCL	12.2±0.2	cm

The changes of mean values for liver and splenic size 100, 1 000, 2 000, 3 000, 4 000, and 5 000 d after OLT were calculated. The mean values for liver size after OLT were all within the normal range and did not change significantly between the studied time intervals. In contrast, the splenic size decreased between the intervals 100 and 1 000 d after OLT. After this interval, the splenic size increased. Consequently, the spleens in the patients more than 1 000 d after OLT were significantly larger than those in the patients less than 1 000 d after OLT (13.6±0.3 cm *vs* 12.2±0.3 cm, *t*; $P<0.01$). The mean splenic size remained higher than the normal range throughout the observed time in this study.

Dynamics of color Doppler parameters in patients after liver transplantation

The mean value of color Doppler data for all patients is shown in Table 4. There was an inverse correlation between (P) V_{max} and time after OLT ($r = -0.41$, $P<0.001$). After exclusion of patients with stenosis and thrombosis of the arterial and portal vein anastomosis in order to eliminate the velocity extremes, the correlation coefficients still remained high ($r = 0.38$, $P<0.001$). There was also an inverse correlation between (A) V_{max} and (A) V_{min} of the hepatic artery and time after OLT [for (A) V_{max} $r = 0.21$, $P<0.01$ and for (A) V_{min} $r = 0.23$, $P<0.01$]. After exclusion of extremes, the correlation persisted [for (A) V_{max} $r = 0.21$, $P<0.01$ and for (A) V_{min} $r = 0.22$, $P<0.01$]. We could not observe a correlation between RI and time after OLT, but we confirmed a significant correlation between RI and age of the patients ($r = 0.24$, $P<0.001$).

The changes of mean values of all color Doppler parameters were calculated 100, 1 000, 2 000, 3 000, 4 000, and 5 000 d post OLT after exclusion of extremes. (P) V_{max} decreased between the time points 100 and 3 000 d after OLT. It was stabilized at a level of 23 cm/s between the time points 3 000 and 4 000 d after OLT and dropped again from day 4 000 (Figure 1A). (A) V_{max} decreased from 100 up to 4 000 d after OLT (Figure 1B). (A) V_{min} decreased from 2 000 d after OLT (Figure 1B). RI increased between 100 and 2 000 d after OLT. From this time point on, we observed a decrease of RI which was stabilized at a level of 0.70 from time point 4 000 d after OLT to the end of the observation time (Figure 1A).

DISCUSSION

All vascular complications detected by duplex measurements in this study occurred within the first 100 d after

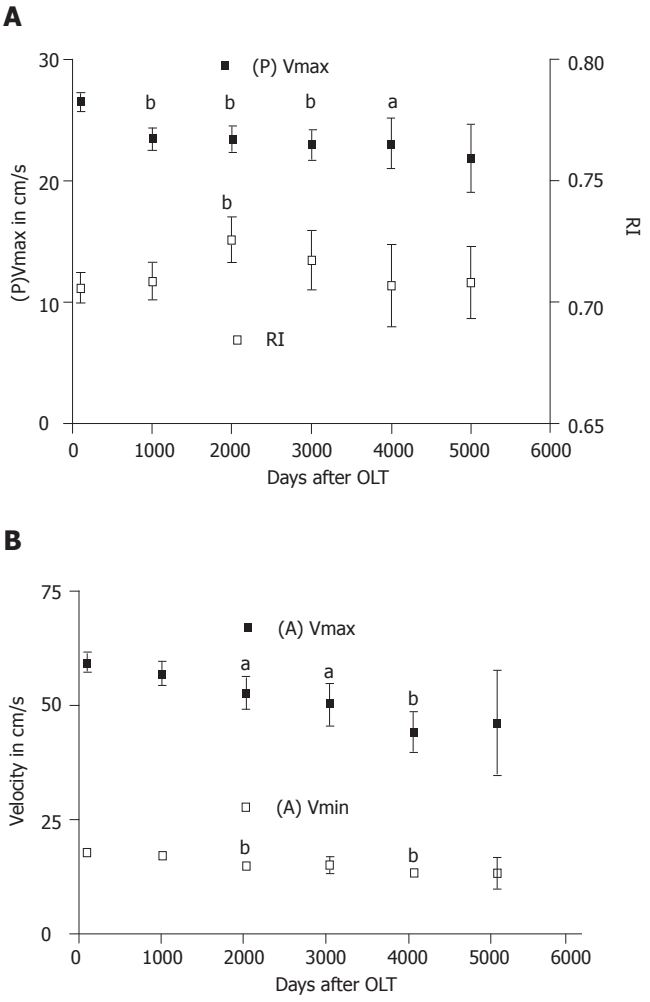

Figure 1 Changes in portal flow velocity and resistance index **(A)** and arterial velocities (A)V_{max} and (A)V_{min} after OLT **(B)** during the course of time after liver transplantation in 260 patients. ($^{a}P<0.05$; $^{b}P<0.01$ *vs* others).

Table 5 Reasons of vascular complications after liver transplantation

Arterial system	
Reperfusion damage	(n = 2)
Thrombosis of the celiac trunk	(n = 1)
Thrombosis of the hepatic artery[1]	(n = 1)
Dissection of the common hepatic artery	(n = 1)
Unknown	(n = 1)
Portal system	
Over average length of the portal anastomosis	(n = 3)
Intraoperative thrombectomy[2]	(n = 2)
Intraoperative thrombectomy of malign thrombus[3]	(n = 1)
Leakage of the biliary anastomosis and consequently	(n = 1)
Systemic infection leading to portal thrombosis	

[1]The patient suffered from fulminant acute hepatitis A with thrombosis of the arterial and portal vascular system at the time of OLT. [2]The patients had Budd-Chiari syndrome as an underlying liver disease. [3]In this particular case, infiltration of a tumor thrombus in the portal venous trunk was observed which led to portal vein stenosis after OLT.

liver transplantation (Table 5). Due to this information as well as the fact that complications such as rejection appear mostly during the early phase after OLT, drastic long-term hemodynamic changes in these patients are not expected. All vascular complications were initially diagnosed by ultrasound examination. Interestingly, a satisfactory blood flow was observed intraoperatively, but these patients developed stenosis after OLT. Routine and protocol ultrasound examinations during this interval are therefore recommended[13,14]. The flow characteristics of patients early after OLT have been reported in prospective studies[6,15]. We therefore focused our study on the long-term changes of these parameters.

The long-term hemodynamic changes in these patients seem to be influenced by factors in the graft itself or alteration of the vascular track. The prospective study of Bolognesi *et al.*[6] is the largest follow-up study investigating the hemodynamic changes in patients after OLT. Compared to this study, our study showed a more heterogeneous spectrum of the underlying liver diseases. Our findings showed that the mean liver size remained within the normal range, independent of the complications, even many years after OLT. Based on the results of liver biopsies after OLT, at least 20% of the patients included in this study had parenchymal changes such as cirrhosis or fibrosis which consequently leads to a smaller liver size. Interestingly, the mean values of liver size still remained stable in the course of studied time points. The mean splenic size was smaller than that of previously reported[6] which may be explained by the heterogeneity of liver diseases with a considerable amount of transplantations without portal hypertension.

Depending on the evaluation time after OLT, an initial increase in portal blood flow in patients with cirrhosis has been reported, which was normalized within 2 years[6]. We observed a decrease of portal blood flow from 100 d to 8.2 years after OLT. This stable decrease may also be influenced by the low prevalence of portal stenosis and thrombosis in our patients. We also detected a decrease of arterial velocities over a long period of time after OLT. This could be caused by the normalization of hyperdynamic circulatory syndromes of patients with cirrhosis at the time of OLT. While the role of arterial RI in patients after kidney transplantation has been extensively studied, the RI changes in liver graft recipients are still unclear. It was reported that a high arterial RI after kidney transplantation is associated with poor subsequent allograft performance and death[16]. In liver graft recipients, an early increase in hepatic arterial resistance has been reported[6,17], which is related to older donor age and prolonged period of ischemia. Higher RI values were found in older patients in our study. RI increase is also attributed to the elevation of portal blood flow early after OLT[6]. In our study, RI did not correlate with portal flow.

Our data have confirmed the reported rate of ultrasound detected complications in patients after liver transplantation. However, the sensitivity of ultrasound for detection of biliary complications is better than that of previously reported[12]. Arterial thrombosis after transplantation has an estimated incidence of 12%[8]. In our patients, thrombosis of the hepatic artery was detected by ultrasound in 0.4% of cases. Since the majority of arterial thromboses occur during the early post-transplantation

period[3] and most of our examinations were performed 100 or more days after OLT, the low prevalence of arterial thrombosis in this study may be related to the time point of investigation. The detection rate of hepatic artery stenosis as well as portal vein thrombosis in our study was comparable to the reported incidence[8,18,7]. The detection rate of biliary tract complications in this study (22.3%) is higher than the reported incidence approaching 18%[19]. Regarding the cases, which were confirmed by ERCP or PTC in our study, ultrasound has a sensitivity of 88%[12].

This study provides an insight into time point of vascular complications as well as hemodynamic and parenchymal adaptive processes present in liver graft recipients. The cross sectional characteristic of our study did not allow a continuous assessment of hemodynamic changes in the course of time, but it enables the analysis of a very long observation period. These data can serve as an orientation for the examining physicians to have a better understanding and interpretation of duplex changes in these patients.

Abstract

AIM: To evaluate the effect of oral intake of branched-chain amino acids (BCAA) on brain perfusion in patients with liver cirrhosis.

METHODS: Single photon emission computed tomography scans were performed in 43 patients with cirrhosis and in 15 age-matched healthy subjects. Twenty-nine out of forty-three patients were randomly treated with either BCAA granules or placebo, and single photon emission computed tomography was performed before and after the treatment. We measured the regional cerebral blood flow values using a three-dimensional stereotaxic region of interest template.

RESULTS: Cirrhotic patients had regions of significant hypoperfusion in the bilateral central (right $P = 0.039$, $P<0.05$; left $P = 0.006$ $P<0.01$), parietal (right $P = 0.018$, $P<0.05$; left $P = 0.009$, $P<0.01$), angular (right $P = 0.039$, $P<0.05$; left $P = 0.008$, $P<0.01$), and left pericallosal segments ($P = 0.038$ P<0.05) as compared with healthy subjects. A significant increase in cerebral perfusion was observed 70 min after the oral intake of BCAA in the angular (right $P = 0.012$, $P<0.05$; left $P = 0.049$, $P<0.05$), temporal (right $P = 0.012$, $P<0.05$; left $P=0.038$, $P<0.05$), pericallosal segments (right $P = 0.025$, $P<0.05$; left $P = 0.049$, $P<0.05$) and left precentral ($P = 0.044$, $P<0.05$), parietal ($P = 0.040$, $P<0.05$) and thalamus ($P = 0.033$, $P<0.05$). No significant change in perfusion was observed in the placebo group.

CONCLUSION: Administration of BCAA rapidly improves cerebral perfusion.

INTRODUCTION

Beneficial effects of branched-chain amino acids (BCAA) supplementation on hepatic encephalopathy (HE) have been previously reported[1-3]. Recently, Marchestini *et al.* carried out a large multicenter, randomized controlled trial with BCAA-enriched dietary supplements in comparison with lactoalbumin or maltodextrin dietary supplementation[4]. The results of this study showed reduced hospital admission rate in patients treated with BCAA compared with the control group[4]. Thus, BCAA therapy may be effective for the treatment of HE, which is a common cause of hospital admission.

Some cirrhotic patients with apparently normal mental status may have abnormalities in cognitive function when they are examined with sensitive and quantitative neuropsychological tests[5,6]. This group of patients is considered to have minimal HE[7]. This HE-associated cognitive impairment may be sometimes associated with a poor quality of life[8-10] and thus early diagnosis and treatment of this condition is important[8]. It has been reported that therapy with lactulose improves neuropsychological functions[11]. However, there are no data on whether BCAA supplementation ameliorates cerebral disturbance in cirrhotic patients.

Single photon emission computed tomography (SPECT) and positron emission tomography studies can demonstrate alterations in regional cerebral blood flow (CBF) and cerebral glucose metabolism in cirrhotic patients[12-19]. We previously reported that administration of solutions enriched with BCAA improves cerebral perfusion in patients with cirrhosis[20]. However, the BCAA-rich solutions used in this previous study in cirrhotic patients contained L-arginine, which is a precursor of nitric oxide, a potent vasodilator[21]. The dose of L-arginine used in previous study might have increased blood flow in the brain[21].

The main aim of the present study was to confirm regional differences in CBF in patients with liver cirrhosis and to evaluate whether alterations in CBF is reversed by the oral administration of BCAA. In this study, we used granules containing only BCAA and a three-dimensional stereotaxic region of interest template (SRT) for objective estimation of anatomically standardized CBF SPECT images[22,23].

MATERIALS AND METHODS

Subjects

Forty-three Japanese patients with liver cirrhosis (30 men and 13 women, mean age 63±8 years) were enrolled in this study. The diagnosis of cirrhosis was based on the results of liver function tests, ultrasonography, computed tomography imaging, laparoscopy and liver biopsy. The cause of liver cirrhosis was viral infection in the majority of patients (n = 37). No patient with alcoholic liver disease was included in the study. In six patients, the cause of liver cirrhosis was unclear. None of the patients had overt HE (grade I or more) at the time of the examination, and none of them exhibited neuropsychiatric signs or symptoms on standard bedside clinical assessment. Patients with focal brain lesions, severe brain atrophy, abnormalities on computed tomography or magnetic resonance images, or neurological or psychiatric disorders were excluded from the study. None of the patients were receiving psychoactive drugs. Twenty-nine out of forty-three patients were randomized into two groups: one group received BCAA granules orally (16 patients) and another group received placebo (13 patients). We have previously reported that the ratio of serum BCAA to tyrosine increases nearly twofold, 1 h after the administration of oral BCAA and that it decreases to basal values after 10 h[24]. The clinical and biochemical characteristics of the patients are summarized in Table 1.

Control SPECT images were obtained from 15 subjects (11 men and 4 women; mean age, 62±9 years) referred to our neurology department for minor subjective symptoms. These subjects were free of liver disease, neurological disorder or dementia and had normal brain magnetic resonance images. The control subjects were not taking any medication.

Informed consent was obtained from all subjects, and the study was performed in accordance with the Helsinki Declaration. The Ethics Committee of Mie University School of Medicine approved the protocol of this study.

BCAA, branched-chain amino acids.

Scan acquisition and image processing

Each subject received 278 MBq of technetium-99 m L,L-ethyl cysteinate dimer (ECD) by intravenous injection in the morning after an overnight fast. Ten minutes after the injection of ECD, brain SPECT images were acquired using a three-head gammacamera system (GCA-9300A/DI, Toshiba, Tokyo, Japan) equipped with low-energy, high-resolution fanbeam collimators. The projection data were obtained using a matrix size of 128×128. SPECT images were reconstructed by filtered back-projection using a ramp filter follower by postprocessing with a Butterworth filter. Attenuation correction was performed using Chang's method[25]. The triple-energy window technique was employed for scatter correction. After baseline SPECT, the patients were orally treated with BCAA granules (8 g BCAA, 8 g protein, 32 kcal, Ajinomoto, Tokyo, Japan: L-isoleucine 1 904 mg, L-leucine 3 808 mg, L-valine 2 288 mg), or placebo (cornstarch, 8 g protein, 32 kcal). After 60 min, 278 MBq of ECD was intravenously administered, and 10 min later a second SPECT acquisition was performed. The methods are briefly summarized in Figure 1.

Image analysis

The spatial normalization was performed using linear and non-linear transformation and SPECT template in the statistical parametric mapping (SPM) 99 (Wellcome Department of Cognitive Neurology, London, UK)

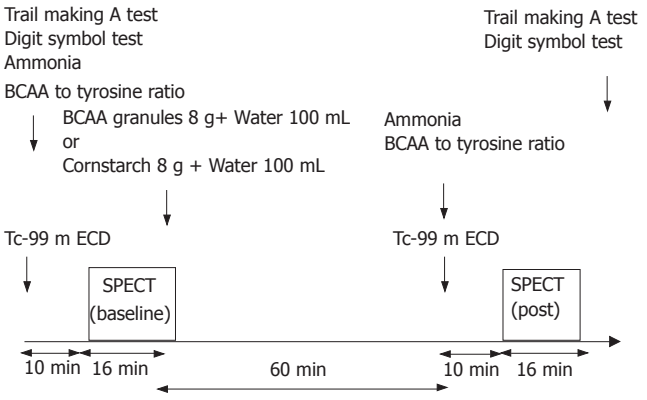

Figure 1 Study protocol. Baseline SPECT imaging was taken 10 min after the injection of 278 MBq ECD. After baseline SPECT, BCAA granules or placebo were orally administered. Sixty minutes later, another 278 MBq of technetium-99 m ECD was intravenously administered and a second SPECT acquisition was performed 10 min after the injection of ECD. Laboratory and neuropsychological tests were taken before and after the administration of BCAA or placebo. SPECT, single photon emission computed tomography; ECD, ethyl cysteinate dimer; BCAA, branched-chain amino acid

program. Smoothing was performed using 12 mm full width at half maximum Gaussian filter in SPM99. To obtain post-BCAA counts, baseline mean SPECT counts were subtracted from the second SPECT counts, multiplied by a correction factor, which is the coefficient of the decay of technetium-99 m between the baseline and post-treatment measurement. In each hemisphere, we estimated the regional CBF values of 270 constant regions of interest (ROI, three-dimensional SRT) grouped into 12 segments as follows: callosomarginal, 48 ROI; precentral, 45 ROI; central, 28 ROI; parietal, 14 ROI; angular, 8 ROI; temporal, 27 ROI; posterior cerebral, 33 ROI; pericallosal, 16 ROI; lenticular nucleus, 12 ROI; thalamus, 11 ROI; hippocampus, 17 ROI; and cerebellum, 11 ROI; and the segmental CBF was calculated as the area-weighed mean value for each of the 12 segments based on the regional CBF of each ROI[22,23].

Semiquantitative analysis was performed to obtain region-to-reference ratios for each segmental CBF value. The CBF value in cerebellum was selected as the reference region, because cerebellar abnormalities were not detected in SPECT images, computed tomography or magnetic resonance images.

Neuropsychological tests and laboratory examinations

The trail making A test (number connection test) and digit symbol test (revised Wechsler adult intelligence scale) were performed as neuropsychological tests. Laboratory examinations included plasma ammonia and BCAA to tyrosine ratio. These data were taken before and after the administration of BCAA or placebo (Figure 1).

Statistical analysis

Results were expressed as the mean±SD of the mean and range. The Mann–Whitney *U* test was used to evaluate the statistical difference in clinical or laboratory variables between BCAA and placebo groups and in CBF between patients and healthy subjects. The analysis of variance with Bonferroni's correction for multiple comparisons in the three groups was analyzed. The Wilcoxon was used to compare pre-, post-BCAA or -placebo values in the same group of patients. A $P<0.05$ was considered as statistical significance.

RESULTS

Baseline study

Cirrhotic patients ($n = 43$) had regions of significant hypoperfusion in the bilateral central (right, $P<0.05$; left, $P<0.01$), parietal (both, $P<0.05$), angular (right, $P<0.05$; left, $P<0.01$), and left pericallosal segments ($P<0.05$) as compared with healthy subjects ($n = 15$, Figure 2).

The influence of the clinical profile on regional CBF was also evaluated. There were no significant differences in cerebral perfusion between the mild (Child–Pugh A, $n = 13$), moderate/severe (Child–Pugh B+C, $n = 30$) liver dysfunction groups and healthy subjects (data not shown). In cirrhotic patients with hyperammonemia (i.e., more than 50 μm/L, $n = 15$), SRT showed regions of significant hypoperfusion in the right parietal ($P<0.05$) and left callosomarginal ($P<0.05$), central ($P<0.01$), angular ($P<0.01$) and pericallosal segments ($P<0.01$) as compared to healthy subjects (Figure 3A, right hemisphere is not shown). Likewise, in cirrhotic patients with severe decrease of serum BCAA to tyrosine ratio (i.e., <3, $n = 19$), SRT showed regions of significant hypoperfusion in the angular (right, $P<0.05$; left, $P<0.01$) and right parietal ($P<0.05$) and left callosomarginal ($P<0.01$), central ($P<001$) and pericallosal segments ($P<0.01$) as compared to healthy subjects (Figure 3B, right hemisphere is not shown).

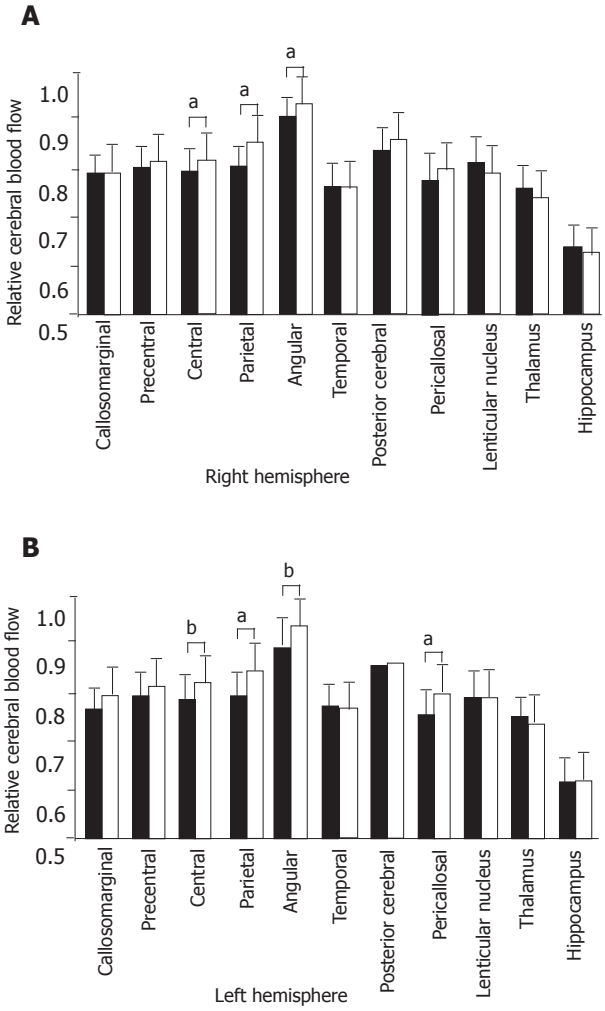

Figure 2 Relative CBF of different brain regions. Comparison of patients with liver cirrhosis (closed bars) and healthy subjects (open bars). Data were expressed as the mean±SD. [a]$P<0.05$, [b]$P<0.01$, [d]$P<0.001$. CBF, cerebral blood flow.

Abnormalities in neuropsychological tests [values more than two SD from the mean values for the age-matched healthy subjects at our hospital (i.e., more than 50 s on the trail making A test and less than 30 points on digit symbol test)] were considered to be indicative of minimal HE. Among cirrhotic patients, 10 showed abnormalities in both neurological tests and thus they were considered to have minimal HE. In patients with abnormalities in neurological tests ($n = 10$), SRT showed significant hypoperfusion in the left parietal ($P<0.01$), pericallosal ($P<0.01$), lenticular nucleus ($P<0.01$) and hippocampus ($P<0.05$) regions as compared to patients with grade-0 HE ($n = 14$, Figure 3C,

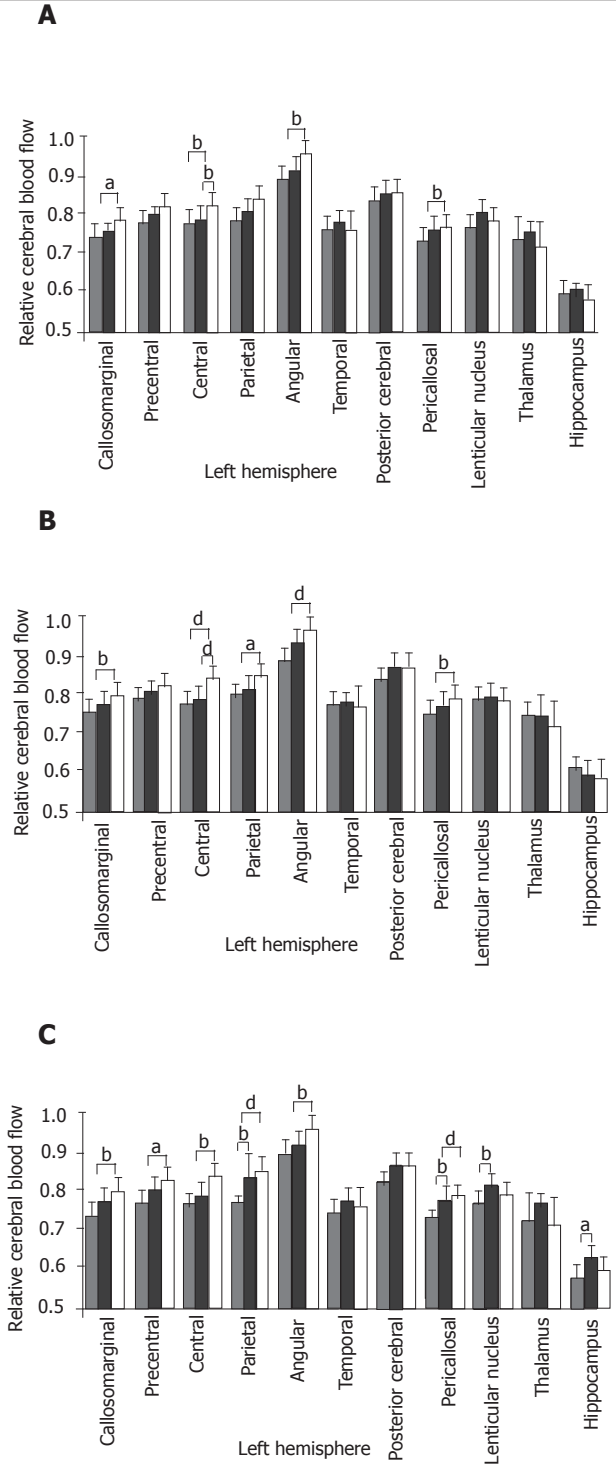

Figure 3 Relative CBF of different brain regions. **A:** Comparison of cirrhotic patients with hyperammonemia (gray bars), normal ammonemia (dashed bars) and healthy subjects (open bars); **B:** Comparison of cirrhotic patients with severe decrease in the levels of serum BCAA to tyrosine ratio (gray bars), with mild decrease in serum BCAA to tyrosine ratio (dashed bars) and healthy subjects (open bars); **C:** Comparison of patients with minimal encephalopathy (gray bars), with grade-0 encephalopathy (dashed bars) and healthy subjects (open bars).

right hemisphere is not shown).

Effect of BCAA

At entry, there was no difference in clinical or laboratory variables between BCAA (n = 16) and placebo (n = 13) groups (Table 2). A significant increase in cerebral perfusion was observed 70 min after oral intake of BCAA in the angular (both regions, P<0.05, Figure 4C), temporal (both regions, P<0.05, Figure 4D), pericallosal segments (both regions, P<0.05, Figure 4E) and left precentral (P<0.05, Figure 4A), parietal (P<0.05, Figure 4B) and thalamus (P<0.05, Figure 4F). In addition, after the administration of oral BCAA, the values of relative CBF improved in almost all segments, reaching values observed in healthy subjects. There were no significant differences in cerebral perfusion between cirrhotic patients after oral intake of BCAA and healthy subjects. No significant change in relative CBF values was observed in the placebo group (Figure 5). In the BCAA group, the serum BCAA to tyrosine ratio increased fourfold, 86 min after the administration of oral BCAA (P<0.01). No significant change in plasma ammonia levels or in neuropsychological tests was observed in BCAA and placebo groups (Table 3).

DISCUSSION

Functional imaging techniques such as CBF SPECT and positron emission tomography can demonstrate abnormalities in patients with cirrhosis[12-19]. In the present study, cirrhotic patients had regions of significant hypoperfusion in central, parietal, angular and pericallosal segments as compared to healthy subjects. These areas included parts of the frontal and parietal associated areas of the cortex and cingulum. Impaired flow and oxygen metabolism in the frontal, parietal and cingulate cortices in cirrhotic patients have also been reported[12-14,16-18]. Cognitive impairment, especially defect in attention is an important feature of HE[26,27]. The anterior cingulate gyri may provide an important connection between widely divergent aspects of attention and visual location[28]. The internal organization of the anterior cingulate gyri shows alternating bands of cells with close connections to the dorsolateral frontal cortex and the posterior parietal lobe[29]. The results of studies using N-13 ammonia positron emission tomography of cerebral ammonia metabolism in patients with cirrhosis and minimal encephalopathy coincide well with these regional differences[30]. This regional hypoperfusion may be the pathophysiological basis for the minimal cerebral dysfunction that is often detected by neuropsychological tests in patients with cirrhosis.

We found no significant relationship between cerebral perfusion and severity of liver disease, as assessed by the Child–Pugh scores. This observation may be due to the fact that non-hepatic factors, such as neurotoxins produced in the gut or toxic agents that cross the blood-brain barrier such as ammonia, contribute to impairment of cerebral function. Although no single metabolic derangement can account for the occurrence of HE, the plasma level of ammonia is believed to be an important causative factor of HE. Lockwood *et al*. reported regional metabolic abnormalities in cirrhotic patients with hyperammonemia[16]. They also reported increased permeability of the blood-brain barrier to ammonia and suggested that ammonia might be responsible for cerebral dysfunction in HE[31]. In

our patients with hyperammonemia, SRT analysis showed several segments, including the cingulum, with significant decreased perfusion as compared to healthy subjects. This finding supports the hypothesis of Lockwood *et al*. In addition, SPECT with SRT analysis showed a significant reduction in relative CBF values in cirrhotic patients with minimal HE as compared to patients with grade-0 HE and normal subjects. This result is also consistent with the observation of Lockwood *et al*.[18]. Moreover, we found that the relative CBF values are significantly correlated with the baseline venous BCAA to tyrosine ratio. Relationship between CBF values and the serum BCAA to tyrosine ratio has not been previously assessed.

There are several studies in which stereotaxic ROI analysis was used[32,33], but in all of them the ROI values were transformed to fit the subjects' individual anatomical arrangements. Inter-individual anatomical variations may exist giving non-consistent relationship between ROI location and anatomy. In the present study, we used a fully automated regional CBF quantification software, SRT. This incorporates an anatomical standardization engine transplant into SPM99 and ROI for quantification on the Montreal Neurological Institute space of the magnetic resonance image anatomically standardized by SPM99. We believe that our results are valid due to the accuracy of the SRT analysis.

We took the cerebellum as reference for the semiquantitative analysis, because brain segments of cirrhotic patients exhibit variable perfusion values whose distribution may affect the validity of the uptake ratios. We previously reported that there is no alteration in cerebellar perfusion in cirrhotic patients as analyzed by SPM with ECD SPECT[13]. In addition, the absence of symptoms and the normal appearance of cerebellar perfusion in our patients led us to consider the cerebellum as the best reference to evaluate regional CBF. However, cerebellar hypermetabolism has been observed in cirrhotic patients with cerebellar degeneration[30], and thus it may be difficult to deal with methodological limitations in such region-to-cerebellar ratios as it was in this study. To evaluate the effect of BCAA, repeated SPECT studies are necessary. In the pre/post studies, the assumption is that the original distribution pattern is still the same during the second SPECT image. Moretti *et al*. reported that during the 50-120 min postinjection period, the regional structures are washing out at the same rate[3]; however, there might be differences between cirrhotic and normal brain. This may be a potential pitfall in split-dose and sequential SPECT method with ECD.

The mechanism by which BCAA granules rapidly improve relative CBF in cirrhotic patients without overt HE is unknown. The rationale for BCAA therapy is based

on the results of studies showing that the use of solutions rich in BCAA reversed the abnormal blood levels of amino acids and led to mental recovery from acute HE in patients with cirrhosis[35,36]. Mental recovery is observed immediately after the treatment with BCAA solution. One of the proposed mechanisms of HE is the interference of cerebral metabolism by ammonia, including depletion of operational rates of tricarboxylic acid cycle by removing α-ketoglutarate for ammonia detoxification[37]. Decreased brain levels of glutamate have been reported in various models of HE. Glutamate is an integral component of malate-aspartate shuttle. It is therefore possible that reduced glutamate levels contribute to impaired cerebral energy metabolism in HE[38]. BCAA is known to cross rapidly the blood-brain barrier and to serve as an energy source in the brain[39,40]. It has been previously shown in animal models of chronic HE that decreased brain BCAA concentrations is normalized and that acceleration of ammonia metabolism occurs by stimulated glutamine synthesis, after intravenous infusion of BCAA[41]. Thus, it is possible that administration of BCAA blocks the vicious cycle of cerebral energy metabolism in HE by providing the amino group for glutamate synthesis from a-ketoglutarate in astrocytes.

In the present study, we found that cirrhotic patients increased thalamic perfusion after the administration of oral BCAA. According to current knowledge, information coming from the cortex passes through the striatopallidal system to the thalamus and then returns to the cortex. Alterations of neurotransmission within the pallidum and thalamus therefore may lead to impairment of cortical function, as in HE[42]. Catafau *et al.* reported that thalamic CBF increases in proportion to neuropsychological deficits as a compensatory effect[12]. Supplementation with BCAA may be effective in the treatment of cirrhotic patients for improving thalamic CBF.

A number of studies have reported association between minimal HE and impairment of quality of life[5,6,8-10]. It has also been suggested that the ability to drive a car is impaired in patients with cirrhosis and minimal HE[43]. Therefore, it is important to initiate therapy to improve neuropsychological function. Protein restriction may not be beneficial for long-term therapy in patients with protein malnutrition. Oral BCAA supplementation may be one of the candidates for the initial treatment of minimal HE. In the present study, there was no significant change in the results of neuropsychological test after the administration of BCAA. Additional study is necessary to clarify the time course of regional CBF changes after oral administration of BCAA. Neuropsychological performance and cerebral perfusion after long-term oral administration of BCAA also needs further evaluation.

In conclusion, this study shows that patients with cirrhosis and no neurologic symptoms have widespread reduction in relative CBF and that this is restored after oral intake of BCAA. These findings suggest that oral supplementation with BCAA may be a therapeutic adjunct of conventional therapy for the treatment of cirrhotic patients for its beneficial action on regional CBF.

Abstract

AIM: To investigate the prevalence, risk factors, and selection of the study population for cholecystolithiasis in an urban population in Germany, in relation to our own findings and to the results in the international literature.

METHODS: A total of 2 147 persons (1 111 females, age 42.8 ± 12.7 years; 1 036 males, age 42.3 ± 13.1 years) participating in an investigation on the prevalence of *Echinococcus multilocularis* were studied for risk factors and prevalence of gallbladder stone disease. Risk factors were assessed by means of a standardized interview and calculation of body mass index (BMI). A diagnostic ultrasound examination of the gallbladder was performed. Data were analyzed by multiple logistic regression, using the SAS statistical software package.

RESULTS: Gallbladder stones were detected in 171 study participants (8.0%, *n* = 2 147). Risk factors for the development of gallbladder stone disease included age, sex, BMI, and positive family history. In a separate analysis of female study participants, pregnancy (yes/no) and number of pregnancies did not exert any influence.

CONCLUSION: Findings of the present study confirm that age, female sex, BMI, and positive family history are risk factors for the development of gallbladder stone disease. Pregnancy and the number of pregnancies, however, could not be shown to be risk factors. There seem to be no differences in the respective prevalence for gallbladder stone disease in urban and rural populations.

INTRODUCTION

Disorders of the gallbladder are a major cause of morbidity and a leading indication for hospital admissions in the United States[1-4] and in Europe[5,6]. In these developed nations, the economic impact of gallstone disease is high[1-5]. In the United States, more than 500 000 cholecystectomies are performed annually and direct costs for the diagnosis and treatment of gallbladder stones are estimated at 5 billion US Dollar per year[7,8]. For the treatment of gallstone disease in Germany, 200 inpatient hospital days per 10 000 health insured persons accumulate every year[9]. This creates costs of more than ½ billion[10]. Gallstone disease is not only an unsolved problem in Western industrialized nations but also in African nations[11,12] as well as in Asian countries like China, India, Bangladesh, and Japan[13-17]. Cholelithiasis is one of the commonest surgical diseases in China and accounted for 11.5% of overall hospitalized patients during the period from 1985 to 1995[18].

The most important risk factors for the development of gallstone disease currently being discussed in the literature include age[19-23], female gender[14,20-22,24], obesity[6,25-28] and heredity[19,20,29-31]. Other factors like pregnancy or number of pregnancies are still discussed are contradictory[12,21,32-34].

To our knowledge, there are no publications that assess the influence of the selection of study population on gallstone disease prevalence.

The present prospective ultrasound-based survey investigates the prevalence and risk factors for cholecystolithiasis in an urban population and also addresses the effect of selection of study population on the different risk factors.

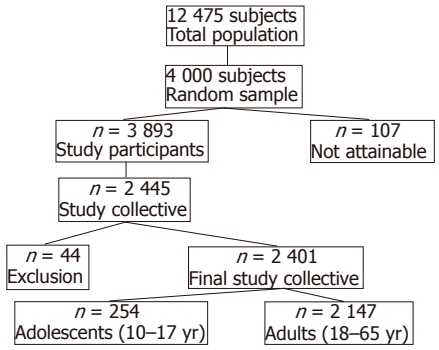

Figure 1 Study collective and participation.

METHODS

Study collective and participation

A random sample of 4 000 subjects was selected from the population of a city in southwestern Germany (total population: 12 475) for participation in a seroprevalence study for *Echinococcus multilocularis*. Of the 4 000 randomly selected and invited subjects, 107 could not be included in the final evaluation due to factors such as non-response to repeated invitations or incompetent legal status (n = 39), or moved away with no forwarding address (n = 68), resulting in a total random sample size of 3 893 subjects. Out of this pool, a total of 2 445 persons actually participated in the study (response rate: 62.8%). The following inclusion and exclusion criteria determined the composition of the collective studied for gallbladder stone disease (Figure 1):

Only persons in the age of 10-65 years were included into the study. Written consent for the examination and collection of personal health information was required.

Failure to visualize and assess the gallbladder or poor or restricted examination conditions lead to the exclusion from the study collective (n = 26 subjects). Significant contraction of the gallbladder following an inadequate fasting period (when no clinical signs of cholecystitis were identified) (n = 9 subjects), a history of cholecystectomy for gallbladder polyps or cholecystectomy of unknown reason (n = 4 subjects) or subject's refusal to undergo examination (n = 1 subject) also constituted exclusion criteria. Missing or invalid data acquisition (n = 4 subjects). Patients with prior cholecystectomy for gallbladder stones were added in the calculations of the gallbladder stone prevalence.

The total collective of subjects undergoing ultrasound examination of the gallbladder was 2 401 persons. In order to enhance comparability with published studies, we explicitly examined adult subjects aged 18-65 years. This non-selected adult collective consisted of 2 147 subjects (1 036 males, 48.3%; 1 111 females, 51.7%).

Subjects' informed written consent was obtained for examination and collection of personal health information. The study met the international agreements of the Helsinki Declaration from 1996 and was approved by the research Ethics Committee of the Baden-Württemberg General Medical Council (Landesärztekammer Baden-Württemberg).

Questionnaire and physical examination

Under the guidance of a trained interviewer, each subject completed a comprehensive questionnaire covering the following parameters: Demographic information (age, sex, nationality, marital status, education, occupation), recreational activities (sports, exercise), medical history (gallbladder stones, gastrointestinal, hepatic, cardiovascular, respiratory, endocrine, renal, rheumatic, or malignant diseases), dietary behavior (meal patterns including intake of certain foods; fluid intake including alcohol, use of tobacco products), family history (gall bladder stone disease, diabetes mellitus, overweight, history of cancer) and medication history.

Based on the recommendations of the WHO[35] for anthropometric measurements, patients then underwent determination of body height and weight and waist and hip circumference. BMI was calculated according to the common formula[35].

Ultrasound examination

Study participants were asked to present for the examination following a 4-h fasting period. All subjects underwent ultrasound examination of the upper abdomen under standard conditions to assure exact evaluation of the gallbladder. In order to enhance visualization of the gallbladder, subjects were asked to raise their right arm over their head, which increases both the intercostal spaces and the distance between the lower margin of the rib cage and the iliac crest. Examination was performed upon deep inspiration and with outward pressure on the abdominal wall.

The gallbladder was examined in three planes (longitudinal, cross-sectional and diagonal), providing the examiner with a three-dimensional impression of the organ. In cases in which cholecystolithiasis was present, the mobility of the stone(s) was assessed. Subjects, in whom differentiation between mobile stones and wall-adhering polyps was difficult, were examined again in standing position in order to reliably distinguish between stone and polyps on the basis of their mobility. The thickness of the gallbladder wall was measured and, in subjects with gallbladder stones, the number, size, and localization of stones before mobilization were determined. Ultrasound examinations were performed by a group of six examiners trained in gallbladder sonography. These examiners worked under supervision of an experienced specialist (>4 000 examinations per year), who also reviewed all questionable findings. Examinations were performed using four identical, state-of-the-art HDI-5000 ultrasound scanners (Advanced Technology Laboratories Ultrasound, Philips Medical Systems, Bothell, WA, USA).

Criteria for the diagnosis of gallstones were as follows: one or more hyperechoic structure(s) in the gallbladder with dorsal shadow; one or more hyperechoic structure(s) in the gallbladder without dorsal shadow but which by means of examination in multiple planes and/or attempt at mobilization can be certainly distinguished from a gallbladder septum, Heister's valve or a gallbladder polyp; a strongly hyperechoic structure with dorsal shadow in

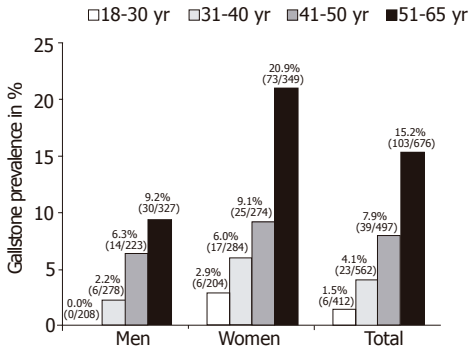

Figure 2 Distribution of gallbladder stone prevalence in relation to sex and age.

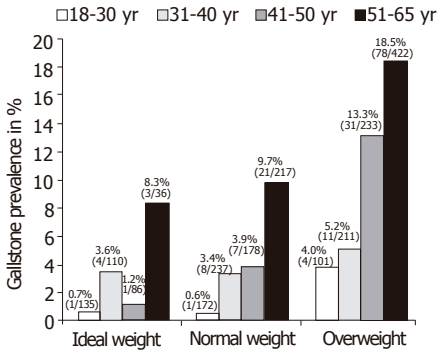

Figure 3 Prevalence of gallbladder stones in relation to BMI and age.

the anatomic location of gallbladder, with no or only slight visualization of residual gallbladder lumen; failure to delineate the gallbladder lumen in patients who have undergone prior cholecystectomy and who demonstrate corresponding surgical incisions in the right upper abdominal quadrant; presence of a significant amount of gallbladder sludge filling at least one-quarter of the gall bladder lumen with corresponding dorsal shadow.

Subjects, who because of recent food intake or other reasons, such as overlying intestinal gas, presented unfavorable examination conditions, were excluded from the study.

Statistical analysis

Multiple logistic regression[36] was performed to assess the impact of the known risk factors age, sex, BMI, and positive family history on the development of gallbladder stones. Two further multiple logistic regression models were fitted for female study participants in order to assess the impact of pregnancy and number of pregnancy, whereby in both models odds ratios were adjusted for the known risk factors like age, BMI, and positive family history for gallbladder stones. Odds ratios with 95% confidence interval and corresponding *P*-value are given. Statistical analyses were performed using the SAS statistical software package (version 8.02).

RESULTS

Prevalence in relation to age and sex

Gallbladder stones were detected at upper abdominal ultrasound examination in 87 of 2 147 subjects examined (4.1%), while gallbladder sludge was identified in two subjects (0.1%). A further 84 subjects (3.9%) had undergone prior cholecystectomy for the treatment of gallbladder stone disease. Thus, 171 subjects satisfied the inclusion criteria for cholecystolithiasis, representing an overall prevalence of cholecystolithiasis of 8.0% in the study population.

Among females, the proportion of subjects with current or prior gallbladder stone disease stood at 10.9% (121 of 1 111 subjects), while 4.8% of males (50 of 1 036 subjects) fulfilled the criteria for the diagnosis of cholecystolithiasis. The prevalence of gallbladder stone disease was higher for females than for males in all age classes. The highest prevalence was found in the group of females aged 51-65 years (20.9%; 73 of 349 subjects; Figure 2). Overall, the prevalence of gallbladder stones (defined as current and past cholecystolithiasis) increases with advancing age from 1.5% among subjects aged 18-30 years to 15.2% in the 51-65 years age group.

Prevalence in relation to BMI

BMI was calculated in 99.6% of study participants (n = 2 138). Mean BMI for the subcollective of subjects without gallbladder stone disease was 25.8±4.9 kg/m^2 (median 25.1 kg/m^2; range: 14.1-52.6 kg/m^2). Corresponding value for subjects with current or prior cholecystolithiasis was 29.2±5.9 kg/m^2 (median 28.7 kg/m^2; range: 17.6-51.5 kg/m^2). For description, BMI results were assigned to one of three classes defined according to the recommendations of the World Health Organization (WHO; Figure 3).

Class I, defined as at or below a subject's respective ideal weight (BMI <21 kg/m^2 in females and <22 kg/m^2 in males), included 367 subjects (17.2%). Class II (BMI 21-25 kg/m^2 in females and 22-26 kg/m^2 in males) included 804 subjects (37.6%), while 967 subjects (45.2%) met the criteria for Class III (BMI >25 kg/m^2 in females and BMI >26 kg/m^2 in males), and thus were considered as overweight. Only 9 subjects (2.5%) in BMI Class I exhibited evidence of gallbladder stone disease compared to 37 subjects (4.6%) in Class II and 124 subjects (12.8%) in Class III (Figure 3).

Prevalence in relation to positive family history of gallbladder stones

Of 2 147 subjects, 105 (4.9%) were unable to provide information on their biological parents; thus, evaluation of the influence of hereditary predisposition was limited to a subcollective of 2 042 subjects. Gallbladder stones were diagnosed more frequently in subjects with a positive family history of cholecystolithiasis. In subjects with a positive family history involving one biological parent, the prevalence of gallbladder stones stood at 12.6% (51 of 405 subjects) and at 14.3% (3 of 21 subjects) in subjects, both of whose biological parents suffered from gallbladder stone disease. In the remaining 1 616 subjects with negative family history of gallbladder stone disease, prevalence of cholecystolithiasis stood at only 6.3% (n = 102).

Table 1 Classical risk factors of cholecystolithiasis in multiple logistic regression

Classical risk factors	Odds ratio (OR)	95%CI	*P*
Age (per yr)	1.06	1.05–1.08	<0.001
Female sex	2.78	1.91–4.07	<0.001
BMI (per kg/m^2)	1.12	1.08–1.15	<0.001
Positive family history	1.89	1.30–2.75	<0.001

Table 2 History of pregnancy and the number of prior pregnancies in the multiple logistic regression model (only females)

Factor tested	Odds ratio (OR)	95%CI	*P*
Age (per yr)	1.06	1.04–1.08	<0.001
BMI (per kg/m^2)	1.11	1.07–1.15	<0.001
Positive family history	1.99	1.28–3.07	0.002
Positive history of pregnancy	0.76	0.44–1.31	0.321

Prevalence in relation to pregnancy

All female study subjects were questioned about their pregnancy status. Fifteen women declined to provide information on prior pregnancy. Of the remaining 1 096 subjects included in this analysis, 26.3% (n = 288) reported never having been pregnant. The group of women with positive history of pregnancy (n = 808, 73.7%) was broken down into the group with one to two pregnancies (560 women, 51.1%) and those with three or more pregnancies (248 women, 22.6%). Gallbladder stones were detected in 22 of 288 nulliparae (7.6%). In the group of 560 women with one or two pregnancies, 55 subjects (9.8%) were positive for past or present cholecystolithiasis, compared to 43 subjects (17.3%) in the group of patients with three or more pregnancies.

Multiple logistic regression analysis

Multiple logistic regression showed a strong association of the factor "age" with the development of gallbladder stones (OR 1.11 per year of age; 95%CI: 1.05-1.08; P<0.001; Table 1). The comparison of females to males yielded an odds ratio of 2.78 (95%CI: 1.91-4.07; P<0.001; Table 1). Body mass index (BMI in kg/m^2) also was an important risk factor (OR 1.12 per-unit; 95%CI: 1.08-1.15; P<0.001; Table 1). Compared to study subjects without known gallbladder stone disease in the biological parents, persons with a positive parental history of cholecystolithiasis showed an odds ratio of 1.89 (95%CI: 1.30-2.75; P<0.001; Table 1).

In separate logistic regression models for females including the risk factors age, BMI, and family history, neither pregnancy nor number of pregnancies showed an association with the development of gallbladder stone disease. The first model revealed an OR of 0.76 for pregnancy yes *vs* no (95%CI: 0.44-1.31; P = 0.321; Table 2) and the second model an OR of 0.65 for one or two pregnancies *vs* no pregnancy and an OR of 1.04 for three or more pregnancies *vs* no pregnancy (95%CI: 0.37-1.15 and 0.56-1.94; P = 0.104; Table 3).

Table 3 Number of pregnancies in the multiple logistic regression model (only females)

Factor tested	Odds ratio (OR)	95%CI	*P*
Age (per yr)	1.06	1.04–1.08	<0.001
BMI (per kg/m^2)	1.11	1.07–1.15	<0.001
Positive family history	2.09	1.34–3.25	<0.001
Number of pregnancies			0.104
One or two *vs* none	0.65	0.37–1.15	
Three or more *vs* none	1.04	0.56–1.94	

DISCUSSION

The present ultrasound-based epidemiological survey is, to our knowledge, the first study conducted in a collective drawn from an urban population in Germany. The prevalence of gallbladder stone disease in our unselected collective stands at 8.0%. Our findings are comparable, on one hand, with those documented in a rural population and in a collective of blood donors in Germany[19,20], and, on the other, with the prevalence figures reported from Italian, British, and Danish studies[21,27,33,37], but our results are not comparable with the low prevalences from Eastern countries such as China, India, Japan, Taiwan, and Thailand[14,16,17,23,38] (Figure 4).

The prevalence of gallbladder stone disease (predominantly cholesterol gallstones) reported from a majority of European and American studies shows a clear female dominance. In Asian countries with a higher prevalence of pigment gallstones, the female dominance is less distinct[6,23,38]. In the present study, female sex was also found to be a clear risk factor (OR = 2.78; 95%CI: 1.91-4.07; P<0.001) and the ratio of males with gallbladder stone disease to females stood at 1 to 2.3. Due to the great importance of the risk factors, age and especially female sex, the selection modalities of study collectives gain paramount importance[6,37]. Comparing gallbladder stone prevalence in women in relation to the method of selecting the study population, the highest prevalence is observed in studies conducted as a cross sectional sample of the total population[20–22] or large random samples[14,24] (Table 4). Most large European studies were conducted either as random samples[24,39,40] or as surveys of entire factories or governmental departments[32,41] (Table 4).

Our findings from Leutkirch (total prevalence 8.0%) are comparable to those reported for populations in Römerstein (7.8%) and blood donors in Ulm (6.0%) as well as to Italian studies conducted in Sirmione (6.9%) and Chianciano (5.9%), all of which were conducted as cross-sectional sample of the total population[19–22] (Figure 4).

The prevalence of gallbladder stones in our study collective is lower in younger persons than in those belonging to older age groups. Similar trends toward higher gallbladder stone prevalence in older persons have been described in nearly all sonographic studies[6,19,20,23,25], as well as in autopsy studies[37] and in studies based on clinical symptoms[42] (Figure 4).

Using multiple regression analysis under consideration

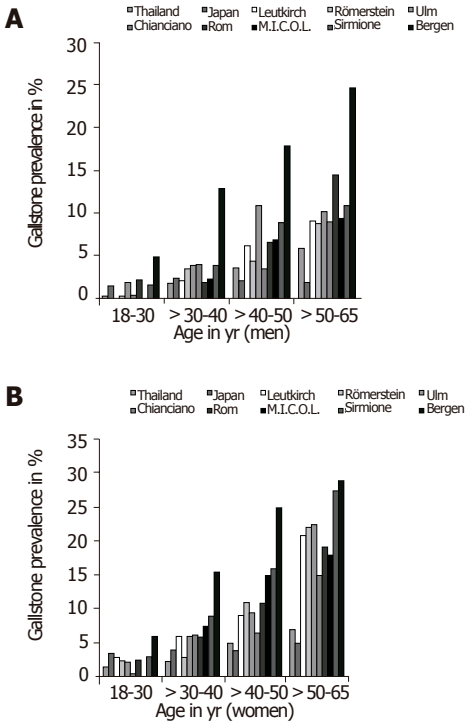

Figure 4 Age adjusted gallbladder stone prevalence in males and females in comparable large studies. **A:** in men; **B:** in women.

of the known risk factors age, sex, and family history, we found an association with study participants' current BMI (OR 1.12/unit; 95%CI: 1.08-1.15; $P<0.0001$). As in most other European studies, our findings showed an increased prevalence of gallbladder stone disease in overweight subjects[6,25–28]. The prevalence of gallbladder stones in subjects with a positive family history in the biological parents (12.7%) is more than twice as high as that in subjects with negative family history (6.3%). Our findings point to a strong effect for genetic factors in the pathogenesis of cholecystolithiasis (OR = 1.89; 95%CI: 1.30-2.75; $P<0.001$), although the mechanism of inheritance is not known. A familial accumulation of cholecystolithiasis cases has been observed in other sonographic screening studies in first-degree relatives of persons suffering from gallbladder stones[6,29-31,39].

The multiple logistic regression model failed to show an increased prevalence of gallbladder stones for female subjects with prior pregnancy (prevalence 12.1% *vs* 7.6%). One reason might be the much lower average age of the nulliparae (33.6±13.7 years) compared to women who had borne children (46.0±10.7 years), suggesting that the higher prevalence may actually be an age-related phenomenon. This effect is also apparent in the increased prevalence of gallbladder stones in women with three or more pregnancies (average age 48.9±9.7 years) compared with women who had been pregnant only one or two times (average age 44.7±10.9 years). The analysis of pregnancy as a risk factor for cholecystolithiasis has lead to different results in the literature[12,21,32–34] which range from no effect to a prevalence that is reduced by a factor of 40 in comparison of nulliparae to women who have been pregnant[15,43] (Table 5). The old clinical experience of an increased prevalence of gallbladder stones in women who have borne children could not be substantiated by the findings of the present study.

Table 4 Relative risk for gall bladder stones in relation to selection of study population

Place/region	Population selection	*n*	Sex distribution male:female
Chiayi[23]	Random sample	923	1:1.0
Rome[32]	Factory	2 325	1:1.1
Bergen[40]	Random sample	1 371	1:1.1
Ulm[19]	Blood donors	1 116	1:1.1
Copenhagen[44]	Random sample	4 807	1:1.4
Chiang Mai[38]	Random sample	6 146	1:1.5
Schwedt[41]	Factory	1 616	1:1.6
Okinawa[17]	Inhabitants of an island	2 584	1:1.7
Jiaotong[14]	Random sample	15 856	1:2.0
M.I.C.O.L[24]	Random sample	29 739	1:2.0
Römerstein[20]	Total survey	2 498	1:2.1
Sirmione[21]	Total survey	1 911	1:2.2
Cianciano[22]	Total survey	1 804	1:2.3
Leutkirch	Random sample	2 401	1:2.3

In conclusion, the classical risk factors age, female sex, body mass index (BMI), and positive family history have been confirmed by the findings of the present study. The female-specific factors of prior pregnancy and number of prior pregnancies, however, could not be shown to exert measurable influence on the prevalence of gallbladder stones. The selection of study populations affects study results i.e. the strength of the effect of female sex on the development of gallbladder stones. There does not appear to be a difference between the prevalence of gallbladder stones in urban and rural populations.

ACKNOWLEDGMENTS

The study was initiated by the Government of the state of Baden-Württemberg, Germany. Financial support was granted via the work of the Baden-Württemberg state health office, District Government Stuttgart, Germany as well as the regional health office from Ravensburg, Germany. Further support was granted by the administration of the city of Leutkirch, Germany. Vials for blood samples and part of the laboratory testing were supplied by Sarstedt AG & Co., Nürnbrecht, Germany. BOB is supported by the German Research Council (GRK 1041). The authors wish to express their gratitude to Mr. Walter Feucht of the ULDO Backwaren Company, Neu-Ulm, Germany for his generous support of this study. Without his participation, the rapid evaluation and prompt analysis of the data would not have been possible. The following members of the EMIL-Study-Group contributed to the accomplishment of this study: Adler G, Armsen A, Banzhaf H-M, Bauerdick M, Bertling U, Boehm BO, Brandner BO, Brockmann SO, Deckert M, Dingler C, Eggink S, Fuchs M, Gaus W, Goussis H, Gruenert A, Haenle MM, Hampl W, Haug C, Hay B, Huetter M-L, Imhof A, Kern P, Kimmig P, Kirch A, Klass D, Koenig

Abstract

AIM: To determine the risk factors for the development of esophageal adenocarcinoma in these patients with columnar-lined esophagus (CLE).

METHODS: Data collected retrospectively on 597 consecutive patients diagnosed at endoscopy and histology to have CLE at Leeds General Infirmary between 1984 and 1995 were analyzed. Factors evaluated included age, sex, length of columnar segment, smoking, and drinking habits, history of non-steroidal ingestion, presence of endoscopic esophagitis, ulceration or benign strictures and presence of *Helicobacter pylori* in esophageal biopsies. Univariate and multivariate analyses were performed to identify risk factors for the development of adenocarcinoma.

RESULTS: Forty-four patients presented or developed esophageal adenocarcinoma during follow-up. Independent risk factors for the development of adenocarcinoma in patients with CLE were males (OR 5.12, 95%CI 2.04–12.84, $P = 0.0005$), and benign esophageal stricture (OR 4.37, 95%CI 2.02–9.45, $P = 0.0002$). Male subjects and patients who developed benign esophageal stricture constituted 86% ($n = 38$) of all patients who presented or developed esophageal adenocarcinoma. The presence of esophagitis was associated with a significant reduction in the development of esophageal carcinoma (OR 0.28, 95%CI 0.13–0.57, $P = 0.0006$). No other clinical characteristics differentiate between the non-malignant and malignant group.

CONCLUSION: In patients with CLE, endoscopic surveillance for the early detection of adenocarcinoma may be restricted to male subjects, as well as patients who develop benign esophageal strictures.

Key words: Barrett's esophagus; Adenocarcinoma; Risk factors; Esophageal adenocarcinoma; Esophageal stricture

INTRODUCTION

Columnar-lined (Barrett's) esophagus (CLE) is defined as the replacement of the normal squamous lining of the lower esophagus by a unique metaplastic columnar epithelium usually as a consequence of chronic gastro-esophageal reflux (GER). The prevalence of CLE has been estimated to occur in 1 in 400 of the general population[1], and in 10–16% of patients with reflux esophagitis[2,3]. Cameron *et al.* suggested that there are 20 times as many cases of CLE in the general population as are clinically diagnosed[4].

Patients with CLE are at increased risk of esophageal adenocarcinoma[5]. The incidence of the latter varies between one in 46 to one in 441 patient-years follow-up[6,7] with an annual incidence of 1%, and is increasing more rapidly than any other type of malignancy[8,9]. Endoscopic surveillance programs are therefore instituted. Nonetheless, the increased cost and workload associated with the surveillance adds to the pressures on available resources. The identification of risk factors for the development of adenocarcinoma in these patients may allow for the selection of patients for intense endoscopic surveillance and a more efficient utilization of health care services and resources.

The current paper examines our experience with 597 consecutive patients diagnosed to have CLE for over a 11-year period. Our aim was to determine clinical factors, which could identify a subgroup of patients who are at a higher risk for the development of adenocarcinoma and who therefore would benefit most from being in a surveillance program. Examining the characteristics of

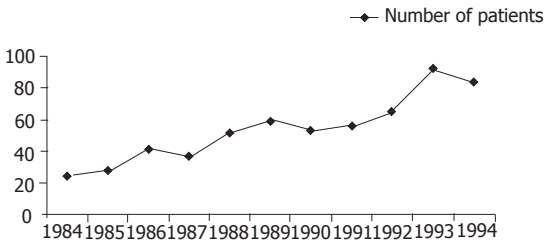

Figure 1 Number of patients diagnosed with columnar-lined esophagus during the study period.

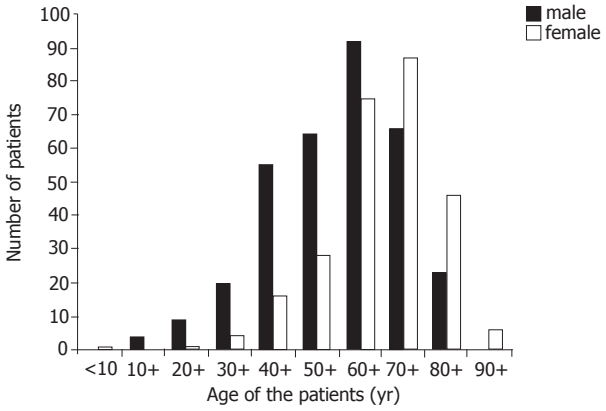

Figure 2 Age of patients at the time of diagnosis of columnar-lined esophagus.

patients with CLE and comparing them between the non-malignant group and both the prevalence and incident cases of adenocarcinoma might serve this purpose.

PATIENTS AND METHODS

Between January 1984 and December 1995, 626 consecutive patients were diagnosed at endoscopy and histology to have a CLE under the care of the Center for Digestive Diseases at the General Infirmary at Leeds. Patients were identified from a computer registry at the Institute of Pathology and their records were retrospectively reviewed. Data, including patient demographic characteristics, endoscopic findings, and histology reports were entered into a computer database.

Columnar-lined esophagus was defined as the presence of columnar-lined epithelium at least 3 cm above the endoscopically determined gastro-esophageal junction or the presence of specialized columnar epithelium (SCE) anywhere in the esophagus. Twenty-nine patients were excluded from this study; 17 patients did not fulfill the definition criteria mentioned above and the medical records of 12 patients could not be located.

Factors that may be associated with increased risk of development of adenocarcinoma were examined. These included age, sex, smoking, regular alcohol use, the ingestion of non-steroidal anti-inflammatory drugs (NSAIDs), length of columnar segment, the presence of hiatul hernia, esophagitis, benign esophageal stricture or ulcers at endoscopy, and the presence of SCE or *H pylori* in esophageal biopsies. Mean follow-up was 43 (range 1-155 mo) mo. Data related to the size of hiatul hernia and body mass index of the patients were incomplete and excluded from analysis. Data related to the result of the surveillance program for these patients were published elsewhere[6].

Patients were defined as smokers if they regularly smoked more than 10 cigarettes per day for at least one year at any time before the diagnosis of CLE. Patients were defined as regular alcohol users if they have a history of drinking 10 units of alcohol or more weekly for at least one year at any time before the diagnosis of CLE. Patients who have a history of regular ingestion of NSAIDs for at least 6 mo at any time before the diagnosis of CLE were regarded as NSAIDs users. *H pylori* colonization was determined upon the basis of hematoxylin and eosin and the use of a modified Giemsa stain of esophageal and gastric biopsy specimens.

All cases with malignant stricture were not regarded as cases of benign esophageal stricture and were not considered for the analysis. Only cases where the stricture was away from the cancer and histologically not involved with cancer were regarded as benign esophageal ulcer.

Statistical analysis

Univariate analysis was performed utilizing the χ^2 test and the Mann–Whitney *U* test as appropriate. Statistical significance was accepted at a $P<0.05$. Stepwise logistic regression analysis was used to identify independent risk factors. Statistical analyses were performed using SPSS for Windows version 10.

RESULTS

Five hundred and ninety-seven patients with histologically confirmed diagnosis of CLE were seen at our institute from 31st January 1984 to 31st January 1995. The number of new patients diagnosed each year during the study period showed an increasing trend (Figure 1). There were 333 (56%) males and 264 (44%) females. The mean age for the total group was 63.4 years (SD 14.86; range 2-94 years). Seventy-three percent of the male patients (244/333) had their diagnosis below the age of 70, while 81% (214/264) of female patients were diagnosed when they were above 60 years of age (Figure 2).

Of the 597 patients included in the analysis, 31 (5.2%) presented or developed adenocarcinoma within 6 mo of initial diagnosis of CLE and 13 (2.2%) developed adenocarcinoma after a mean follow-up of 55 mo (range 8-155 mo). Patients were divided into two groups: Non-malignant group: 553 patients had no esophageal adenocarcinoma either at initial presentation or during follow-up. There were 299 (54%) males and 254 (46%) females. Malignant group: 44 patients presented (31 patients) or developed (13 patients) esophageal adenocarcinoma. There were 34 (77%) males and 10 (23%) females.

Table 1 summarizes the details of patients and the results of the univariate analysis of the risk factors studied. Table 2 summarizes the results of multivariable analysis.

Table 1 Univariate analysis of potential risk factors for the development of esophageal adenocarcinoma in patients with columnar-lined esophagus

	Non-malignant group (n = 553)	Malignant group (n = 44)	P

CLE – columnar-lined esophagus; NSAIDs – non-steroidal anti-inflammatory drugs; Hp – *Helicobacter pylori*. +Information regarding smoking was available in only 356 patients of the non-malignant group and 41 patients of the malignant group; ‡information regarding alcohol consumption was available in only 342 patients of the non-malignant group and 40 patients of the malignant group.

Table 2 Risk factors associated with the development of adenocarcinoma in patients with CLE; results of multivariable regression analysis

Risk factors	Odds ratio	95%CI for Odds ratio	P
Age ≥60 yr	1.65	0.75–3.64	0.216
Male sex	5.12	2.04–12.84	0.0005
Regular alcohol use	1.15	0.46–2.90	0.760
NSAIDs	1.41	0.68–2.93	0.352
Esophagitis	0.28	0.13–0.57	0.0006
Esophageal stricture	4.37	2.02–9.45	0.0002

CLE – columnar lined esophagus; NSAIDs – non-steroidal anti-inflammatory drugs

Significant independent risk factors for the development of esophageal adenocarcinoma in patients with CLE were male sex, and benign esophageal stricture. Male subjects and patients who developed benign esophageal stricture constituted 86% (n = 38) of all patients who presented or developed esophageal adenocarcinoma. Among the 24 patients who presented with esophageal adenocarcinoma, 9 patients had histologically proven benign peptic stricture above and away from the cancer and the strictures were located at the junction of the columnar mucosa with the squamous epithelium. Among the seven patients who developed esophageal adenocarcinoma within 6 mo after the diagnosis of CLE, four of them had histologically proven benign peptic stricture at the time of diagnosis of CLE. Among the 13 patients who developed esophageal adenocarcinoma after a mean follow-up of 55 (range 8-155 mo) mo, three patients had histologically proven benign peptic stricture at the time of diagnosis of CLE, and these three patients developed adenocarcinoma 17, 24, and 35 mo after the diagnosis of CLE, respectively.

The presence of esophagitis was associated with a significant reduction in the development of esophageal carcinoma. Although univariate analysis identified the length of columnar-lined esophageal segment and the presence of SCE on endoscopic biopsies as significant variables (P = 0.001, P = 0.047 respectively), these did not reach significance on multivariable analysis. Age >60 years, smoking, alcohol consumption, the presence of hiatul hernia or esophageal ulcer, and the presence of *H pylori* in the esophageal biopsies were insignificant risk factors for malignant progression.

Symptoms as a risk factor

For the purpose of comparison between the two groups, the main principal symptom for each patient was considered at the time of diagnosis, although many patients had more than one symptom. In the non-malignant group, the main symptoms at presentation were as follows: In 259 patients (46.8%), the main symptoms were those of GER (heartburn, regurgitation) or dyspepsia. Anemia or gastro-intestinal bleeding was the main symptom in 137 patients (24.8%). Dysphagia was the main symptom in 111 patients (20%) and chest pain was the main symptom in 26 patients (4.7%). Weight loss was the main symptom in only 20 patients (3.6%). Ninety-four patients (17%) in the non-malignant group had no esophageal symptoms at the time of diagnosis and CLE was diagnosed when endoscopy was performed to investigate iron deficiency anemia. In the malignant group, the main symptom was dysphagia in 21 patients (47.7%). Anemia or gastrointestinal bleeding was the main symptom in nine patients (20.5%). GER symptoms were the main symptoms in 10 patients (22.7%). Weight loss was the main symptom in four patients (9%). Dysphagia rather than reflux symptom was the main complaint of the patients in the malignant group at the time of diagnosis. This was mainly due to dysphagia being prominent in the prevalent adenocarcinoma cases (61%; 19/31) as would be expected; in contrast among the 13 patients who developed adenocarcinoma during follow-up, dysphagia was the main symptom in only two patients (15%; 2/13).

Length of the columnar segment

The length of the columnar segments for all patients is shown in Figure 3. Twenty-three patients had short segment (<3 cm) of SCE; none of this group were adenocarcinoma patients. The mean length of the columnar segment in the non-malignant group was 5.8 cm; range 2-20 cm and for the malignant group was 7.2 cm; range 3-15 cm. There was no correlation between the extent of the columnar segment and the presence or absence of symptoms of GER.

Esophageal and gastric H pylori

Forty-four patients only (7.4%) had *H pylori* detected in their esophageal biopsies. Only 234 patients of this series had gastric biopsies in addition to their esophageal specimens. Among this subgroup who had biopsy demonstrated CLE and from whom concomitant gastric biopsies were taken, 77 patients (32.9%) had *H pylori* in

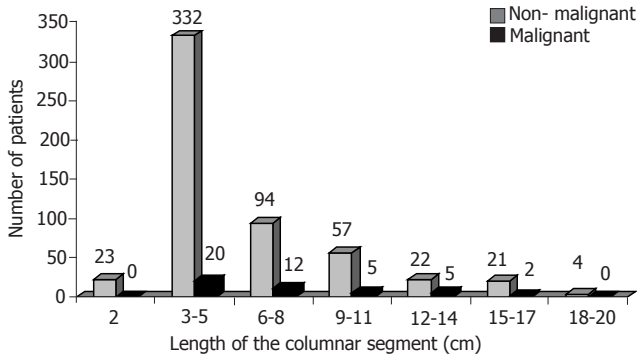

Figure 3 Length of the columnar segments in all patients.

their gastric biopsies, 20 of them had *H pylori* in both the esophageal and gastric specimens. The finding of *H pylori* in CLE biopsies was not associated with increase in the prevalence of esophagitis (52% *vs* 58%), esophageal strictures (11% *vs* 16%), esophageal ulcers (23% *vs* 21%) or esophageal adenocarcinoma (4.5% *vs* 7.6%).

DISCUSSION

The present series confirms the findings of other studies[10,11] that the prevalence of CLE increases with age and reaches a peak in late middle age. Eighty-two percent of our patients (487/597) were diagnosed when they were over 50 years of age. The high prevalence of CLE occurs mainly in later middle age and the elderly as shown by our population with a mean age of 59 in males and 68 in females, although it can be seen in younger patients also. However, only 2.5% of patients (15/597) were under 30 years of age at the time of diagnosis. One patient had a diagnosis of CLE below the age of 10 and this was a 3-year old girl who presented with repeated vomiting. Endoscopic and histological examination confirmed the diagnosis of CLE and anti-reflux surgery was performed on this patient at the age of four. This case could be explained on the basis of the few cases of congenital Barrett's esophagus reported previously[12].

Although there were slightly more males than females in the whole of our series (56% *vs* 44%), we have found that below the age of 60, there is a clear male predominance of 3:1. In contradiction to other published data, which showed either a male predominance[13] or an equal sex distribution[10,14], we observed a female predominance of 1.5:1 in patients above the age of 70.

A large proportion of patients with CLE in the general population will remain undiagnosed unless complications or carcinoma develop. CLE itself causes no symptoms[15] whereas the main symptoms, which bring patients to medical attention, are related to the reflux symptoms or complications of CLE such as ulceration, stricture, bleeding or adenocarcinoma. There is no correlation between severity of symptoms and histological findings, as about 17% of our patients with CLE had no esophageal symptoms. It is clear therefore that the selection of patients for a surveillance program cannot be based on symptomatology. This conclusion was also made in earlier patient series[10,16,17].

Our study confirms that patients with CLE have an increased incidence of esophageal adenocarcinoma. There were 7 patients who developed adenocarcinoma within 6 mo of initial diagnosis, before their first annual review endoscopy. This is likely to reflect the presence of undetected malignancy at the time of initial endoscopy. This probably represents a sampling error in the biopsies taken and therefore these seven patients were included in the prevalence rather than the incidence data[6].

This study identified male sex, and benign esophageal stricture to be independent risk factors (at least four-fold increased risk) for the development of esophageal adenocarcinoma in patients with CLE. Male patients with benign esophageal stricture constituted 86% of all patients who developed esophageal malignancy. The risk of malignancy was not related to the age of the patients, smoking, presence of SCE, length of columnar-lined segment, or the presence of esophageal ulceration or hiatul hernia on endoscopy or *H pylori* in esophageal or gastric biopsies. Previous reports identified white ethnicity[18], older age[19], male sex[13,14,20], SCE[21,22], long columnar segment[10,19,23-28], large hiatal hernia size[26,27], esophageal ulcer or stricture[10,29-31], severe acid reflux[26,32], obesity[33,34] and smoking and alcohol[20,35] to be associated with the progression from columnar epithelium to adenocarcinoma. However, some of these reports were based on observations or univariate analyses, and did not control for other variables as in the current study.

There was no significant association between age >60 years and the risk of malignant progression. Most patients are diagnosed with CLE in their sixth or seventh decade of life. Patients with Barrett's are often reported to be of the same age as those who develop cancer[26]. On the other hand, other studies have reported that the risk of esophageal adenocarcinoma increases with age. Gopal *et al.* reported that the risk of dysplasia increased by 3.3% per year of age[19]. A potential problem is that the mean age of patients with dysplasia is quite high, increasing the expected operative mortality and tending to preclude operative intervention. Clearly, surveillance should be offered only for those patients in whom esophagectomy is considered as a therapeutic option, if early carcinoma is detected. On the other hand, with the availability of ablation therapy, one can argue that even patients who are not fit for esophagectomy will benefit from the treatment of their high-grade dysplasia or early adenocarcinoma using photoablation irrespective of their age.

The increased susceptibility of male subjects with CLE to the development of esophageal malignancy has been reported previously[20,36,37]. In these series, men constituted 67–100% of all patients who developed esophageal adenocarcinoma (77% in this report). Our finding that benign stricture formation, which complicated 16% of all patients with CLE, was a risk factor for malignant transformation that supports previous reports[10,30,31,38,39]. Careful endoscopic surveillance of patients with benign

esophageal strictures is therefore required, despite the fact that malignant progression occurred in only one in eight patients.

We found no evidence to support the suggestion that a longer CLE segment is associated with a greater risk of carcinoma. Although the length of columnar segment was significantly greater in patients who developed esophageal adenocarcinoma compared with those who did not, this was not an independent risk factor for malignant transformation. This finding is in concordance with that of Robertson *et al*. who showed that the progression of the metaplastic epithelium up the esophagus, which occurred in 20% of their patients, was not associated with an increased risk of malignancy, as out of the 11 patients who had progression up to 6 cm, only 1 developed carcinoma[16]. Additionally, the marked association between adenocarcinoma of the gastroesophageal junction and 'short-segment' Barrett's mucosa[21,22,25,40] underscores the importance of the 'short-segment', and calls for follow-up program similar to that of longer segments of CLE. Rudolph *et al*. reported that segment length was not related to cancer risk in the full cohort of patients with CLE, and when patients with high-grade dysplasia at baseline were excluded; however, a non-significant trend was observed; a 5 cm difference in segment length was associated with a 1.7-fold increase in cancer risk. These authors concluded that the risk for esophageal adenocarcinoma in patients with short-segment Barrett esophagus was not substantially lower than that in patients with longer segments. They suggested that until more data are available, the frequency of endoscopic surveillance should be selected without regard to segment length[28].

There are some indications that the risk of cancer is proportionate to the anatomic extent of CLE[19,26,27]. A few studies have shown that the risk of adenocarcinoma increases with the length of the columnar segment and they suggested considering patients with CLE of more than 8 or 10 cm in length for surveillance. For example, Iftikhar *et al*.[24] reported that among 102 patients with CLE, 12 were found to have dysplasia; all of them had a columnar segment of 8 cm or more at the time of diagnosis and no patient with a columnar segment of less than 8 cm was found to have dysplasia or adenocarcinoma. In two retrospective studies conducted by Harle *et al*.[41] and Rosenberg *et al*.[42], 94% and 88% of patients with adenocarcinoma had long segments (>10 cm) of columnar epithelium. Both series suggested that an extended length of Barrett's esophagus is associated with a higher risk of malignant progression. Schnell *et al*.[23] reported a series of 238 patients with CLE. Adenocarcinoma was found in 7% of the 129 patients with segments less than 2 cm in length, in 12% of 50 patients with 3-5 cm segments, in 31% of 45 patients with 6-10 cm Barrett's segments and in 43% of the 14 patients who had segments of more than 10 cm in length. They concluded that there is a strong association between the length of CLE and risk of adenocarcinoma. Gopal *et al*. reported that the risk of dysplasia increased by 14%/cm of increased length[19], and similarly Avidan *et al*. reported that each 1-cm elongation of Barrett's mucosa carried with it a 17% increase in the risk of developing high-grade dysplasia or carcinoma[26]. On the other hand, other studies have suggested that shorter lengths of CLE may have been obscured by the tumor and therefore missed at resection. For example, Hamilton *et al*.[40] found that 64% of the resected specimens of adenocarcinoma of the esophagus and GEJ were associated with Barrett' s esophagus although the Barrett's mucosa was identified by endoscopic biopsies in only 38% of cases. When adenocarcinoma develops in a short segment of specialized epithelium, the tumor may destroy the area of specialized epithelium leaving no trace of such epithelium. Schnell *et al*.[21] did indeed report four patients with adenocarcinoma in short segment of specialized epithelium. Cameron *et al*.[22] reported that SCE was found in 9 of 9 (100%) cases of esophageal adenocarcinomas and in 10 of 24 (42%) of cases of junctional adenocarcinomas. SCE was found in 8 of 12 (67%) of junctional adenocarcinoma of 6 cm or less in length but in only 2 of 12 (17%) of larger tumors. Again they concluded that junctional adenocarcinomas are associated with both short and long segments of Barrett' s esophagus and larger tumors probably overgrow and conceal the underlying SCE from which they arise. In 38% of the patients who developed cancer, the metaplastic segment was less than 3 cm[43] Schnell *et al*.[21] emphasizes that patients with short segments should be considered at risk and should be followed in the same way as their counterparts with longer segments of CLE. The above studies clearly demonstrate that carcinoma can develop in short as well as long segment of CLE. It is now established that short segment CLE does carry a risk of malignant progression, *albeit* currently this is difficult to quantify[44].

Specialized epithelium is the most common and distinctive type of columnar epithelium found in CLE. Although dysplasia and carcinoma develop mainly in the presence of SCE, we cannot regard this type of epithelium as the sole indication for surveillance because histology has shown that it is present in most patients with CLE. Indeed nowadays its presence is rather a criterion to establish the diagnosis of CLE. There are, however, a few cases of adenocarcinoma, which can develop in columnar epithelium of other histological types (junctional or fundic type).

The reported data concerning the influence of alcohol consumption on the malignant progression of CLE is controversial. Most published reports including the current study suggest that alcohol ingestion has no or only little effect[26]. The reported decline in the incidence of oral cavity and pharynx cancers, which are traditionally, related to alcohol consumption contrasts with the increase in the incidence of esophageal adenocarcinoma[45]. Gammon *et al*. reported a decrease in the risk associated with wine drinking and no increase in the risk by the use of other alcoholic beverages[46]. Similarly, Garridou *et al*. reported that wine might have a protective effect[47]. On the other hand, other investigators have reported an increased risk of esophageal adenocarcinoma with high alcohol intake[20,35,48-50]. Zhang *et al*. reported a statistically not significant twofold increase in the risk of esophageal

adenocarcinoma in those who consume alcohol when compared with nondrinkers[48]. Kabat *et al*. reported that only hard liquor intake was associated with esophageal adenocarcinoma in males, and only daily beer intake was associated with adenocarcinoma in females[49]. Barrett's esophagus was reported to occur more frequently among subjects who consume large amounts of alcohol and alcohol consumption was also a risk factor for an increased length of Barrett's mucosa[51,52]. There is a well-known association between alcohol intake and risk of upper digestive tract cancers from epidemiological studies[53]. One possible mechanism is that this increased risk is due to a direct exposure of the esophageal mucosa to high alcohol concentrations but systemic effects could also be important.

There were no differences between smokers and non-smokers with regard to the length of the columnar segment and the presence or absence of Barrett's complications such as ulcer, stricture or adenocarcinoma. Several reports[26,54,55], as well as the current one, did not support the suggested increased risk of malignant transformation with smoking. Cooper and Barbezat[54] reported a series of 52 patients with CLE and 25 of them were smokers or ex-smokers. They also found no difference in the clinical characteristics between the smokers and non-smokers. Other investigators have shown a higher proportion of smokers in patients with CLE[56] and some suggested that the malignant progression of Barrett's metaplasia was higher in patients who smoked[20,35,50]. On the other hand, Levi *et al*.[55] evaluated the relationship between tobacco, alcohol and the risk of esophageal adenocarcinoma in CLE in an endoscopy-clinic-based case-control study of 30 cases of adenocarcinoma and 140 controls with non-malignant CLE. Among the cases, 18 (60%) were non-smokers and 14 (47%) non-drinkers, the corresponding proportions in the controls being 52% and 44%. Thus, there was no apparent relation between tobacco, alcohol and the risk of esophageal adenocarcinoma. They suggested that the findings of their study, although based on a limited number of cases, indicate that alcohol and tobacco are unlikely to play a major role in the etiology of adenocarcinoma in CLE. Overall, alcohol and tobacco may be risk factors for esophageal adenocarcinoma, but are not as important as they are in the etiology of esophageal squamous cell carcinoma[57].

Esophagitis and hiatal hernia were more common in the non-malignant group than the malignant group. But these differences have no clinical value, as it will not differentiate between the two groups. The apparent protective effect of esophagitis against malignant progression reflects the natural history of the disease. Esophagitis precedes the replacement of squamous with columnar epithelium, which in turn may become progressively dysplastic with final transformation into adenocarcinoma[12,58,59]. Additionally, columnar epithelium, unlike squamous, is less sensitive to injury secondary to GER and thus more resistant to inflammation[60].

There was an association between the prevalence of esophagitis and esophageal ulcerations with the history of NSAIDs ingestion within the non-cancer patients; however, there was no significant difference between the non-malignant group and malignant group regarding the prevalence of NSAIDs ingestion. It is likely that NSAIDs are prescribed or self-prescribed for esophagitis. Fifty-five percent of patients in the non-malignant group were taking these drugs at the time of diagnosis and 62% of them were found to have esophagitis or esophageal ulcerations. Cooper and Barbezat[54] reported similar findings and suggested that patients with CLE should avoid taking NSAIDs. However, NSAIDs are now proposed in intervention trials for patients with CLE. Increased expression of the cyclooxygenase 2 enzyme is proposed to be central to the development of esophageal cancer. Since this enzyme is inhibited by NSAIDs, these drugs hold promise as cancer chemopreventive agents in Barrett's esophagus patients[61]. Several preventive strategies against esophageal adenocarcinoma are under investigation using NSAIDs[62].

We found that esophageal ulcerations were present in 25% of patients in the carcinoma group (11/44) and in 21% of the patients who had no carcinoma (117/553); a difference that was not statistically significant. No case of esophageal perforation due to these ulcers was found in our series. These findings disagree with previous series, which suggested that the risk of developing carcinoma is increased in the presence of esophageal ulcers[10,29–31].

In concordance with previous work suggesting that stricture formation in CLE is a risk factor of malignant progression[10,30,31,39], we observed that esophageal strictures were present in 36% of patients in the carcinoma group (16/44) and in only 14% of the patients without carcinoma (77/553); a difference that was statistically significant. Theoretically it is possible that some of the strictures of the patients who presented or developed adenocarcinoma within 6 mo of CLE diagnoses could be malignant strictures (missed cancers) which were not detected histologically due to sampling error.

We found that *H pylori* colonization of the esophagus was not a risk factor for malignant progression. Our data indicate that *H pylori* can colonize the CLE, but its prevalence rate in the esophageal biopsies of these patients or in the subgroups that had complications or carcinoma is low and it is unlikely that *H pylori* has a significant role in the pathogenesis of CLE or its complications. Similar conclusion was reported before[63,64]. The prevalence rate of *H pylori* in the gastric biopsies of the same patients is similar or less than that in the normal population. Weston *et al*.[65] found that Barrett's high-grade dysplasia and adenocarcinoma were significantly more prevalent in patients who are not infected with *H pylori*. They suggested that *H pylori* appear to have a protective effect against the development of Barrett's adenocarcinoma.

While the role of endoscopic surveillance in low-risk patients with CLE is controversial, efficient and effective screening would target high-risk patients. This study suggests that such programs may be largely directed to male subjects and those who develop benign esophageal strictures. We have previously shown that

immunohistochemical detection of cyclin D1 in esophageal biopsies of patients with CLE is a sensitive tool for identifying subgroup of patients who may be at a higher risk[66]. But given that multiple genetic alterations, which are implicated in the natural history of esophageal adenocarcinoma, a combination of clinical risk factors and carefully validated biomarkers including cyclin D1, might improve still further the predictive value of the molecular approach[66,67].

In conclusion, we have found that 44 patients presented or developed esophageal adenocarcinoma of which 34 (77%) were males. Independent risk factors for progression from columnar metaplasia to esophageal adenocarcinoma were male sex, and the development of benign esophageal stricture. No other clinical characteristics differentiate between the non-malignant and malignant group. Most esophageal adenocarcinoma occurs in men with specialized epithelium. This subgroup may constitute a clinically recognized group at a high risk of cancer and particularly suitable for endoscopic surveillance. In patients with CLE, endoscopic surveillance for the early detection of adenocarcinoma may be restricted to male subjects, as well as patients who develop benign esophageal strictures. A large proportion of patients with CLE have no esophageal symptoms making recruitment into endoscopic surveillance programs problematic.

Abstract

AIM: To investigate the presence of the *cag*-pathogenicity island and the associated histological damage caused by strains with complete *cag*-PAI and with partial deletions in correlation to the disease status.

METHODS: We analyzed the complete *cag*-PAI of 174 representative *Helicobacter pylori* (*H pylori*) clinical isolates obtained from patients with duodenal ulcer, gastric ulcer, gastric cancer, and non-ulcer dyspepsia using eight different oligonucleotide primers viz *cag*A1, *cag*A2, *cag*AP1, *cag*AP2, *cag*E, *cag*T, LEC-1, LEC-2 spanning five different loci of the whole *cag*-PAI by polymerase chain reaction (PCR).

RESULTS: The complete screening of the genes comprising the *cag*-PAI showed that larger proportions of subjects with gastric ulcer (97.8%) inhabited strains with complete *cag*-PAI, followed by gastric cancer (85.7%), non-ulcer dyspepsia (7.1%), and duodenal ulcer (6.9%), significant differences were found in the percentage distribution of the genes in all the clinical groups studied. It was found that strains with complete *cag*-PAI were able to cause severe histological damage than with the partially deleted ones.

CONCLUSION: The *cag*-PAI is a strong virulent marker in the disease pathogenesis as it is shown that a large number of those infected with strain with complete *cag*-PAI had one or the other of the irreversible gastric pathologies and interestingly 18.5% of them developed gastric carcinoma. The presence of an intact *cag*-PAI correlates with the development of more severe pathology, and such strains were found more frequently in patients with severe gastroduodenal disease. Partial deletions of the *cag*-PAI appear to be sufficient to render the organism less pathogenic.

Key words: *Helicobacter pylori*; *cag*-pathogenicity island; Genetic diversity; Gastro-duodenal diseases

INTRODUCTION

Gastric cancer is the second most deadly malignant neoplasia worldwide. According to the presently available statistics, approximately 74% of those diagnosed succumb to this disease every year[1]; this is because of poor prognosis as it is often made when the disease has assaulted the muscularis propria. Evidences show that the pathogenesis of gastric cancer is a multistep process[2,3]. This 'cascade' is believed to be triggered by *Helicobacter pylori* (*H pylori*) infection, a Gram negative pathogen. Chronic infection with this gastric pathogen is known to be the major factor driving the precancerous process via mechanisms including direct transformation of cells, induction of immunosuppression with consequently reduced cancer immunosurveillance, or by causing chronic inflammation[4,5]. In 1994, the International Agency for Research on Cancer (IARC) declared *H pylori* a Class 1 (definite) carcinogen based on the epidemiological and interventional studies in human beings[6] and convinced that this bacterial infection indeed plays a key role in the initiation of the neoplastic process in the stomach.

Although many attempts in the past have been made to understand and associate the causal link between *H pylori* infection and the sequelae that leads to gastric carcinoma[7,8], there are conflicting data in the literature due

to differences in the study population and designs[9,10].

In the past few years, many *H pylori* virulence factors have been described that contribute to the survival of this pathogen in an extremely hostile acidic milieu of the stomach and its colonization in that organ[11,12]. Other putative virulence determinants such as vacuolating cytotoxin gene A (vacA), cytotoxin associated gene pathogenicity island (*cag*-PAI) and induced by contact with epithelium gene A (iceA) are not present in all *H pylori* strains or are known to exhibit different allelic variations[13]. The cytotoxin-associated gene island also referred to as the *cag*-PAI is an approximately 40-kb cluster of genes and is the most studied marker of the *H pylori*. In many studies[20,22,24], this large fragment has been a criterion of typing *H pylori* into pathogenic and non-pathogenic strains (Type I and Type II). Studies emphasizing on the functional importance of this island have reported that strains possessing *cag*-PAI induce more notable phenotypic changes *in vivo*, such as higher levels of IL-8 production than *cag*-PAI negative ones[30]. Recent studies made from within our institute[14,15] and other parts of the world[16,17] have mainly focused on the presence of this large fragment and its association with the disease status. Therefore, in a continuing attempt to further establish a strong epidemiologic relation between the *cag*-PAI and the disease conditions with reference to the histopathologic changes lead to the inception of the present study. As it is reported[18] that the presence of *cag* island and the consequent *cag* instability may produce differences in the pathogenicity and host adaptability within a bacterial strain, detailed analyses of the genes of the *cag* island in human beings isolates with reference to histologic damage and disease outcome would be essential. Therefore, compelled by these observations, the present study was designed to identify the distribution of different genes of the *cag*-PAI in clinical *H pylori* isolates by assessing the presence of representative genes located in different segments of the *cag*-island and its correlation with the histologic changes and disease status.

MATERIALS AND METHODS

Patients and sampling

The study population consisted of 174 patients (100 males and 74 females) with a mean age of 48.4 years (range 21-73 years). The patients were classified at the time of endoscopy into those suffering from active ulcers disease [duodenal ulcers (n = 58), gastric ulcers (n = 46), gastric carcinoma (n = 14)] and those with no evidence of mucosal ulcer and gastritis, but suffering from mild or severe dyspeptic symptoms, i.e. non-ulcer dyspepsia (n = 56). None of the patients included in the study had received NSAIDs or antibiotics within the previous 2 mo. Informed consents were taken from the patients who underwent upper gastrointestinal endoscopy at the department of gastroenterology, Deccan College of Medical Sciences, Hyderabad.

Four gastric biopsies were collected: one in urea solution for the rapid urease test (RUT), one in supplemented broth for isolating culture, one in phosphate-buffered saline (PBS) for testing by PCR assay, and one in 10% buffered formalin for histological examination by modified Giemsa stain for the presence of *H pylori*.

H pylori strains

A total of 174 clinical *H pylori* strains were screened for the presence of *cag*-PAI genes. These strains were recovered from individual subjects undergoing upper gastrointestinal endoscopy presenting with various symptoms. This included 43 live strains and 131 genomic DNA isolated from the gastric biopsy.

Extraction of genomic DNA

H pylori culture and DNA extraction from the culture and biopsy was carried out as described elsewhere[19].

PCR analysis of the *cag*-PAI genes

The genes of the *cag*-PAI were PCR amplified under the conditions described by Ikenoue *et al*.[20]. One microliter of the extracted genomic DNA was used in a 20 μL reaction volume containing 1´ PCR buffer, 1 U Taq DNA polymerase, 1.5 mmol/L $Mg2^{+}$, 200 μmol/L each dNTP and 10 pmol/L of each primer.

The cycling parameters were optimized and are as follows: Initial denaturation at 95 °C for 5 min, followed by 40 cycles each of denaturation at 94 °C for 30 s, annealing at 52 °C for 30 s and extension at 72 °C for 1.5 min and finally after the last cycle, extension was continued for another 7 min.

Eight sets of oligonucleotide primers spanning the 40 kb *cag*-PAI were used in the study. Appropriate positive and negative controls were included in each set to avoid misinterpretation of results. The details of the primers used with their product sizes are enlisted in Table 1. Amplicons were separated by electrophoresis on 2% agarose gel and stained by ethidium bromide.

Histopathological analysis

The biopsy specimen collected from the gastric antrum was used for histopathologic examination to grade

Table 1 List of primers

the severity of disease after they were embedded in paraffin and stained with hematoxylin and eosin. A single experienced pathologist (ZA), who was blinded to the patient's history and molecular data of the isolate, evaluated all histological data. The grade of gastritis was determined on the basis of the updated Sydney system[21].

Statistical analysis

The data were analyzed by means of χ^2 test and the Mann –Whitney *U* test.

RESULTS

In a total of 174 isolates screened, only 65 (37.4%) was found to carry the complete *cag*-PAI, while 109 (62.6%) carried the *cag*-PAI with partial deletions. No isolate was found with completely deleted *cag*-PAI (Table 2).

With reference to the clinical status, we found majority of the duodenal ulcer (DU) isolates and non-ulcer dyspepsia (NUD) isolates to possess partially deleted *cag*-PAI, while on the contrary we found ~97.8% of the gastric ulcer (GU) isolates and 85.7% of the gastric carcinoma (GC) isolates possessed the intact *cag*-PAI. The details of the results obtained are given in Table 2 and Figure 1. Statistically these differences were highly significant.

Table 2 Relationship between the presence of cag-PAI and the clinical status

Clinical status (*n*)	Intact PAI (%)	*cag*-PAI type Partially deleted PAI (%)	Completely deleted PAI (%)
DU (58)	4 (6.9)	54 (93.1)	0
GU (46)	45 (97.8)	1 (2.2)	0
NUD (56)	4 (7.1)	52 (92.9)	0
GC (14)	12 (85.7)	2 (14.3)	0
Total (174)	65 (37.4)	109 (62.6)	0

χ^2=130.71 .

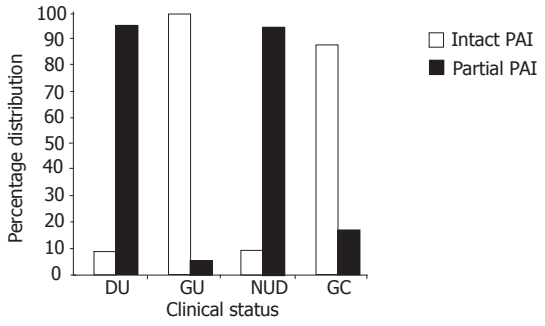

Figure 1 Distribution of *cag*-PAI in dyspeptic subjects.

When checked for the presence of each locus, we could find that the total *cag*A gene (i.e. with promoters) to be present in 69 (39.7%) of all the isolates screened, 4 (2.3%) isolates had total deletion of the gene and 101 (58%) were carrying partial deletions. Of the 69-*cag*A positive isolates, prevalence of *cag*A gene was predominant among gastric ulcer (GU) and gastric carcinoma (GC) strains (Table 3 and Figure 2) simultaneously *cag*A gene with partial deletions were more prevalent among *H pylori* isolated from duodenal ulcer (DU) and non-ulcer dyspepsia (NUD) subjects.

Table 3 *cag*A status of *H pylori* isolates

Clinical status (*n*)	*cagA* +ve (%)	Partial *cagA* +ve (%)	*cagA* –ve (%)
DU (58)	8 (13.8)	46 (79.3)	4 (6.9)
GU (46)	45 (97.8)	1 (2.2)	0
NUD (56)	4 (7.1)	52 (92.9)	0
GC (14)	12 (85.7)	2 (14.3)	0
Total (174)	69 (39.7)	101 (58)	4 (2.3)

DU *vs* GU, DU *vs* GC, GU *vs* NUD and NUD *vs* GC combinations are highly significant at 0.1% level. DU *vs* NUD and GU *vs* GC combinations are not significant at 0.1% level.

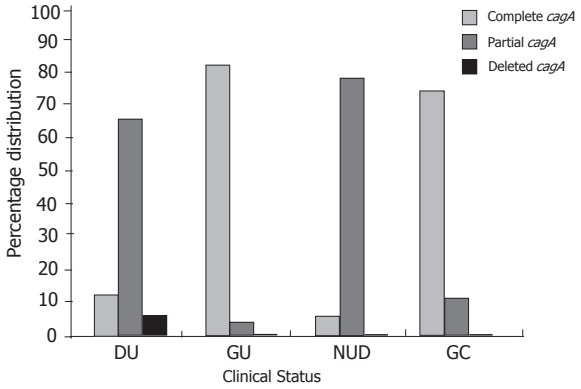

Figure 2 Distribution of *cag*A in clinical isolates.

Observing the prevalence patterns of *cag*A deletion mutant strains, we further analyzed the predominance of deletions in the promoter and body part of the *cag*A gene. The body part of *cag*A gene (i.e. A1+A2) was present in a maximum number of isolates i.e. 134 (77%), among which a considerable number of isolates lacked the promoter region (i.e. AP1+AP2) (Table 4).

Screening of the *cag*II region of the *cag*-PAI revealed *cag*E, *cag*T, LEC-1, and LEC-2 to be present in 143 (82.1%), 145 (87.3%), 142 (81.6%) and 111 (63.7%) of the total isolates, respectively. The distribution of these genes with reference to disease status is illustrated in detail in Table 5 and Figure 3. We found the difference between DU and GU, GU and NUD, GC and NUD to be highly significant statistically.

In the present study, histopathological examination of antral biopsies from a total of 174 subjects was carried out

Table 4 Distribution of *cag*A gene and *cag*A promoter in *H pylori* isolates

Clinical status (*n*)	A1+A2 (%)	AP1+AP2 (%)
DU (58)	43 (74.1)	8 (13.8)
GU (46)	45 (97.8)	46 (100)
NUD (56)	32 (57.1)	6 (10.7)
GC (14)	14 (100)	12 (85.7)
Total (174)	134 (77)	72 (41.4)

Table 5 Distribution of *cag*E, T, LEC1, and LEC2 in *H pylori* isolates

Clinical status (*n*)	*cag*E (%)	*cag*T (%)	LEC1 (%)	LEC2 (%)
DU (58)	47 (81)	56 (96.5)	44 (75.8)	33 (56.8)
GU (46)	46 (100)	46 (100)	46 (100)	46 (100)
NUD (56)	36 (64.2)	36 (64.2)	38 (67.8)	18 (32.1)
GC (14)	14 (100)	14 (100)	14 (100)	14 (100)
Total (174)	143 (82.1)	152 (87.3)	142 (81.6)	111 (63.7)

For *cag*E, GU *vs* NUD is highly significant at 0.1% level ($P<0.001$), DU *vs* GU, NUD *vs* GC combinations are significant at 1% level ($P<0.01$), DU *vs* NUD combination is significant at 5% level ($P<0.05$) and DU *vs* GC . For *cag*T, DU *vs* NUD, GU *vs* NUD combinations are highly significant at 0.1% level ($P<0.001$), NUD *vs* GC combination is significant at 1% level ($P<0.01$) and DU *vs* GU, DU *vs* GC, GU *vs* GC are not significant at 1% level. For LEC1, DU *vs* GU, GU *vs* NUD combinations are highly significant at 0.1% level ($P<0.001$), NUD *vs* GC is significant at 1% level ($P<0.01$), DU *vs* GC is significant at 5% level ($P<0.05$). For LEC2, DU *vs* GU, GU *vs* NUD, NUD *vs* GC combinations are highly significant at 0.1% level ($P<0.001$), DU *vs* NUD, DU *vs* GC combinations are significant at 1% level ($P<0.01$) and GU *vs* GC is not significant at 1% level.

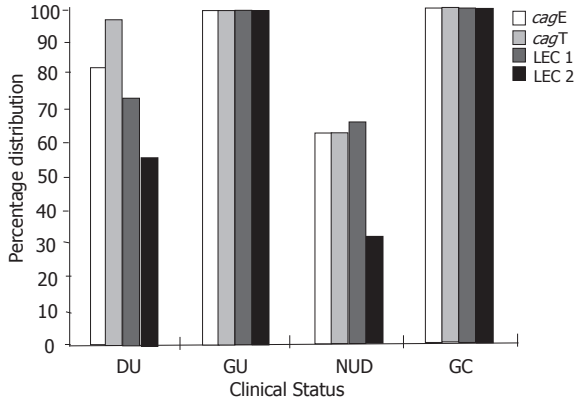

Figure 3 Distribution of *cag*E, T, LEC1, LEC2

to check the grade of gastritis and the differences between the pathologies of intact *cag*-PAI and partial *cag*-PAI infection. Of the 174 subjects included for the study, we screened 160 subjects as 14 of them had endoscopically proven gastric carcinoma and hence histopathology confirmed features of carcinoma. Out of the 160 subjects screened, all showed chronic gastritis and on further screening for any other advanced type of gastritis, we found 112 (70%) of the total 160 to possess topographic chronic superficial gastritis, 20 (12.5%) showed atrophic changes, whereas 18 (11.25%) and 10 (6.25%) of the subjects showed IM and dysplasia respectively (Table 6). When each of these histological lesions were scored individually in relation to their respective clinical status, we found that among the 58 duodenal ulcer cases, 52 (89.7%) showed chronic superficial gastritis, 2 (3.4%) showed atrophy and 4 (6.9%) showed intestinal metaplasia while none of the subjects had dysplasia (Table 6).

In the gastric ulcer category, we found that 9 (19.6%) showed chronic superficial gastritis, 13 (28.3%) showed atrophy, 14 (30.4%) showed intestinal metaplasia and 10 (21.7%) showed dysplasia. For atrophy, metaplasia and dysplasia, the difference between GU and DU was statistically highly significant ($P<0.001$, Table 6).

In the NUD category, we found that 51 (91.1%) showed chronic superficial gastritis and 5 (8.9%) showed atrophic gastritis while none had intestinal metaplasia and dysplasia. For metaplasia and dysplasia, the difference between GU and NUD, was statistically highly significant ($P<0.001$, Table 6).

Table 6 Frequency of atrophy, metaplasia, and dysplasia in chronic gastritis subjects

Clinical status (*n*)	Acute gastritis (%)	Chronic gastritis			
		Superficial gastritis	Gastritis with atrophy (%)	Gastritis with metaplasia (%)	Gastritis with dysplasia (%)
DU (58)	0	52 (89.7)	2 (3.4)	4 (6.9)	0
GU (46)	0	9 (19.6)	13 (28.3)	14 (30.4)	10 (21.7)
NUD (56)	0	51 (91.1)	5 (8.9)	0	0
Total (160)	0	112 (70)	20 (12.5)	18 (11.25)	10 (6.25)

For atrophy, DU *vs* GU combination is highly significant at 0.1% level ($P<0.001$), GU *vs* NUD is significant at 1% level ($P<0.01$) and DU *vs* NUD combination is not significant at 1% level. For metaplasia, DU *vs* GU, GU *vs* NUD combinations are highly significant at 0.1% level ($P<0.001$) and DU *vs* NUD combination is significant at 5% level ($P<0.05$). For dysplasia, DU *vs* GU, GU *vs* NUD combinations are highly significant at 0.1% level ($P<0.001$) and DU *vs* NUD combination is not significant at any level.

When we analyzed the histological status, with reference to the strain infecting with either intact PAI or partially deleted ones, we found a significant difference among them. As evidenced from Table 7, we found that, of the 65 subjects infected with intact PAI, 8 (12.3%) showed chronic superficial gastritis, 17 (26.1%) showed atrophic changes, 18 (27.7%) showed intestinal metaplasia (all of them were Type III), 10 (15.4%) showed high grade dysplastic changes and 12 (18.5%) showed intestinal type gastric carcinoma. On the contrary, when we checked those subjects, who inhabited partially deleted strains, we found 104 (95.4%) to possess chronic superficial gastritis, 3 (2.8%) showed atrophy while 2 (1.8%) showed gastric carcinoma and these differences were statistically very significant ($P<0.001$, Table 7).

When a correlation between the histological status of the subjects infected with either intact *cag*-PAI or partially deleted strains isolated from subjects with varied disease status was made, we found that among 58 DU subjects, 4 had intact *cag*-PAI and all of them were Type III intestinal metaplasia, among the remaining 54, which had partial deletions in the *cag*-PAI, 52 (96.3%) showed chronic superficial gastritis and 2 (3.7%) showed atrophic changes. Among the GU subjects, of the 46 infected, 45 were known to possess the *cag*-PAI and 8 (17.8%) of them showed chronic superficial gastritis, 13 (28.9%) showed atrophic gastritis, 14 (31.1%) showed Type III intestinal metaplasia and 10 (22.2%) showed high grade dysplastic changes (Table 8). Among the 56 NUD subjects, 4 with intact *cag*-PAI showed atrophic changes and of the rest with partial deletions 51 (98.1%) showed chronic superficial gastritis and 1 (1.9%) showed atrophic gastritis (Table 8) while among the 14 isolated from

gastric carcinoma 12 had intact *cag*-PAI while the other 2 partial deletions and when scored for the type of gastric carcinoma all of them showed intestinal type of carcinoma (Table 8).

DISCUSSION

The *cag*-PAI is an approximately 40-kb cluster of genes in *H pylori* chromosome, and a quite conservative entity. Censini *et al*.[22] in 1996 first identified strains with partially deleted *cag*-PAIs. The molecular mechanism of these genetic rearrangements was explained by incorporation of an insertion element, IS605, in *cag*-PAI. Recently, the composition of the *cag*-PAI in clinical *H pylori* isolates has been studied in different populations by various methods, including PCR, dot blotting and long distance PCR[20,23,24].

In the present study, we used simple PCR for structural screening of *cag*-PAI in clinical isolates of *H pylori*. Out of the 174 clinical isolates, we found only 37.4% were carrying the complete *cag*-PAI (Table 2), whereas Mukhopadhyay *et al*.[25] reported more than 96% in Calcutta strains of peptic ulcer and non-ulcer dyspepsia. In our study, 97.8% of gastric ulcer and 85.7% (Table 2 and Figure 1) of the gastric carcinoma strains were carrying complete PAI, which are considered to be severe forms of the gastro-duodenal diseases. Even though duodenal ulcer is also considered to be a severe form of the gastro-duodenal disease, the proportion of DU strains that carried was just 6.9%. Jenks *et al*.[23] reported that the presence of certain genes (*cag*A, *cag*E, *cag*M, T, ORF 6, 10, 13) in the *cag*-PAI is highly associated with duodenal ulcers. We too found a similar type of observation, but not for all the seven genes which they selected. We observed the same kind of correlation with only two genes i.e. *cag*E and *cag*T, where DU cases carried *cag*E with 81% and *cag*T with 96.5% (Table 5 and Figure 3). Whereas NUD isolates were carrying the genes with an average of 65% (Table 5 and Figure 3). Further, Day *et al*.[26] revealed that isolates containing *cag*E were associated with duodenal ulceration.

Among non-ulcer dyspepsia strains, we found 7.1% to carry the complete *cag*-PAI, which is statistically almost equal to DU percentage, and a report from Sweden[27] showed 58% of *cag*-PAI positivity in NUD isolates. In the same report, the authors showed that 5% of isolates from severe pathology i.e. gastric carcinoma and duodenal ulcer, and 15% of the isolates from NUD lacking the *cag*-PAI. Not only the data from other continents, but from the same Indian sub-continent showed total deletions from ulcer group and non-ulcer group[25], whereas we could not come across a single isolate with entirely deleted *cag*-PAI from any of the disease condition indicating strain diversity. This kind of diversity, i.e. absence of completely deleted PAIs and presence of just 6.9% complete *cag*-PAIs in duodenal ulcer cases, might be particularly true for the south Indian of Telugu linguistic group who are mainly Dravidian and married consanguineously for millennia[28]. Their genetic separation from other Indian communities during much of the human history has already been reported[29].

Strains with intermediate genotypes, lacking parts of the *cag*-PAI, were found in 62.6% (Table 2) and more frequently found in patients with non-ulcer dyspepsia and duodenal ulcer (Figure 1). A probable mechanism for the establishment of these internal deletions within the *cag*-PAI would be that the short repeated sequences found by Nilsson *et al*.[27] may serve as homologies enabling slipped strand mispairing and consequently excision of the enclosed DNA fragment especially in DU and NUD subjects. Moreover, in our observation, the partially deleted *cag*-PAI represented a genotype more common than a complete *cag*-PAI and no strain was found with completely

deleted *cag*-PAI.

Conventionally *cag*A was used and is still used as a marker for the presence of an intact *cag*-PAI and for virulence. Recently, Backert *et al*.[30] showed a good correlation of *cag*A with the presence of *cag*-PAI. In this study, we found that 39.7% of the strains carried the complete *cag*A gene (Table 3) and the presence of *cag*A gene did not correlate with the genetic presence of complete *cag*-PAI. Further, for - 4 kb *cag*A gene, we used four sets of primers i.e. two primers for body of the gene and two primers for promoter, designed from various locations of the body region and promoter, whereas other studies taken up earlier had used a single set of primer for complete *cag*-PAI. This might be the reason for the correlation, which they obtained. The typical observation was when 77% of the isolates were carrying the body region (A1+A2) only 41.4% of them carried promoter region (Table 4), which means that in our isolates even though the strains carried the *cag*A gene, most of them lacked the promoter of the gene, without which *cag*A is not functional. Further, four isolates i.e. 2.3% completely lacked the *cag*A gene and all the four isolates belonged to duodenal ulcer cases.

Among many virulence markers present in the *H pylori* genome, *cag*-PAI is the major virulence factor and is associated with severe gastroduodenal pathology[31,32] that includes both duodenal and gastric ulcers along with carcinomas. Some studies have identified a correlation between an intact *cag*-PAI and development of disease[20,23,24,27], as we are trying to show with this present study in Indian scenario, whereas others could not find such a relationship[33,34].

"Infection with *H pylori* always causes chronic active gastritis"[35]. This phrase has become true in our observation. As it is observed in Table 6, there are no acute gastritis subjects. Moreover, the subjects infected with *cag*-PAI positive strains were found to show severe forms of histopathological changes, like atrophic gastritis, intestinal metaplasia, and neoplasia. This might be the reason for IARC-WHO to designate *H pylori* a class I (definite) carcinogen[6].

Out of the 174 isolates, 65 (37.4%) had complete *cag*-PAI and 109 (62.6%) had partial deletions in the *cag*-PAI (Table 2). As evident from Table 7, it can be observed that subjects infected with *H pylori* strains with intact *cag*-PAI had many remarkable histopathological changes, when compared to those who had partially deleted *cag*-PAI. It is quite clear from the statistics ($P<0.001$) that among 65 *H pylori* strains with intact *cag*-PAI, 18.5% subjects had advanced cancerous lesions, while only 1.8% of the 109 subjects, who harbored *H pylori* with partial *cag*-PAI had advanced to carcinoma thus allowing us to delineate that persons with intact *cag*-PAI are 10-fold more prone to develop carcinoma in comparison to the partially deleted *cag*-PAI strains.

Parallelly, a small group of population, i.e. 12.3% with intact *cag*-PAI, were shown to have only chronic superficial gastritis, but according to Ohkuma *et al*.[36] *H pylori* positive cases with chronic gastritis have increased risk of atrophy and intestinal metaplasia. On the other hand, partial *cag*-PAI subjects were also shown to have chronic gastritis (Table 6), but the percentage of disease progression was very high among *cag*-PAI positive subjects (Table 7) than those with partially deleted ones. Moreover, Type-3 metaplasia and high-grade dysplasia were seen only in *cag*-PAI positive subjects, where Type-3 metaplasia is closely linked to carcinoma[37] and dysplasia is nothing but a non-invasive type of neoplasia[38]. The results of this study are in contrast to those obtained by Keates *et al*.[39] who determined that gene products of the *cag* pathogenicity island are required for maximal activation of mitogen-activated protein kinases (MAPK) in gastric epithelial cells, which regulate cell proliferation, differentiation, inflammatory responses, stress, and programmed death, leading to induce gastroduodenal inflammation, ulceration and neoplasia. Further, Naumann *et al*.[40] stated that the integrity of whole *cag*-PAI is also a pre-requisite for efficient activation of early transcription factor AP-1, which is known for its immuno-stimulatory function.

In relation with disease status, among DU, GU, and NUD, gastric ulcers are considered to be more prone to the gastric carcinoma[41]. The observations of this study are in correlation to that obtained by Hansson *et al*.[41]. When we compare GU subjects with DU and NUD, the percentage of predisposing factors was much more among GU subjects. Recently, Wanatabe *et al*.[42] proved this in animal models. In their study at 26 wk, Mongolian gerbils developed chronic gastritis, ulceration and metaplasia. At 62 wk, 31% of them developed adenocarcinoma. Interestingly the inoculum used for the infection was obtained from a patient with gastric ulcer. Moreover, there have been reports that gastric cancer mortality rates bear an inverse relationship to duodenal ulcer disease rates[43], suggesting that they are directly relating with gastric ulcer in ulcer groups.

Further, in partial *cag*-PAI subjects, 2.8% showed atrophy, 1.8% showed carcinoma (Table 7) suggesting the role of other virulence genes and risk factors. Parallelly high incidence rate of gastric carcinoma among the gastric ulcer cases might be true, but it should not be assigned to a single determinant such as *cag*-PAI, but it is a result of many factors such as host genetic factors, environment, low socio-economic status, irregular dietary habits in addition to *H. pylori* with complete *cag*-PAI[44].

Hence, we can suggest that the *cag*-PAI is a strong virulent marker in the disease pathogenesis because more than 85% of the *cag*-PAI positive subjects were shown to have one or the other of the irreversible gastric pathologies and interestingly 18.5% of them developed gastric carcinoma and GU is the major risk/predisposing factor for the gastric carcinoma. Moreover, duodenal ulcer is not at all a risk factor for severe gastric pathologies and it is not a severe kind of disease, like gastric ulcer in our population.
