Abstract

AIM: To compare the efficacy and safety of single daily amikacin *vs*. cefotaxime in the 5-d treatment of spontaneous bacterial peritonitis (SBP).

METHODS: Thirty-seven cirrhotic patients with SBP, 19 in group A and 18 in group B, were studied. Group A received 1 g of cefotaxime every 6 h, and group B received 500 mg of amikacin qd. Both antibiotics were administered up to 5 d and the responses were compared.

RESULTS: Infection was cured in 15 of 19 patients (78.9%) treated with cefotaxime and in 11 of 18 (61.1%) treated with amikacin. Four patients of the Cefotaxime group (21.1%) and five patients of the Amikacin group (27.8%) died. Two in each group (10.5% *vs* 11.1%) had renal impairment during study period. One in each group (5.3% *vs* 5.6%) may be considered to suffer from nephrotoxicity due to increased urinary β_2-microglobulin concentration.

CONCLUSION: In this study, single daily doses of amikacin in the treatment of SBP in cirrhotics were not associated with an increased incidence of renal impairment or nephrotoxicity. However, a 5-d regimen of amikacin is less effective than a 5-d regimen of cefotaxime in the SBP treatment.

Key words: Spontaneous bacterial peritonitis; Amikacin; Cefotaxime

INTRODUCTION

Some studies have suggested that liver disease is a risk factor for aminoglycoside-induced nephrotoxicity[1-4]. However, aminoglycosides are still frequently used to treat sepsis in patients with liver disease[5]. In recent studies[6-8], single daily parenteral aminoglycoside administrations have shown some benefits as compared with multiple daily doses. These benefits include reduced toxicity, possible enhanced efficacy, greater convenience, and reduced costs. However, results of single daily aminoglycoside treatments of bacterial infections in cirrhotics have not been evaluated.

Spontaneous bacterial peritonitis (SBP) is a common complication of cirrhotic ascites. In a recent study, 5-d cefotaxime treatment of SBP was as efficacious as a 10-d course[9].

Because of these reasons, we have designed this prospective randomized study to compare the efficacy and nephrotoxicity of single daily amikacin dosage versus that of cefotaxime in the 5-d treatment of SBP in cirrhotics.

MATERIALS AND METHODS

Materials

Between July 2000 and June 2002, patients admitted to the Kaohsiung Veterans General Hospital who fulfilled all of the following criteria were enrolled into this study: (1) had liver cirrhosis; (2) had an ascitic fluid absolute neutrophil count > 500 cells/mm^3 with SBP as the only suspected cause. Patients were excluded from the study for any of the following reasons: (1) had a history of allergy to penicillins, cephalosporins, or aminoglycoside; (2) considered to be a terminal or critical case with life expectancy of less than one month; (3) had secondary peritonitis or tumor rupture; (4) had a serum creatinine level >2 mg/dL; (5) had an antibiotic treatment during previous 2 wk.

Methods

Patients were randomly allocated into two different therapeutic groups. Group A received 1 g of cefotaxime every 6 h. Group B received 500 mg of amikacin qd or 8 mg/kg of body weight qd if patient's body weight was less than 60 kg. The subsequent dosages of amikacin were adjusted according to renal function so that the trough level of plasma amikacin remained ≤30 μg/mL Both antibiotics were administered by intravenous infusion for 30 min. The antibiotics were not changed in any case during the first 72 h unless a nonsusceptible organism was isolated in the initial cultures. Antibiotics

were administered up to 5 d to patients who responded to the treatment. For patients who did not respond to the treatment after 5 d, antibiotic treatment was changed according to antibiotic susceptibility tests when a resistant organism was isolated, or empirically when the causative bacteria was not cultured.

Blood, urine, and ascites samples were obtained for culture, routine cell counts, and chemistry screening before initiation of antibiotic treatment. Other body fluids were cultured when indicated.

Abdominal paracentesis was repeated every 72 h until the culture became sterile and the ascitic fluid neutrophil count decreased to <250 cells/mm^3. Clinical signs and symptoms of infection, e.g., fever, chills, abdominal pain, abdominal tenderness, ileus, and mental status change, were recorded daily. Patients infected by organisms resistant to cefotaxime or amikacin were treated with appropriate alternative antibiotics according to the culture result and susceptibility tests. Two days after completion of antibiotic therapy, abdominal paracentesis was performed for culture test and cell count. Blood culture was repeated if bacteremia had been documented previously. If signs or symptoms of infection developed after discontinuation of the antibiotic, paracentesis for cell count and culture of blood were also repeated.

Infection was considered cured when all clinical and laboratory signs of infection disappeared during therapeutic period and cultures performed 2 d after antibiotic withdrawal were negative. Antibiotic treatment was considered a failure when the symptoms and signs of infection did not improve, or worsened, or when a nonsusceptible bacteria was isolated in the initial cultures. Patients discharged alive were followed closely throughout their illness for 4 wk after completion of treatment. Recurrence within 4 wk after discontinuation of therapy was defined as recurrent SBP or bacteremia. Relapse within 4 wk after discontinuation of therapy was defined as recurrent infection of ascitic fluid or blood with the same organism (identical species) that caused the initial infection. Reinfection within 4 wk after discontinuation of therapy was defined as recurrent bacteremia or recurrence of SBP with an organism different from the original pathogen. Superinfection was defined as development of SBP or bacteremia caused by a different pathogenic bacterium from the original organism during therapy. Infection-related mortality was defined as death caused by bacterial infection of ascitic fluid or blood, with clinical or bacteriologic evidence of uncontrolled infection. Hospitalization mortality was defined as death due to any cause during the hospitalization. In evaluating antibiotic efficacy, patients who died within the first 3 d after inclusion in the study were not considered.

Serum and urine creatinine levels were measured before treatment, every 2 d during treatment, and 24 h after completion of therapy. The 24-h urine was collected every 2 d for assessment of the creatinine clearance.

For patients who were treated with amikacin, blood and ascites samples for the determination of the trough and peak levels of amikacin were obtained 30 min before and one hour after administration of the drugs for every alternate day during treatment. The samples were stored at - 30 ^{o}C until assay. The amikacin levels were measured by radioimmunoassay.

According to previous investigations[4], urinary β_2-microglobulin is a useful test to discriminate antibiotic-induced nephrotoxicity from functional renal failure (or hepatorenal syndrome) in cirrhotic patients. Therefore, in the current study, the urinary concentration of β_2-microglobulin was measured in all patients studied before therapy, 3 d after initiation of treatment, and 2 d after antibiotic withdrawal. Fresh urine samples were collected and stored at pH 6 to 7 (with the addition of 1 N sodium hydroxide) and at - 30 ^{o}C until assayed. The analysis was performed using a commercial radioimmunoassay. Results of β_2-microglobulin were not available during the study.

In this study, renal impairment was defined as a rise in serum creatinine of 0.5 mg/dL or a ≥50% fall in creatinine clearance during the period. In the absence of other possible causes of renal tubular damage, renal impairment was considered to be secondary to nephrotoxicity if urinary β_2-microglobulin concentration increased from normal values (before treatment) to more than 2 000 mg/L (during treatment). Otherwise, renal impairment was considered functional. Patient who died within the first 3 d after inclusion in the study were not considered in evaluating the incidence of nephrotoxicity.

The *t*-test with Yates' correction, χ^2 with Fisher's exact test, or the nonparametric Mann-Whitney *U* test were used for statistical analysis. Data are presented as mean±SD. In each instance a two-tailed test was used. A *P* value of < 0.05 was considered significant.

RESULTS

A total of fifty- seven patients met inclusion criteria. Twelve patients were excluded because of either critical case with shock on presentation (4), prior treatment with antibiotics (2), initial serum creatinine concentration > 2 mg/dL (4), evidence of secondary peritonitis (1), or tumor rupture (1). Forty-five patients were eligible for the study and were randomized. Twenty-two patients were randomized to cefotaxime treatment and twenty-three patients to amikacin treatment. Two patients in amikacin group were later disqualified, because secondary peritonitis and tuberculous peritonitis were diagnosed after evaluation. Three patients in each group were not considered in the analysis of the result, because they died or fled against medical advice within 48 h after entry into the study. The remaining 37 patients, 19 in cefotaxime group and 18 in amikacin group, were the subjects of this analysis.

There was no significant difference between patients of the two groups (Table 1), in relation to sex, age, etiology of cirrhosis, severity of cirrhosis as expressed by Child-Pugh score, and renal function before treatment (expressed by serum creatinine level). In each group only one patient was Child-Pugh class B. The others were class C. Only 22 patients (59.5%) had normal serum creatinine level

Table 1 Comparison of clinical and laboratory characteristics of the patients

Characteristics	Treatment regimen		
	Cefotaxime	Amikacin	*P*
Number of patients	19	18	
Male/female	17/2	11/7	NS
Age(yr)[1]	54 ± 17	58 ± 11	NS

Alcoholism	3 (16)	2 (11)	
Chronic hepatitis B	14 (74)	11 (61)	
Chronic hepatitis C	1 (5)	4 (22)	
Child-Pugh score[1]	11.4 ± 1.2	11.1 ± 1.1	NS
Serum creatinine(mg/dL)[1]	1.5 ± 0.5	1.4 ± 0.4	NS

[1]Data are presented as mean ± SD. [2]Data are presented as number and percentage of total. NS: not significant

(<1.5 mg/dL) before treatment.

Nine (24%) of the 37 patients grew a pathogen from their ascitic fluid, and 8 (21.6%) were bacteremic. The ascites and blood isolates were similar between the two groups (Table 2). Two pathogens in the blood (group B *Streptococcus* and *Vibrio amalonaticus*) were resistant to cefotaxime and amikacin. Although the clinical signs of infection disappeared during therapeutic period with cefotaxime, crystal penicillin and tetracycline were given according to the susceptibility tests since the sixth day. The other isolates were sensitive to cefotaxime and amikacin.

Table 2 Flora of ascites and blood

	Treatment regimen		
	Cefotaxime (%)	Amikacin (%)	*P*

Streptococcus group B	1 (5)	0	NS
Vibrio amalonaticus	1 (5)	0	NS

Data are presented as number and percentage of total. NS: not significant.

The clinical response to treatment and survival were similar between the groups (Table 3). Infection was cured in 15 of 19 patients (78.9%) treated with cefotaxime and in 11 of 18 (61.1%) treated with amikacin. However, there was no statistic significance between these two groups. Three patients in cefotaxime group had recurrent infection within 4 wk after completion of treatment. One was considered relapse due to recurrent bacteremia with the same organism that caused the initial bacteremia. The other two also suffered from bacteremia, but the previous infection episode was not bacteremic. Recurrent SBP concurrent with new episodes of bacteremia rather than relapse were considered in these two patients. Among the 8 bacteremic patients in the initial treatment, 2 in the cefotaxime group had resistant isolates. Although they became well during the initial therapeutic period and cured without recurrence within 4 wk after changing antibiotics, treatment failure was still considered according to the study's design. The other 6 bacteremic patients were bacteriologically cured by repeated culture after 5-d of antibiotic treatment. Only one patient (16.6%) in the cefotaxime group had relapse 10 d after completion of treatment.

Table 3 Results of treatment

	Treatment regimen		
	Cefotaxime (%)	Amikacin (%)	*P*
Number of patients	19	18	
Cure[2]	15 (78.9)	11 (61.1)	NS
Normalized PMN count[2]	18 (94.7)	15 (83.3)	NS

Infection-related mortality[2]	0	3 (16.7)	0.105
Hospitalization mortality[2]	4 (21.1)	5 (27.8)	NS
Days of hospitalization[1]	12 ± 8	13 ± 9	NS

[1]Data are presented as mean ± SD. [2]Data are presented as number and percentage of total. NS: not significant

There was no significant difference between these two groups in the mortality rate. During the whole hospitalization period, 4 patients of the cefotaxime group (21.1%) and 5 patients of the amikacin group (27.8%) died. Although for most patients the cause of death was multifactorial, in three cases of the amikacin group infection was considered to be the main cause of death due to no other major event or infection identified.

There was no significant difference in the incidence of renal impairment or nephrotoxicity between patients treated with cefotaxime or amikacin (Table 4). Two in each group (10.5% *vs* 11.1%) had renal impairment during study period. The urinary β_2-microglobulin concentration increased in both groups during treatment and decreased after antibiotics withdrawal. One in each group (5.3% *vs* 5.6%) may be considered nephrotoxicity due to increased urinary β_2-microglobulin concentration from normal values (before treatment) to more than 2 000 mg/L (during treatment). The patient who developed nephrotoxicity in the amikacin group died on the 6th d of the study period.

Table 4 Evaluation of nephrotoxicity

	Treatment regimen		
	Cefotaxime(%)	Amikacin(%)	*P*
Number of patients	19	18	
Renal impairment (%)[2]	2 (10.5)	2 (11.1)	NS
Urinary β^2-microglobulin (mg/L)			
Before treatment[1]	402 ± 80	1220 ± 392	NS
3 d after initiation[1]	779 ± 2465	612 ± 814	NS
2 d after withdrawal[1]	126 ± 119	173 ± 44	NS
increase > 2 000 mg/L (%)[2]	1 (5.3)	1 (5.6)	NS

[1]Data are presented as mean ± SD. [2]Data are presented as number and percentage of total. NS: not significant.

The mortality was considered infection-related. The patient in the cefotaxime group died on the 5th d due to hepatic and renal failure even though the infection appeared under controlled.

Wide range of peak and trough levels of amikacin in patients treated with amikacin was noted in this study (Table 5).

Table 5 Amikacin concentration (mean ± SD)

Blood peak level (μg/mL)	19.6 – 127.3 (40 ± 32)
Blood trough level (μg/mL)	1.3 – 73.7 (12 ± 22)
Ascites peak level (μg/mL)	4.3 – 80.1 (20 ± 25)
Ascites trough level(μg/mL)	1.2 – 78.9 (15 ± 26)

DISCUSSION

The aminoglycosides are potent antibiotics, with peak concentration-dependent bactericidal activity against Gram-negative pathogens and staphylococci. They display trough concentration-dependent nephrotoxicity and ototoxicity. Aminoglycosides exhibit enduring antibacterial activity (especially against Gram-negative bacilli) many hours after tissue concentrations become negligible. Appreciation of this postantibiotic effect leads to replacement of conventional multiple daily doses by large single daily doses. The latter regimens confer at least equivalent efficacy and less risk of nephrotoxicity[7]. Among the aminoglycosides available in our hospital, we used amikacin in this study, because it is the least susceptible to degradation by bacterial enzymes and causes less nephrotoxicity than gentamicin and tobramycin[7]. Because some studies have suggested that liver disease is a risk factor for nephrotoxicity in patients treated with aminoglycoside[1-4], we used only about half of the recommended single daily dosage of amikacin (15 mg/kg q24 h in usual study[7]) in this study.

The optimal duration of antibiotic treatment for SBP had been investigated recently. Ten to fourteen days intravenous therapy had been recommended[10-12]. However, it had been argued that, because SBP had a low bacterial load (often only 1 organism/mm^3 of ascitic fluid), a shorter duration of treatment might suffice. A recent randomized controlled study comparing 5 d *vs* 10 d treatment with cefotaxime found no difference in efficacy and mortality rate [9].

In this study the cure rate was higher in the group of patients treated with cefotaxime (78.9%) than in the group of patients treated with amikacin (61.1%), although there was no significant difference. Larger sample sizes in further studies may confirm this finding. The cure rate for SBP in patients treated with cefotaxime in this study is similar to the previous studies. In Runyon's study[9], the cure rate for SBP treated by 5-d cefotaxime is 93.1%. On the other hand, the cure rate in patients treated with amikacin in this study is also similar to the previous studies that treated cirrhotic patients with severe infection using aminoglycosides combining with other antibiotics. In Felisart's study which compared cefotaxime *vs.* ampicillin-tobramycin in cirrhotics with severe infections (most were peritonitis), the cure rates were 85% and 56% respectively[13]. The response rate in the McCormick's study which used netilmicin plus mezlocillin in the empirical therapy of presumed sepsis in cirrhotic patients was 56%[5]. Single daily dosage of aminoglycoside in the treatment of infections in cirrhotic patients seemed as effective as combining with other antibiotics in traditional dosages but less effective than cefotaxime.

It is well known that in traditional dosages, the serum, the tissue and the body fluid levels of aminoglycosides are unpredictable, varying from one patient to another[14, 15]. We conducted this study by using a single daily dose of aminoglycoside for easy monitoring of the drug level. Just like previous reports, our study also showed that there were wide ranges of drug levels in blood and ascites between the patients regardless of whether their renal function were normal or not. Some levels might not achieve the bactericidal levels. For example, the MIC of amikacin for *E coli* was 2 mg/mL in this study. Only 13 of the 18 patients (72%) had 4-fold or higher for their peak level of ascites. On the other hand, it is well established that cefotaxime has a wide range between therapeutic and toxic dosages. Also, the ascitic fluid concentration of cefotaxime is several-fold higher than the MIC of most susceptible organisms at any time throughout the treatment[16]. This may explain the difference of efficacy of treatment between cefotaxime and amikacin.

The incidence of nephrotoxicity in this present study was 5.6% in patients treated with amikacin. This was similar with the Felisart's study in patients treated with ampicillin-tobramycin (7%)[13], but almost six times lower than the Cabrera's study in patients treated with cephalothin-gentamicin or cephalothin-tobramycin (32%)[4]. Previous investigations have suggested that combined therapy, i.e. cephalothin, might enhance the nephrotoxicity of aminoglycosides[17, 18]. Although some study suggested that the risk for aminoglycoside nephrotoxicity was 5 times higher in a patient with liver disease than without[2], we found that a single daily dosage of amikacin did not cause marked nephrotoxicity in cirrhotic patient in this study. The incidence was between 3% and 11% in patients treated with aminoglycosides, similar with previous reports[19, 20].

In this study, eight patients (22%) had positive blood culture concurrent with SBP. Two of them were resistant isolates to cefotaxime and had other antibiotic treatment. Six patients were all bacteriologic cured after 5-d of treatment. This was confirmed by negative culture result repeated after treatment. However, one of the six patients (17%) who was treated with cefotaxime had bacteremic relapse 10 d after completion of treatment. In Runyon's study, 9 bacteremic patients treated with 5-d cefotaxime were documented to become sterile during the first 72 h of therapy. No relapse was mentioned. 9 Because bacteremia in cirrhosis is a severe prognostic sign, it has been considered common practice to treat it for 10 to 14 d[21]. Do patients with SBP in addition to bacteremia require longer treatments than patients without bacteremia? Is a

5-d course adequate for treating bacteremia in cirrhotic patients? These issues remain to be clarified.

In spite of the lower antibiotic efficacy of amikacin, the hospitalization mortality rate resulting from this antibiotic regimen was similar to that observed in patients treated with cefotaxime. This may be explained by the fact that both groups of cirrhotics had a similar degree of liver failure. Most mortalities were related to infective complications in patients treated with amikacin and to noninfective complications in patients treated with cefotaxime.

In summary, we found that single daily doses of amikacin in the treatment of SBP in cirrhotics were not associated with an increased incidence of renal impairment or nephrotoxicity. However, the efficacy of a 5-d regimen of amikacin is less than a 5-d regiimen of cefotaxime in SBP treatment.

Abstract

AIM: To evaluate a series of patients with hepatocellular carcinoma (HCC) treated with several different protocols and devices.

METHODS: We treated 138 patients [chronic hepatitis/liver cirrhosis (Child–Pugh A/B/C), 3/135 (107/25/3)] with two different devices and protocols: cool-tip needle [initial ablation at 60 W (standard method) (n = 37) or at 40 W (modified method) (n = 28)] or; ablation with a LeVeen needle using a standard single-step, full expansion (single-step) method (n = 39) or a multi-step, incremental expansion (multi-step) method.

RESULTS: Eleven patients experienced rapid and scattered recurrences 1 to 7 mo after the ablation. Nine patients were treated by the cool-tip original protocol (60 W) (9/37 = 24%) and the other two by the LeVeen single-step method (2/39 = 5%). The location of the recurrence was surrounding and limited to the site of ablation segment in three cases, and spread over one lobule or both lobules in the other eight cases. There was no recurrence in the patients treated with the modified cool-tip modified method (40 W) or the LeVeen multi-step method.

CONCLUSION: There is a risk of rapid and scattered recurrence after RFA, especially when the standard cool-tip procedure is used. Because such recurrence would worsen the prognosis, we recommend that modified protocols for the cool-tip and LeVeen needle methods should be used in clinical practice.

INTRODUCTION

Image-guided radio frequency ablation (RFA) is an emerging technique for the treatment of hepatocellular carcinoma (HCC)[1-5], as well as for metastatic liver tumors[6]. The procedure has been adopted worldwide as a safe and effective method, and is replacing percutaneous ethanol injection therapy (PEIT) as the treatment of choice. Livraghi *et al*.[7] and Lencioni *et al*.[8] have compared RFA and PEIT for the treatment of small-sized HCC. Although both studies concluded that RFA resulted in a higher rate of complete necrosis, Livraghi *et al*.[7] also indicated that the complication rate was higher with RFA than with PEIT.

A number of reports have described complications associated with RFA[9-14]. The major complications reported were peritoneal bleeding, hepatic abscess, hemothorax, perforation of the gastrointestinal wall, and rapid hepatic decompensation. These complications occurred during or just after RFA, however, and delayed complications have been reported much less frequently. Takada *et al*.[15] described two cases in which rapid and aggressive recurrence accompanied by portal thrombus occurred 4 to 6 mo after RFA. Nicoli *et al*.[16] described a peculiar form of recurrence after RFA for HCC that was characterized by numerous and equally-sized recurrence nodules and which occurred after only one month post-treatment. More recently, Ruzzenente *et al*.[17] also described a series of patients with rapidly spreading recurrence after RFA.

In the past several years, we have observed cases similar to those presented by Nicoli *et al*.[16]. We have previously reported a significant increase in pressure in the ablated area during RFA[18], and concluded that scattered recurrence is attributable to an explosion caused by excessive increases in intra-tumor pressure. In our experience, intra-operative complications are easily avoidable by confirming the safety of a puncture route

before the treatment, whereas a rapid recurrence after RFA is a serious clinical problem that can influence the prognosis of patients.

In this report, we have evaluated a series of HCC cases treated by RFA with different devices and protocols, and have analyzed cases with rapid and scattered recurrence after RFA.

PATIENTS AND METHODS

RFA

Between April 2000 and December 2004, 138 patients with HCC were treated with the RFA procedure in Kyushu University Hospital or National Hospital Organization Kyushu Medical Center. Characteristics of the candidates are shown in Table 1. They consisted of 79 males and 59 females, aged 40 to 83 years with a mean of 68.2 years. All of them had chronic liver damage; 121 patients were hepatitis C virus (HCV) positive and 17 were hepatitis B virus (HBV) positive. Among them, 135 patients were diagnosed with liver cirrhosis by liver biopsy, clinical laboratory data, ultrasonography and/or computed tomography. According to the hepatic functional reserve evaluation for the cirrhotic patients just before RFA, 107, 25, and 3 were classified as Child–Pugh's class A, B, and C, respectively. The diagnosis of HCC was confirmed by aspiration tumor biopsy for all patients prior to treatment.

RFA was performed with either a LeVeen™ multipolar array needle in combination with an RF 2000 generator™ (Radio Therapeutics Corporation, Mountain View, CA, USA) or a Cool-tip™ RF System (3.0 cm exposure length) (Radionics, Burlington, MA, USA). One of the two devices was selected randomly for RFA. All procedures were performed by hepatologists who had at least 10 years of experience performing image-guided *in situ* tumor ablation therapy. The original standard protocol was used for cool-tip needle RFA until December 2002, and the modified protocol was used thereafter. For LeVeen needle RFA, the original standard protocol was used until April 2002, and the modified method was used thereafter. The details of each protocol are described below.

Original procedure with cool-tip needle: Cool-tip electrode with 3 cm of exposed tip was used to deliver RF (radio frequency) energy to the tumors. RF energy was delivered as described previously[19]. In short, after needle puncture of the tumor, generator output was increased to 100–120 W and maintained at this level until the end of the procedure. If an increase in impedance equal to or greater than 10 Ω above baseline was observed, the current was reduced, until stable impedance was observed and then increased again.

Modified procedure with cool-tip needle: The needle used was the same type as was used for the original procedure. The method differed from the original procedure in that the ablation was started at a low voltage of 40 W, and the electric power was increased by 10 W every minute. The maximum of electric power was 120 W, and the RF energy delivery was continued, until the impedance increased beyond the limit of the generator.

Original procedure with LeVeen needle: The electrode used for this procedure was a 3 or 3.5 cm LeVeen needle depending on the tumor size. Before delivery of RF power, the tumor was punctured with a needle and the ten tines were then fully expanded. The ablation was started at 40 W (3-cm needle) or 50 W (3.5-cm needle) RF power and was further increased by 10 W/min up to 75 W (3-cm needle) or 90 W (3.5-cm needle). If the impedance had not increased after 10 min, the RF power was again increased by 10 W increments. The procedure was terminated when a marked increase in impedance ("roll off") occurred.

Modified procedure with LeVeen needle: The needle used was the same type as was used for the original procedure. In the modified version, the tines of the electrode were expanded step by step in 10 steps, and at every step, the length of tine expansion was one-tenth of the full expansion length. Ablation at each step was continued, until the impedance increased to "roll off". Furthermore, at the first step, the ablation was started at a low voltage of 30 W. If it took more than 30 s for "roll off" at a step, the power was increased by 10 W before starting the next step. The maximum electric power for this protocol was 75 W (3-cm needle) or 90 W (3.5-cm needle), which was maintained until the final step.

After RFA treatment, all of the patients were followed up every one or two months with US or CT. When recurrence was detected by imaging examination, additional treatment was instituted with RFA, PEIT, transarterial chemoembolization (TACE) or a combination of these therapies. The prognosis was based on the data obtained up to December 2004.

Statistical analysis

Baseline characteristics of the patients prior to RFA treatment are shown as mean±SD and statistical comparisons were performed using χ^2 test for categorical data and non-paired *t*-test for numerical data.

Table 1 Characteristics of the patients

RESULTS

Eleven patients suffered from rapid and scattered intrahepatic recurrences, which occurred between one month and seven months after ablation. These 11 cases consisted of eight males and three females, ranging in age from 51 to 79 years. The ablated tumors were located variably in either lobe of the liver. Among the baseline characteristics of patients prior to RFA treatment, the cirrhosis stage was significantly more advanced in patients without scattered recurrences (Table 1). Of the patients with scattered recurrences, nine were treated with the cool-tip device according to the original protocol and the other two with the LeVeen needle and original full-expansion method (Tables 1 and 2). After switching from the original to the modified protocols, no scattered recurrences were observed.

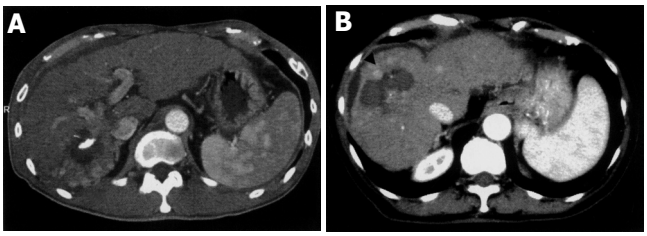

Figure 1 CT images of scattered recurrences after RFA. **A:** Recurrences around the ablated tumor after RFA (case 10 in Table 2); **B:** Multiple recurrences scattered over the whole liver after RFA (case 6 in Table 2). The white arrows indicate the ablated area without enhancement by contrast medium, and the black arrowheads indicate scattered recurrence with enhancement.

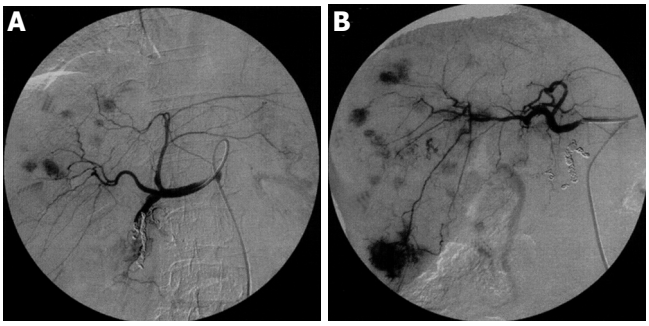

Figure 2 Angiographic images of scattered recurrences after RFA, which were treated by TACE in most of the cases. **A:** Multiple recurrences were located surrounding the ablated tumor (case 8 in Table 2). **B:** Multiple recurrences were scattered in the whole liver (case 9 in Table 2). In both patterns, recurrent tumors were almost equal in size.

Scattered recurrent tumors occurred in two different patterns. One pattern consisted of scattered tumors that were located in a single lobe (three patients). This pattern is shown in Figures 1A (CT) and 2A (angiography), appearing as multiple tumors around the ablated tumor that were localized in the segment. The other pattern consisted of tumors spread over a single lobule in the several segments (one patient) or both lobules (Figures 1B and 2B) (seven patients). Regardless of the scattering pattern, the tumors were roughly equal in diameter. When recurrences were found, neither tumor thrombus nor extrahepatic metastasis was observed by CT or US imaging.

Follow-up of patients to December 2004 showed that the prognosis was significantly worse for patients with scattered recurrences. Among the 127 patients without scattered recurrences, 40 patients died within the observation period; 8 due to liver failure caused by progression of liver cirrhosis, 2 from variceal rupture, and the remainder due to the progression of HCC. In contrast, 8 of 11 patients with scattered recurrences died and all had advanced HCC.

DISCUSSION

There are several common characteristics among the cases described in this study. First, recurrence occurred rapidly following RFA. Most of these cases were detected within 6 mo. Second, multiple recurrent tumors were almost equal in diameter. Finally, the recurrent tumors were either scattered around the ablated tumor or all over the lobe(s), and the location had no relation to the puncture route used for RFA.

Nicoli *et al.*[16] recently reported a similar form of recurrence that is, rapid and numerous bilobular recurrent tumors, and proposed that this type of recurrence would result from new communication formed between two vascular regions (arterial and venous-portal) as a result of RFA needle puncture. It was also suggested that the new communication facilitated the migration of tumor cells

from a high pressure arterial regions to a low pressure portal liver regions. However, we disagree with this speculation because the tumor treated with RFA in that study was only 3.5 cm in diameter, and the feeding artery would not likely have sufficient pressure to spread the malignant cells throughout the lobes. Ruzzenente *et al*.[17] also identified a series of patients with similar recurrences and suggested that increased intra-tumor pressure might be the cause.

In recent *in vitro* and *in vivo* experiments, we demonstrated that the pressure in an ablated area can increase drastically during RFA[18]. We assumed that the peculiar scattered recurrence was caused by an explosion due to increased intra-tumor pressure. The explosion could strew the malignant cells, as a large cluster, which would enable the metastatic tumors to grow in a short time.

A substantial increase in pressure would be necessary for the tumor to explode during RFA, and in rider for this to occur either of the two different conditions would be necessary; namely a fibrotic capsule around the tumor, or parenchymal fibrosis surrounding the tumor accompanied by cirrhosis. Without these conditions, the pressure produced by ablation would easily escape through the microvasculature or sinusoids adjacent to the ablated tumor. In our study, all of the patients with scattered recurrences also had liver cirrhosis, and the rate of advanced-stage cirrhosis was higher in patients with recurrence. This suggests that accumulated collagens in the liver of patients with cirrhosis could form a wall that traps in pressure.

Once a scattered recurrence occurs, focal treatment such as ablation therapy can no longer be used, and the only remaining treatment options are TACE or systemic chemotherapy. The incidence of recurrent tumors is also associated with a poor prognosis. We found that within the observation period, the mortality rate of patients with scattered recurrences was higher than that of patients without scattered recurrences.

In order to avoid scattered recurrences, we believe that modified protocols for RFA should be used. After changing to the modified protocols, we found no cases of scattered recurrence associated with either the cool-tip or LeVeen needle procedures. Another way to avoid scattered recurrence is to use alternative procedures to RFA such as ablation by PEIT, which is performed with a thinner needle than that used for RFA and has a lower risk of complications[7,8,20]. There are no reports that we are aware of to indicate that PEIT can cause scattered recurrences. PEIT is generally considered to be inferior to RFA for the following two reasons. First, in contrast with RFA, PEIT requires multiple sessions. Second, local recurrence following PEIT may be more likely when the surgeon is inexperienced, while a highly-skilled surgeon can achieve complete tumor necrosis.

We conclude that critical complications of rapid and scattered recurrences after RFA can be avoided by the use of modified protocols. If the need arises, it is also necessary to select PEIT, not to cling to use RFA procedure. In some cases, PEIT should be considered as a suitable alternative to RFA.

Abstract

AIM: To evaluate the effect of antiviral treatment on plasma levels of transforming growth factor-β1 (TGF-β1), metalloproteinase 1 (MMP-1), and tissue inhibitor of metalloproteinase-1 (TIMP-1) in patients with chronic hepatitis C.

METHODS: TGF-β1, MMP-1, and TIMP-1 plasma concentrations were measured by an enzyme immunoassay in 28 patients, during 48 wk of treatment with pegylated interferon-alpha 2b (PEG-IFN-α2b) plus ribavirin (RBV) and after 24 wk of follow-up. Patients were divided into two groups: responders (R) and non-responders (NR) related to achieved sustained virologic response. Normal values were evaluated in plasma samples of 13 healthy volunteers.

RESULTS: Baseline plasma concentrations of TGF-β1 and TIMP-1 (30.9±3.7 and 1 506±61 ng/mL respectively) measured in all subjects significantly exceeded the normal values (TGF-β1: 18.3±1.6 ng/mL and TIMP-1: 1 102±67 ng/mL). In contrast, pretreatment MMP-1 mean level (6.5±0.9 ng/mL) was significantly lower than normal values (11.9±0.9 ng/mL). Response to the treatment was observed in 12 patients (43%). TGF-β1 mean concentration measured during the treatment phase decreased to the control level in both groups. However at wk 72, values of NR patients increased and became significantly higher than in R group. TIMP-1 concentrations in R group decreased during the treatment to the level similar to normal. In NR group, TIMP-1 remained significantly elevated during treatment and follow-up phase and significant difference between both groups was demonstrated at wk 48 and 72. MMP-1 levels were significantly decreased in both groups at baseline. Treatment caused rise of its concentration only in the R group, whereas values in NR group remained on the level similar to baseline. Statistically significant difference between groups was noted at wk 48 and 72.

CONCLUSION: These findings support the usefulness of TGF-β1, TIMP-1, and MMP-1 in the management of chronic hepatitis C. Elevated TIMP-1 and low MMP-1 plasma concentrations during antiviral therapy may indicate medication failure.

INTRODUCTION

Transforming growth factor-β1 (TGF-β1) is considered as a pivotal inducer of liver fibrosis acting through activation of hepatic stellate cells (HSCs) and their transformation to myofibroblasts, which are the main source of extracellular matrix (ECM) proteins[1,2]. Moreover, TGF-β1 stimulates the production of tissue inhibitor of TIMP-1 that inhibits MMP activity. This effect is responsible for the inhibition of ECM protein breakdown and its accumulation[3]. TGF-β1 inhibits DNA synthesis serving as a terminator of regenerative cell proliferation and induces apoptosis of hepatocytes[4]. Additionally, TGF-β1 may inhibit stellate cell apoptosis and promote their survival, at least in part as a result of anti-apoptotic effect of TIMP-1[5,6]. On the other hand, TGF-β1 exerts regulatory, mostly immunosuppressive effects on the immune system and as demonstrated recently can also suppress hepatitis C virus (HCV) replication[7,8]. Since HCV infection is related to an immune response, cell proliferation and fibrosis as well as modulation of TGF-β1 can affect the course of chronic hepatitis C. As demonstrated recently, HCV core and

nonstructural proteins regulate biological functions in HSC and increase the secretion of TGF-β1 and the expression of ECM proteins in both HSCs and parenchymal hepatic cells[9,10]. The possible role of TGF-β1, TIMP-1, and MMP-1 as predictive biomarkers of chronic hepatitis activity and progression is supported by recent clinical studies[11-19]. These studies demonstrated association with hepatic function impairment or fibrosis, and only few evaluated possible effects of antiviral treatment on growth factors, but they did not include possible metalloproteinase involvement[20,21].

We undertook this study to evaluate the effect of pegylated interferon-α2b plus ribavirin (PEG-IFN-α2b/RBV) treatment on plasma TGF-β1, TIMP-1, and MMP-1 levels in patients with chronic hepatitis C.

MATERIALS AND METHODS

Patients

Ethical approval for the study was obtained from the Bioethical Committee of the Medical University of Bialystok. Informed consent was obtained from 28 patients (8 females and 20 males, mean age 49±12 years) with chronic hepatitis C, who were included into the protocol of PEG-IFN-α2b (Pegintron™, Schering-Plough) and RBV (Rebetol™, Schering-Plough) treatment. All patients had proven chronic hepatitis C through the presence of anti-HCV antibodies with elevated ALT activities demonstrated at least twice during a 6-mo observation period. Additionally, the disease activity was confirmed by the presence of viral replication and liver biopsy (Hepafix System, Braun, Melsungen, Germany). Patients with HBV infection and a history of alcohol abuse or psychiatric disorders were excluded from the study. Patients received combination therapy with weekly doses of 100 μg PEG-IFN-α2b administered subcutaneously and RBV administered orally at daily doses of 1 000 or 1 200 mg/d based on body weight <75 or ≥75 kg, respectively. The total duration of treatment was 48 wk. Liver biopsy was performed before and after antiviral therapy. Patients were divided into two groups related to sustained virologic response (SVR), defined as undetectable HCV RNA, 24 wk after the end of therapy. Patients who achieved SVR were included into the responder group (R) and those without SVR into non-responder group (NR). Paraffin-embedded biopsy specimens were stained and evaluated using the scoring system according to Scheuer[22]. TGF-β1, TIMP-1, and MMP-1 plasma concentrations were measured at baseline, 24 and 48 wk after treatment and additionally 24 wk after the termination of the treatment (wk 72). Serum liver function tests and scored histological changes were investigated for the possible correlation with TGF-β1, TIMP-1, and MMP-1. Normal values of TGF-β1, TIMP-1, and MMP-1 were collected from 13 healthy volunteers (5 females and 7 males , mean age: 48± 6 years).

Methods

Venous blood for plasma TGF-β1, TIMP-1, and MMP-1 was collected on ice using tubes with EDTA. Samples for TGF-β1 were immediately activated with acetic acid and urea and assayed with ELISA using recombinant human TGF-β soluble receptor Type II (TbR-II) as a solid phase precoated onto a microplate (Quantikine®, R&D Systems Inc., Minneapolis, USA) as described previously[23]. TIMP-1 and MMP-1 were assayed by the two-site ELISA sandwich technique (Amersham Pharmacia Biotech, Little Chalfont, Buckinghamshire, UK) using specific antibodies as a solid phase. MMP-1 assay recognized total human MMP-1, namely free and complexed with TIMP-1. TIMP-1 assay recognized total human TIMP-1, including free and complexed with any of the metalloproteinases bound to the solid phase. TIMP-1 or MMP-1 bound to the solid phase was detected by peroxidase-labeled antibodies. There was no cross-reactivity between TIMP-1 and MMP-1 in these assays. Alanine and aspartate aminotransferase (ALT and AST) activity and bilirubin concentration were measured in serum using a Cobas Mira instrument (Roche).

Statistical analysis

Values were expressed as mean±SE. The significance of the difference was calculated by two-tailed Student's *t* test. For correlation analysis, the Pearson's product moment correlation was performed. $P<0.05$ was considered statistically significant.

RESULTS

Plasma concentrations of TGF-β1 and TIMP-1 measured before PEG-IFN-α2b/RBV treatment (mean: 30.9±3.7 and 1 506±61 ng/mL respectively) significantly exceeded the normal values (18.3±1.6 and 1 102±67 ng/mL respectively). Treatment resulted in a significant decrease of TGF-β1 by wk 24, and its further decline at the end of the treatment as well as 24 wk after its completion to the level similar to normal (Table 1). TIMP-1 plasma mean concentration also decreased, but did not differ significantly from baseline. Moreover, it remained on the level significantly exceeding controls during treatment and follow-up period (Table 1). Mean MMP-1 baseline level (6.5±0.9 ng/mL) was significantly lower than normal (11.9±0.9 ng/mL) but increased during the treatment. After treatment, its level still remained lower than normal but the difference was not significant (Table 1). There was a significant positive correlation between TIMP-1 and aminotransferases as well as between TGF-β1 and AST at baseline (Table 2). A significant correlation was also demonstrated between baseline TGF-β1 or TIMP-1 concentrations and scored fibrosis in pre-treatment liver biopsy specimens (Table 3). No association was

Table 1 Plasma concentrations of TGF-β1, TIMP-1, and MMP-1 during treatment (mean±SE)

	Controls	Weeks after starting treatment			
		0	24	48	72

demonstrated between MMP-1 and biochemical or histological signs of liver injury (Tables 2 and 3).

SVR was observed in 12 among 28 patients (43%). Evaluation of baseline liver function tests showed no statistically significant differences between R and NR groups (Table 4). Treatment did not affect bilirubin levels in both groups. Responders demonstrated a significant decrease of ALT and AST activities during the treatment and follow-up. Decline of aminotransferases activity in NR group was only temporal and rose to values significantly higher than in R group after discontinuation of the treatment (Table 4). As demonstrated in Figure 1, scored values of histologic changes were similar before the treatment. There were no significant differences between biopsies preformed before and after the treatment in NR group. In contrast, responders demonstrated improvement after the treatment; however, statistically significant difference between score values at wk 0 and 48 was noted only in respect to portal inflammation.

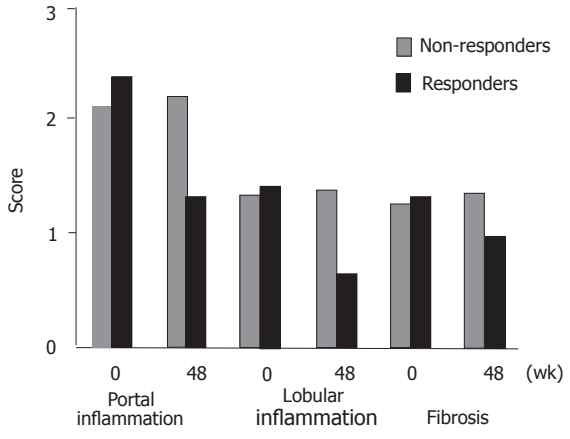

Figure 1 Mean score values of histologic changes in liver biopsy specimens before (wk 0) and after (wk 48) treatment. Statistically significant difference is indicated with arrows.

Table 4 Values of biochemical indices of liver injury during treatment (0, 24, and 48 wk) and 24 wk after its completion (wk 72) in both groups

		Weeks after the beginning of treatment			
		0	24	48	72

[a]$P<0.05$ responders *vs* non-responders, [c]$P<0.05$ *vs* baseline.

There were no statistically significant differences in TGF-β1, TIMP-1, and MMP-1 concentrations between R and NR groups at the baseline and 24 wk after the treatment. As demonstrated in Figure 2A, TGF-β1 mean concentration decreased to the control level during treatment in both groups. However, 24 wk after the treatment (wk 72), values in NR patients increased (23.2± 2.3 ng/mL) and became significantly higher than those in R group (18.6±3.7 ng/mL). As shown in Figure 2B, mean concentration of TIMP-1 decreased during the treatment only in R group and there were no statistically significant differences in comparison with controls at wk 24, 48, and 72. In contrast, TIMP-1 concentration in NR group remained significantly elevated (above 1 500 ng/mL) during treatment and follow-up (Figure 2B). Significant difference between both groups was demonstrated at wk 48 and 72. As shown in Figure 2C, MMP-1 levels were significantly decreased in both groups at baseline. Treatment caused rise of its concentration only in the R group, whereas the values in NR group remained on the level similar to baseline. Statistically significant difference between groups was noted at wk 48 and 72 (Figure 2C).

DISCUSSION

The effect of TGF-β1 on liver fibrosis is at least in part related to stimulation of TIMP-1 that affects MMP activity and is responsible for inhibition of ECM protein breakdown[3]. The pivotal role of TGF-β1 in fibrogenesis is initially proved in transgenic mice with overexpression of TGF-β1, causing increase of its plasma levels up to 700 ng/mL and a marked upregulation of TIMP-1 gene expression[24-26]. Recent studies demonstrated that HCV proteins can stimulate secretion of TGF-β1 and production of ECM proteins by HSCs[9,10]. On the other hand, Murata *et al*.[8] showed that TGF-β suppresses viral HCV-RNA replication and can affect the mechanism of liver disease caused by HCV. Chronic liver injury leading to fibrosis displays diminished ECM degradation mainly through TIMP induction following MMP inhibition[3]. As demonstrated recently, TIMP-1 recombinant plasmid has inhibitory effects on the production of types I and III collagens secreted by activated rHSCs *in vitro*[27].

The most important factor affecting TGF-β1 measurement in human beings is from platelets which are an important source of this cytokine[28]. The Quantikine ELISA System is recommended because

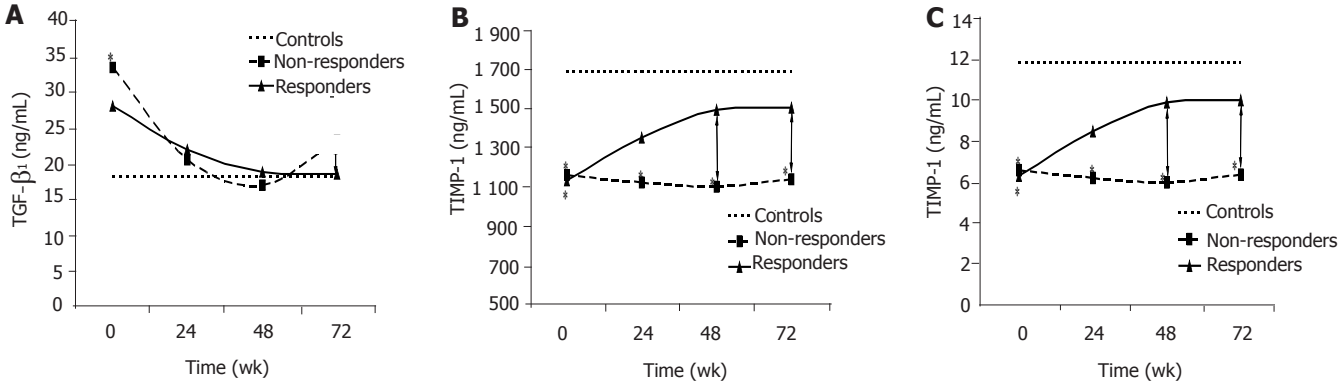

Figure 2 Mean TGF-β1 (**A**), TIMP-1 (**B**), and MMP-1 (**C**) plasma concentrations before and during IFN-α plus RBV therapy as well as 24 wk after its completion (wk 72) in respect to the treatment efficacy. Statistical significance in comparison to normal values is indicated with asterisks and between groups with arrows.

of quick and simple activation with acid and urea that disrupt the majority of TGF-β1 complexes. Mean plasma concentration of TGF-β1 measured in our healthy controls with this method is consistent with the range from more than 20 studies reviewed by Grainger *et al*.[28].

According to our previous research, TGF-β1 and TIMP-1 correlate with the degree of liver insufficiency, hepatocyte injury and degree of fibrosis in human beings with liver cirrhosis and chronic viral hepatitis[12,23,29]. Association between TGF-β1 mRNA in liver specimens and fibrogenic activity in chronic hepatitis is demonstrated for the first time by Castilla *et al*.[30]. Ten years after the association between circulating or tissue TGF-β and liver fibrosis in HCV infection has been confirmed by Kanzler *et al*.[13]. As demonstrated by Yoo *et al*.[31] and Lee *et al*.[32], HBV antigens also stimulate TGF-β1 synthesis. According to Neuman *et al*.[20,33], serum TNF-α reflects the progression of inflammation, whereas TGF-β reflects the degree of fibrosis in HCV patients. A similar relationship has been demonstrated with respect to primary biliary cirrhosis and alcoholic liver disease[34]. Our previous study showed that a positive predictive value of TGF-β1 plasma levels exceeding the upper normal range reaches 96% for liver cirrhosis[23]. According to Boeker *et al*.[11] measurement of plasma TIMP-1 detects cirrhosis with 100% sensitivity but a lower specificity. Lichtinghagen *et al*.[14] demonstrated that MMP-1 mRNA expression increases steadily with fibrosis progression during the course of chronic hepatitis C. Walsh *et al*.[17] who studied liver histology in patients with chronic hepatitis C have underlined the high sensitivity of TIMP-1 and TIMP-2 in detecting advanced liver disease. According to Nie *et al*.[35], there is a significant correlation between circulating and liver levels of TIMP-1 in cirrhotics, indicating that its measurement in plasma may be useful in fibrosis management. These observations indicate the usefulness of both TGF-β1 and TIMP-1 as possible early non-invasive biomarkers for liver fibrosis.

In this study, we confirmed the association between the degree of hepatocyte injury or liver fibrosis and plasma TGF-β1 or TIMP-1 levels in patients with chronic hepatitis C. As the levels of TGF-β1 showed a similar behavior in both groups during therapy, it is unclear whether its decrease is a direct effect of medication on the expression or an effect caused by HCV inhibition. However, measurement carried out 24 wk after treatment demonstrated an association with treatment efficiency. Similar effects on plasma TGF-β1 have been observed by Castilla *et al*.[30] and Neuman *et al*.[20] and in our previous study of chronic hepatitis B[29]. TIMP-1 and MMP-1 concentrations demonstrated significant differences between groups at the end of the treatment and after 24 wk of follow-up. Since plasma TIMP-1 and MMP-1 remained on the baseline level in non-responder group only, lack of their normalization should be considered as a possible indicator of ineffective antiviral therapy. Results of the present study are in accordance with our previous findings, demonstrating the strong association between TGF-β1 or TIMP-1 plasma levels and scored hepatic fibrosis evaluated in biopsy specimens of patients with chronic hepatitis B and C[12]. Since the findings of increased TGF-β1 and TIMP-1 are accompanied with an elevation in plasma carboxyterminal cross-linked telopeptide of type 1 procollagen (ICTP), indicating type I collagen degradation, collagenolytic mechanisms precede TGF-β1/TIMP-1 dependent stimulation of liver fibrosis[12]. Low MMP-1 plasma levels before the treatment in the present study are consistent with this observation as well as in accordance with Murawaki *et al*.[15] who demonstrated a decrease in MMP-1 concentration during histological progression of chronic hepatitis. Moreover, significantly decreased baseline plasma MMP-1 followed by an increase during treatment supports the role of TGF-β1/TIMP-1 dependent mechanism of liver fibrosis in patients with active chronic hepatitis C. Similar effects on MMP-1 and TIMP-1 in patients with chronic hepatitis C have been observed by Ninomiya *et al*.[16] who showed improvement of liver histology after treatment with IFN-α alone. Downregulation of the mechanism causing an increase of MMP-1 activity should be considered as the probable reason for this effect. As we demonstrated recently, treatment of chronic hepatitis B with lamivudine affects TGF-β1, TIMP-1, and MMP-1 plasma levels in a similar way and this mechanism should be recognized as an effect of response to the antiviral treatment,

irrespective of the etiology[29].

Results of this study support the role of TIMP-1 and MMP-1 balance in the TGF-β1 dependent mechanism of liver fibrosis related to HCV infection. Association between hepatic injury and antiviral treatment efficacy suggests their possible usefulness in chronic hepatitis C management. Elevated TIMP-1 and low MMP-1 plasma concentrations during antiviral therapy may indicate medication failure.

Abstract

AIM: To assess the frequency and the risk factors of stress-induced gastrointestinal (GI) bleeding in children admitted to a pediatric intensive care unit (PICU).

METHODS: The medical records of children aged between 1 month and 15 years admitted to the PICU between January 2002 and December 2002 were reviewed. Demographic data, indications for PICU admission, principle diagnosis, and basic laboratory investigations were recorded. Previously described factors for stress ulcer bleeding (mechanical ventilation, sepsis, acute respiratory distress syndrome, renal insufficiency, coagulopathy, thrombocytopenia, and intracranial pathology) were used as independent variables in a multivariate analysis.

RESULTS: One hundred and seventy of two hundred and five medical records were eligible for review. The most common indication for PICU admission was respiratory failure (48.8%). Twenty-five children received stress ulcer bleeding prophylaxis with ranitidine. The incidence of stress ulcer bleeding was 43.5%, in which 5.3% were clinically significant bleeding. Only mechanical ventilation and thrombocytopenia were significantly associated with stress ulcer bleeding using the univariate analysis. The odds ratio and 95% confidence intervals were 5.13 (1.86-14.12) and 2.26 (1.07-4.74), respectively. However, the logistic regression analysis showed that mechanical ventilation was the only significant risk factor with the odds ratio of 14.1.

CONCLUSION: The incidence of gastrointestinal bleeding was high in critically ill children. Mechanical ventilation was an important risk factor for gastrointestinal bleeding.

INTRODUCTION

Stress ulcer bleeding is one of the common complications in critically ill patients admitted to the intensive care unit. Its incidence in adults ranges from 0.17% to 14%, depending on the diagnostic criteria, patient selection, and methods of investigation[1-4]. There have been a few reports of this condition in pediatric populations with the incidence varying from 10% in a pediatric intensive care unit to 53% in a neonatal intensive care unit[5,6]. This study was designed to assess the frequency and the risk factors of stress-induced upper gastrointestinal bleeding in critically ill children admitted to a pediatric intensive care unit.

MATERIALS AND METHODS

Patients

All medical records of children younger than 15 years admitted to the PICU between January 2002 and December 2002 at Chiang Mai University Hospital were retrospectively reviewed. Our hospital is a tertiary care center with a facility of six-bed PICU, taking care of approximately 83% of medical and 17% of surgical pediatric patients. The general indications for admission included respiratory/cardiovascular failure, shock, coma, post-operative care, and patients requiring intensive monitoring. The patients with duration of admission in PICU shorter than 48 h, positive previous history of GI bleeding, recent GI tract surgery, brain death, and epistaxis/oropharyngeal bleeding were excluded. Demographic data, indications for PICU admission, and principle diagnosis as well as basic laboratory investigations including hemoglobin level, platelet count, coagulation studies, blood urea nitrogen (BUN), creatinine (Cr), and liver function tests were recorded. Upper GI bleeding during PICU admission was categorized as overt and clinically significant bleeding. Overt GI bleeding (OB) was diagnosed, if there was evidence of hematemesis, coffee ground gastric content, or melena;

whereas clinically significant bleeding (CSB) was defined as overt GI bleeding associated with major changes in vital signs, namely a decrease in blood pressure greater than 20 mmHg, an increase in heart rate of >20 beats above the baseline value, and a decrease in hemoglobin level of more than 2 g/dL. Based on previous studies in adults, potential risk factors were used. These were the use of mechanical ventilation, sepsis, acute respiratory distress syndrome (ARDS), renal insufficiency, coagulopathy, thrombocytopenia, and intracranial pathology. The diagnostic criteria for these conditions were: sepsis-at least two of the following, body temperature >38 °C or <36 ° C, heart rate >160/min (infant) or >150/min (child) or >90/min (adolescent), WBC >15 000 or <4000/mm^3, and band form >10% or there was a positive blood culture; ARDS - positive alveolar infiltration in both lungs on chest X-ray and PaO_2/FiO_2 <200 without evidence of left-sided heart failure; *renal insufficiency* - Cr >2 mg/dL, or requiring dialysis; *coagulopathy* - prothrombin time (PT) >3s and partial thromboplastin time (PTT) >10 s above the control value; *thrombocytopenia* -'platelet count<100 000/mm^3; *intracranial pathology* - abnormal imaging study, meningitis, or encephalitis. This study protocol was approved by the Research Ethic Committee of Chiang Mai University.

Statistical analysis

All data were assessed by SPSS program. Cross-tabulations were analyzed using the χ^2 test, presented as the odds ratio and 95% confidence interval, in which a $P<0.05$ was considered statistically significant. Multivariate analysis of various independent variables was performed using logistic regression modeling.

RESULTS

Over the 12-month period, 205 of 258 medical records were available for review (53 records were missing). Thirty-five cases were excluded for the following reasons: duration of admission shorter than 48 h (n = 28), incomplete medical records (n = 3), epistaxis (n = 2), brain death (n = 1), and recent gastrointestinal surgery (n = 1). Therefore, a total of 170 charts were eligibly reviewed. There were 89 males (52.4%) with an average age of 3.8 years. The total duration of admission was 7.2 d (2-35 d). The most common indication for PICU admission was respiratory failure (48.8%). The demographic data of children with and without bleeding are shown in Table 1. Twenty-five children received stress ulcer bleeding prophylaxis, in which ranitidine was used in 22 cases with a dosage of 3 mg/kg/d; whereas the other three patients received antacids. In the subgroup of children who received stress ulcer prophylaxis, 14 cases developed upper GI hemorrhage (3 CSB and 11 OB); whereas stress ulcer bleeding occurred in 60 of 145 cases who did not receive the prophylactic treatment (6 CSB and 54 OB). GI bleeding complicated 43.5% of cases admitted to the PICU and 5.3% had clinically significant bleeding. Twenty-two percent of patients with CSB were diagnosed as dengue hemorrhagic fever, compared to none in the patients without bleeding.

Table 1 Demographic data of children with and without stress-induced GI bleeding

Characteristic	Bleeding (n = 74)	No bleeding (n = 96)	P
Age (yr)[1]	3.82 (0.44)	3.84 (0.40)	0.977
Sex, male	41	48	0.484
Duration of admission (d)[1]	8.23 (0.78)	6.41 (0.58)	0.062
Underlying diseases

[1]Presented as mean±SE.

Among the independent variables, only mechanical ventilation and thrombocytopenia were significantly associated with stress ulcer bleeding using the univariate analysis. The odds ratio and 95%CI were 5.13 (1.86-14.12) and 2.26 (1.07-4.74), respectively (Table 2). Using multivariate analysis, only mechanical ventilation was found to be significantly associated with the development of gastrointestinal bleeding in critically ill patients ($P<0.05$). In our study, stress ulcer prophylaxis did not reduce the risk of bleeding. The overall mortality rate was 18.8%. Gastrointestinal bleeding and transfusion requirements were associated with high mortality ($P<0.05$).

DISCUSSION

Stress-induced gastrointestinal lesions, including gastritis, erosions, gastric, and duodenal ulcers, can result in significant upper gastrointestinal hemorrhage, increased morbidity and mortality[2]. The prevalence varies between studies[1-6]. In our series, 5% of the cases developed clinically significant bleeding which is considerably higher than that in previous studies performed in pediatric population[5,7]. This might result from a relatively high prevalence of hemorrhagic fever which commonly causes thrombocytopenia and subsequent gastrointestinal bleeding in our region. As noted in our report, 22% of the cases with CSB were diagnosed as dengue hemorrhagic fever. Additionally, we did not routinely use stress ulcer prophylaxis in all patients, and patients with ranitidine prophylaxis did not receive the recommended dose of 6 mg/kg/d[8]. This may explain the poor beneficial prophylactic effect noted in our study. Apart from clinically significant bleeding, we also found a high prevalence of overt upper gastrointestinal bleeding (38.2%), which is comparable to the retrospective report section from Kuusela *et al.* in neonates[6]. However, this figure could be exceptionally high due to a possibility of inclusion of traumatic nasogastric tube injuries which are very difficult to be documented in such a retrospective design and we did not routinely perform endoscopy in all children to delineate the cause of upper GI bleeding during the study period. Although we believe that the prevalence

Table 2 Risk factors for stress-induced GI bleeding in children (*n* = 170)

Risk factors		*n*	Gastrointestinal bleeding (%)	Odds ratio (95%CI) simple regression	Odds ratio (95%CI) multiple regression
Mechanical ventilation	Yes	139	49.6	5.126 (1.861–14.118)	14.096 (2.205–90.112)

reported in this study might be over-estimated, it discerns a significant magnitude of the problem that requires careful medical attention. Similar to previous studies in adults and children, the mechanical ventilation was found to be the most significant risk factor for stress-induced gastrointestinal bleeding in our study[1,2,5,6]. Although coagulopathy is also noted as a significant independent risk factor in some studies[1,2,5,7], this was not observed in our series using multivariate analysis. A further prospective study with a larger sample size is needed.

Imbalance between protective and destructive factors has been postulated as a basic pathophysiology of GI bleeding. Increased acid production and decreased gastric blood flow, secondary to hypotension and metabolic acidosis, are composed of major physiologic responses leading to mucosal injuries. Hemorrhagic gastritis affects mainly the gastric body as it is the most vulnerable area for ischemic injury[4]. As a result, prophylactic strategies with H_2RA and cytoprotective agents have been widely prescribed to the critically ill patients admitted to the intensive care unit. Lacroix *et al.*[9] have reported a significant increase in the gastric pH following cimetidine prophylaxis stress ulcer bleeding in children, but no prophylactic benefit was demonstrated in their study. Kuusela *et al.*[10] showed that short-term prophylactic ranitidine treatment could prevent gastric mucosal lesions in newborn infants under stress. Cook *et al.*[11] performed a meta-analysis and showed that H_2RA significantly reduces clinically important bleeding over sucralfate and antacids. However, overgrowth of Gram-negative bacteria following the increase of gastric pH by antisecretory agents can be associated with ventilator-associated pneumonia (VAP)[12,13]. Lopriore *et al.*[14] reported that 8.4% of mechanically ventilated children develop VAP. Among these, more children prophylactically treated with ranitidine tend to be associated with VAP than those in the control group (11.1% *vs* 6.2%), despite no statistical significance. The use of sucralfate, since its introduction, seems logically useful in preventing this complication. Unfortunately, this hypothesis was not supported by the large meta-analysis study[11].

Ben-Menachem *et al.*[15] did a cost-effective analysis on stress ulcer prophylaxis and suggested that the cost of prophylaxis is substantial and may be prohibitive in ICU patients at low risk of developing stress-related hemorrhage. Therefore, several authors have recently suggested that such prophylaxis should be selective and may be indicated only for patients at high risk, particularly in those with mechanical ventilation and coagulopathy[2,7]. However, the cost estimation in PICU on this issue has not been well studied.

In conclusion, the incidence of gastrointestinal bleeding is high in critically ill children. Mechanical ventilation is a significant risk factor for gastrointestinal bleeding.

Abstract

AIM: To investigate the influence of infliximab (Remicade) on experimental colitis produced by 2,4,6,trinitrobenzene sulfonic acid (TNBS) in rats.

METHODS: Thirty-six Wistar rats were allocated into four groups (three groups of six animals each and a fourth of 12 animals). Six more healthy animals served as normal controls (Group 5). Group 1: colitis was induced by intracolonic installation of 25 mg of TNBS dissolved in 0.25 mL of 50% ethanol and infliximab was subcutaneously administered at a dose of 5 mg/kg BW; Group 2: colitis was induced and infliximab was subcutaneously administered at a dose of 10 mg/kg BW; Group 3: colitis was induced and infliximab was subcutaneously administered at a dose of 15 mg/kg BW; Group 4: colitis was induced without treatment with infliximab. Infliximab was administered on d 2–6. On the 7th d, all animals were killed. The colon was fixed in 10% buffered formalin and examined by light microscopy for the presence and activity of colitis and the extent of tissue damage. Tumor necrosis factor-alpha (TNF-α) and malondialdehyde (MDA) were also measured.

RESULTS: Significant differences concerning the presence of reparable lesions and the extent of bowel mucosa without active inflammation in all groups of animals treated with infliximab compared with controls were found. Significant reduction of the tissue levels of TNF-α in all groups of treated animals as compared with the untreated ones was found (0.47±0.44, 1.09±0.86, 0.43±0.31 *vs* 18.73±10.53 respectively). Significant reduction in the tissue levels of MDA was noticed in group 1 as compared to group 4, as well as between groups 2 and 4.

CONCLUSION: Subcutaneous administration of infliximab reduces the inflammatory activity as well as tissue TNF-α and MDA levels in chemical colitis in rats. Infliximab at a dose of 5 mg/kg BW achieves better histological results and produces higher reduction of the levels of TNF-α than at a dose of 10 mg/kg BW. Infliximab at a dose of 5 mg/kg BW produces higher reduction of tissue MDA levels than at a dose of 15 mg/kg BW.

INTRODUCTION

Ulcerative colitis is a chronic relapsing inflammatory condition involving the large bowel of unknown etiology. Clinical manifestations are considered to be the result of an imbalance between proinflammatory and inflammatory cytokines, resulting in inflammation and clinical symptoms. Activated T-lymphocytes release cytokines, thereby recruiting a large number of inflammatory cells in the mucosa. Activation of these cells causes further production of cytokines, cell recruitment and inflammation. In addition to cytokines, leukotrienes, thromboxane, and reactive oxygen species are released from activated mucosal cells[1]. This uncontrolled immune system activation results in the sustained overproduction of reactive metabolites of oxygen and nitrogen[2]. It has been suggested that self-sustaining cycles of oxidant formation may amplify flare-ups of inflammation and mucosal injury in ulcerative colitis[3]. Treatment of ulcerative colitis includes a wide range of anti-inflammatory and immunosuppressant drugs

with satisfactory results.

TNF-α is a pleiotropic cytokine with important proinflammatory and immunomodulatory properties. This cytokine plays a significant role in a number of inflammatory disorders including inflammatory bowel disease[4]. It has been shown that administration of the chimeric anti-TNF-α antibody in patients with active Crohn's disease results in a dramatic improvement of many clinical and laboratory parameters[5,6]. One of the most striking findings of the initially performed clinical trials is the observation that infliximab administered at a dose of 5 mg/kg BW results in better patients' improvement than at the dose of 10 or 15 mg/kg BW. Infliximab has also been administered in severe ulcerative colitis patients with promising results[7-9], though the clinical benefit is not prominent in patients refractory to previous administration of steroids[10,11]. Experimental evidence suggests that TNF-α may also play a role in the pathogenesis of experimental colitis[12].

The aim of this study was to investigate the influence of infliximab on experimental colitis in rats, produced by TNBS and to estimate its influence on the oxidative stress accompanying this model of colitis.

METHODS

The experimental procedures described below were approved by the Animal Care Committee according to the European Union Act and Greek Law 160, A-64, May, 1991.

General preparation

Adult male Wistar rats weighing 200-240 g were allowed to adapt to our laboratory conditions 1 wk prior to the experiment. They were housed individually in cages at a constant temperature (22 °C) and in a 12-h d/night cycle with free access to food and water. A total number of 36 rats were used. They were randomly allocated into five groups. *Group 1*: experimental colitis was induced and infliximab was subcutaneously administered at a dose of 5 mg/kg BW ("Infliximab 5"); *Group 2*: experimental colitis was induced and infliximab was subcutaneously administered at a dose of 10 mg/kg BW ("Infliximab 10"); *Group 3*: experimental colitis was induced and infliximab was subcutaneously administered at a dose of 15 mg/kg BW ("Infliximab 15"); *Group 4*: experimental colitis was induced without treatment with infliximab (12 animals) ("Untreated"). Six more healthy animals served as controls (Group 5). On the 7th d, all animals were killed and the colon was removed. The same part of rat's colon was used for histology as well as for MDA and TNF-α estimation.

Induction of experimental colitis

Distal colitis was induced by intracolonic installation of 25 mg of TNBS dissolved in 0.25 mL of 50% ethanol. The solution was injected into the colon 8 cm proximal to the anus with a PE-50 cannula. In order to ensure that TNBS-ethanol solution was not immediately expelled by the rat, the cannula was left in place for 15 s prior to its removal.

Drug administration

Infliximab was administered subcutaneously only in groups 1, 2, and 3 on d 2-6 at the doses of 5, 10 and 15 mg/kg BW, respectively. The subcutaneous administration has not previously been tried in both men and animals. We chose to administer the drug for five consecutive d and not to follow the usual scheme of administration of infliximab in patients with Crohn's disease because we were unable to predict the exact serum levels of the drug following the subcutaneous administration. A second reason was the fact that in this model of experimental colitis, the recommended time to kill the animals was 7 d. Following two or more weeks, the macro- and microscopic lesions were usually not detectable in the survived animals. Healthy control animals were given a subcutaneous dose of normal saline from d 2 to 6.

Histology

Specimens were fixed in 10% buffered formalin and embedded in paraffin blocks (3-4 blocks for each case). Then hematoxylin-eosin stained sections were blindly examined by two pathologists. In each case, the extent of lesions (expressed as a percentage of tissue damage of the whole bowel length) was estimated. The histological lesions such as active ulcers and erosions and reparable lesions (newly re-epithelized lesions or granulation tissue beneath cylindrical epithelium) were estimated. The extent of mucosa without signs of active inflammation was also estimated as previously described[13-16].

Tissue malondialdehyde (MDA) estimation

The MDA measurement was based on the reaction of a chromogenic reagent, *N*-methyl-2-phenylindole (MPI), with MDA at 45°C. One molecule of MDA reacted with two molecules of MPI to yield a stable chromophore with maximum absorbance at 586 nm. The reagents used included Reagent MPI, 10.3 mmol/L *N*-methyl-2-phenylindole in acetonitrile, MDA standard, 10 mmol/L 1,1,3,3-tetramethoxypropane in 20 mmol/L Tris-HCl, 500 mmol/L butylated-hydroxytoluene, in acetonitrile, 20 mmol/L Tris buffer pH 7.4, 0.9% NaCl, 37% (12 mol/L) HCl, methanol, HPLC grade, acetonitrile and HPLC grade. Before the procedure, three volumes of the MPI reagent were diluted with one volume of 100% methanol. Tissue samples were rinsed with ice-cold isotonic saline before homogenization which was carried-out using Tris buffer 20 mmol/L pH 7.4 and an ULTRA-TURRAX (IKA-Labortecnik) blender. One milliliter buffer was used for 0.1 g of tissue. Ten milliliters of 500 mmol/L BHT was added to 1 mL of tissue homogenate to prevent sample oxidation. The homogenate was centrifuged at 3 000 r/min at 4 °C for 10 min. Then 0.2 mL of sample (plasma or supernatant of tissue homogenate) and 0.65 mL of diluted MPI reagent were added to a polypropylene microcentrifuge tube. The mixture was vortexed and then 0.15 mL of 12 mol/L HCl was added. Tubes were incubated at 45 °C for 60 min and centrifuged at 6 000 r/min.

Table 1 Comparison of histological lesions in treated and untreated groups of animals (mean±SD)

Group	Active ulcers and erosions	*P* value	Reparative lesions	*P* value
1 (Infliximab 5, *n* = 6)	0.07±0.12	0.30	0.38±0.12	0.0001
2 (Infliximab 10, *n* = 6)	3.77±5.07	0.42	0.80±0.14	0.0001
3 (Infliximab 15, *n* = 6)	25.02±38.90	1.00	1.00±0.47	0.0001
4 (Untreated, *n* = 12)	25.00±38.91		15.00±5.48	

Table 2 Percentage of bowel area without active inflammation in treated and untreated groups of animals (mean±SD)

Group	Percentage of mucosa without active inflammation	*P* value
1 (Infliximab 5)	99.55±0.19	0.049
2 (Infliximab 10)	95.43±5.15	0.088
3 (Infliximab 15)	73.98±39.29	0.705
4 (Untreated)	60.00±37.18	

Table 3 Tissue TNF-α levels in treated and untreated groups of animals (mean±SD)

Group	Tissue TNF-α (pg/mL)	*P* value
1 (Infliximab 5)	0.47±0.44	<0.0001
2 (Infliximab 10)	1.09±0.86	<0.0001
3 (Infliximab 15)	0.43±0.31	<0.0001
4 (Untreated)	18.73±10.53	
5 (Healthy animals)	0.00+/–0.0	

Table 4 Mean value of tissue malondialdehyde in treated and untreated groups of animals (mean±SD)

Group	Serum malondialdehyde (μmol/l)	*P* value
1 (Infliximab 5)	1.85±0.20	0.017
2 (Infliximab 10)	1.84±0.37	0.011
3 (Infliximab 15)	2.29±0.56	0.272
4 (Untreated)	2.73±0.46	
5 (Healthy animals)	1.11+/–0.19	

for 15 min. Then 0.8 mL of the supernatant was measured at 586 nm. MDA standards for the standard curve were made by dilutions of the stock 10 mm TMOP solution. The final concentrations were 2.08, 4.16, 8.33, 12.5 and 16.66 μmol/L and the assay procedure was followed as for the samples. The absorbance was 0.059, 0.124, 0.264, 0.4, and 0.545 respectively.

Tissue TNF-α estimation

TNF-α was determined after tissue homogenization by ELISA. In order to avoid errors in the interpretation of results, a specific rat antibody was used (antirat, DIACLONE Research) instead of human antibody against TNF-α.

Statistical analysis

Data were presented as mean±SD. Statistical comparisons between groups were made by one-way ANOVA followed by Dunnett's (two-sided) test. A difference between treated (1-3 groups) and untreated (group 4) animals was considered statistically significant at the level of $P<0.05$. Computations were done using the statistical package SPSS (version 11.0).

RESULTS

Histology

Table 1 shows the percentage of bowel area with the presence of active ulcers and erosions and reparative lesions observed in the treated and untreated groups of animals. Significant differences concerning the presence of reparable lesions between all groups of animals treated with infliximab compared to the untreated ones were found. Though differences were obvious between groups 1 and 2, they did not reach statistical significance (Table 1).

Table 2 shows the extent of mucosa without active inflammation in all groups of animals expressed as a percentage (mean value). Significant differences between the three groups of treated animals compared to the untreated ones were observed.

TNF-α tissue levels (pg/mL) (mean value)

The levels of tissue TNF-α in all groups are shown in Table 3. A significant reduction of the tissue levels of TNF-α was found in all groups of treated animals compared to the untreated ones.

Tissue malondialdehyde levels (μM)

The levels of tissue MDA in the treated and untreated animals are shown in Table 4. A significant reduction was noticed in group 1 compared to group 4, as well as between groups 2 and 4. No significant differences between groups 3 and 4 were noticed.

DISCUSSION

The findings of this experimental study in rats suggested that subcutaneous administration of infliximab was biologically effective; infliximab at doses of 5, 10, and 15 mg/kg BW could reduce the histological changes as observed in this particular experimental model; infliximab could significantly reduce tissue levels of TNF-α and MDA; suggesting that this molecule has probably antioxidant properties though the latter could be the consequence of its anti-inflammatory action.

In more details, subcutaneous administration of infliximab resulted in a significant amelioration of inflammatory histological lesions, a finding which was more prominent in the group of animals receiving 5 mg/kg per d. Administration of the drug resulted in a statistically significantly smaller area of large bowel with reparable lesions compared to the untreated group of animals, although the percentage of bowel area with active ulcers and erosions did not differ significantly between treated and untreated animals. It was also shown that the percentage of bowel area with normal mucosa was

significantly larger only in the group treated with 5 mg/kg BW of infliximab as compared to untreated animals. The percentage of bowel area with normal mucosa did not differ significantly between groups receiving 10 and 15 mg/kg BW and the untreated group of animals. Wooddruff *et al*.[17] also showed that a single IV dose of infliximab before the induction of experimental colitis results in a significant reduction of the severity of the lesions.

In our study, all doses of infliximab significantly reduced the tissue levels of TNF-α, suggesting that TNF-α plays a significant pathogenetic role in this model of colitis as well. The IV dose of 5 mg/kg BW is the currently recommended one for the treatment of patients with active Crohn's disease. The beneficial effect of infliximab observed in this experimental model is in accordance with clinical observations showing beneficial clinical effects on some patients with severe ulcerative colitis[7-9]. TNF-α is a 17-ku proinflammatory cytokine produced by monocytes, macrophages, and T cells. The biological actions of this cytokine include induction of acute-phase response, cachexia, and potentially lethal shock[18]. Furthermore, TNF-α stimulates secretion of IL-1 and IL-6, expression of adhesive molecules and fibroblast proliferation. Release of TNF-α is mediated by a specific metalloproteinase (TNF-α convertase). After secretion, TNF-α binds as a soluble ligand to two cell-bound transmembrane TNF receptors, namely TNFR1 and TNFR2[19]. Chronic inflammation in Crohn's disease can be attributed mainly to the production of proinflammatory cytokines, especially TNF-α. This cytokine is considerably increased in the histologically normal as well as inflamed large bowel mucosa of patients with Crohn's disease. It has been described that thalidomide, a drug with well-known anti-TNF-α action, significantly reduces colonic inflammation induced by iodoacetamide, probably via the inhibition of TNF-α[20]. This experiment is another paradigm of amelioration of colitis by a drug with inhibitory influence of TNF-α.

An important finding of this study is the increased tissue levels of tissue MDA in the untreated rats and the reduced tissue levels of MDA in the groups treated with 5 and 10 mg/kg BW. However, the animals treated with 15 mg/kg BW did not show any statistically significant difference from the untreated ones. There is no obvious explanation for that, though it seems that the reduction of MDA levels could not be a phenomenon related to quantity of the reactive elements. We must emphasize that the results of the 5 and 10 mg/kg BW administration of infliximab on MDA levels were quite similar with the results concerning the corresponding histological lesions. We suppose that the reduction in lipid peroxidation and cellular damage originating from oxidative stress following the administration of infliximab is an important factor contributing to amelioration of experimental colitis. A growing number of data suggests that in experimentally-induced colitis, the colon may be subjected to considerable oxidative stress[21]. Oxidative stress leads to the extension and propagation of crypt abscesses either through direct membrane disruption by lipid peroxidation or through generation of secondary toxic oxidants such as chloramines. Subsequently, chemotactic products of lipid peroxidation provide positive feedback to accelerate the inflammatory/oxidative process[22]. Colonic mucosa may be overwhelmed during active inflammation resulting in intestinal inflammation due to the inability of the mucosa to ameliorate the generating stress because of the small amount of antioxidant enzymes contained in it. It could be possible that colonic injury and dysfunction observed in inflammatory bowel disease are due to the elaboration of these reactive species. Infliximab may have antioxidant properties as well, as it can be suggested by the significant reduction of MDA levels observed in all treated groups of animals though this could simply be the consequence of its anti-inflammatory action.

Another point of interest of this study is the fact that subcutaneous administration of the drug resulted in the reduction of inflammation and tissue damage. The recommended route of administration of infliximab is the IV route. The beneficial effect observed in this model suggests that the other routes of administration of the drug could be effective in human beings as well.

In conclusion, the results of the present study suggest that subcutaneous administration of infliximab reduces the inflammatory activity, as well as tissue TNF-α and MDA levels in chemical colitis in rats. Moreover, infliximab at a dose of 5 mg/kg BW achieves better histological results and produces higher reduction of the levels of TNF-α than at a dose 10 mg/kg BW. Finally, infliximab at a dose of 5 mg/kg BW produces higher reduction of tissue MDA levels than at a dose of 15 mg/kg BW. The administration of infliximab in rats with chemical colitis supports the clinical observations that the dose of 5mg/kg BW produces better results than the dose of 10 or 15 mg/kg BW. The possible antioxidant properties of infliximab must be further investigated both from clinical and experimental points of view.

Abstract

AIM: To determine the predictive factors for hepatocellular carcinoma (HCC) development in patients after spontaneous or therapeutic HBeAg seroconversion.

METHODS: In 48 patients who seroconverted to anti-HBe positive during follow-up, the background factors for HCC development were analyzed.

RESULTS: HCC was developed in six patients during follow-up (average follow-up after HBeAg seroconversion: 10.9±5.4 years). The incidence of HCC evaluated by Kaplan–Meier analysis was significantly higher in patients with abnormal aspartate aminotransferase (AST> 40 IU/L) level, lower platelet counts (PLT<10×10^4/μL), lower albumin level (Alb<30 g/L), positive HBV-DNA or older age at seroconversion (>40 years). However, lower platelet count was the only predictive factor for HCC development shown by multivariate proportional-hazard analysis.

CONCLUSION: Active hepatitis or advanced hepatitis at HBeAg seroconversion or progressive hepatitis even after HBeAg seroconversion would be the risk factors for HCC development. These predictive factors should be taken into account in determining the frequency of biochemical study or imaging studies for HCC surveillance.

Key words: HBeAg seroconversion; Hepatocellular carcinoma; Predictive factors

INTRODUCTION

Hepatitis B virus

Hepatitis B virus (HBV) in Japan, where genotype C is dominant, is generally infected during delivery or early childhood with immature immune systems, and those children become HBV carriers before HBV vaccine was introduced. In adolescents, hepatitis e antigen (HBeAg) seroconversion to its antibody (anti-HBe) often occurs after multiple exacerbations, which coincide with subsidence of hepatic inflammatory activities[1,2]. The failure of seroconversion usually results in chronic progressive liver diseases and hepatocellular carcinoma (HCC). The calculated annual incidence of acute exacerbation was two times higher in patients with positive HBeAg or HBV-DNA than those without these markers[3]. The patients who have recurrent episodes of acute exacerbations with bridging hepatic necrosis are more likely to develop cirrhosis[4]. These observations suggest that HBeAg seroconversion to anti-HBe confers favorable long-term outcomes. On the other hand, most HCC occurred in HBeAg-negative patients with undetectable HBV-DNA[5,6], suggesting that all HBV patients should be carefully followed-up for HCC even after HBeAg seroconversion. However, there seems to be some predictive factors for HCC in our clinical experiences. Previous reports demonstrated the natural history of anti-HBe positive patients. However, they included patients with spontaneous reactivation, which may be the major cause of progressive hepatic damage[7,8]. To our knowledge, there are no reports about incidences of HCC that selected only patients who seroconverted to anti-HBe during follow-up. Therefore, we focused on anti-HBe-positive patients without any reactivation of HBeAg and tried to determine the risk factors for HCC development to select high risk group for HCC.

MATERIALS AND METHODS

Three hundred and thirty-one HBsAg-positive patients were followed-up in our hospital between 1990 and 2004. Inclusion criteria in this study were: (1) follow-up until death or October 2004; (2) sufficient data to evaluate; and (3) careful follow-up for HCC with evaluation of both tumor markers (alpha-fetoprotein or des-gamma-carboxyprothrombin) and image studies (USG or CT) every 3-6 mo. HBeAg serocoversion was determined if anti-HBe completely became positive and HBeAg was never recovered retrospectively. We excluded the cases that showed fluctuation of HBeAg or anti-HBe levels.

None of the patients had any other viral infections, such as hepatitis C virus (HCV) or human immunodeficiency virus (HIV). Patients were followed-up by biochemical studies and image studies for at least 3-6 mo intervals. The biochemical tests were measured using routine automated techniques. HBsAg, HBeAg, and anti-HBe were assayed using commercial enzyme immunoassay kits (Abbott Japan, Tokyo). HBV-DNA was determined by a transcription-mediated amplification (TMA) method. The detection sensitivity of this assay is 3.7 LGE/mL. All HCC were initially found by USG or CT and confirmed by CT during abdominal angiography.

Statistical analysis

Fisher's exact test or the χ^2 test was used to compare patients' backgrounds. Kaplan–Meier analysis and log-rank test were performed to test a cumulative incidence of HCC in each group. Multivariate proportional-hazards survival analysis was used to determine the important risk factors for HCC. $P<0.05$ was considered statistically significant.

RESULTS

One hundred and thirty-four out of the 331 HBV patients were enrolled in this study. Forty six patients (M:F = 34:12) were HBeAg-positive and 88 (M:F = 64:24) patients were anti-HBe-positive. There were no patients who had positive tests for both HBeAg and anti-HBe. Regarding the patients' backgrounds, age, sex, platelet counts, albumin level and AST level were similar in both HBeAg-positive and anti-HBe-positive patients. However, ALT level was significantly higher in HBeAg-positive patients as compared with anti-HBe-positive patients (P = 0.001, Table 1). HCC developed in 15 HBeAg-positive patients and in 11 anti-HBe-positive patients during follow-up. The average age for the appearance of HCC was similar in both groups (55±8 years in HBeAg-positive and 53±12 years in anti-HBe-positive patients). The cumulative incidence of HCC was significantly higher in HBeAg-positive patients than in anti-HBe-positive patients as previously reported (P = 0.016, Figure 1). However, the incidence of HCC was found to be increased with age even in patients with anti-HBe, especially in those who were over 70 years. Out of 88 patients with anti-HBe, the time of HBeAg seroconversion was observed in 48 patients. Other 40 patients already showed anti-HBe positive when the patients first presented. The current study focused on these 48 patients. The average age of 48 patients was 50

Table 1 Patients' characteristics

Feature	HBeAg	Anti-HBe	*P*
n	46	88	NS
Age	53±12	54±14	NS
Male sex	34 (74%)	64 (73%)	NS
Platelet ($\times10^4/\mu L$)	14.3±6.6	18.7±6.4	NS
Alb (g/dL)	4.0±0.5	4.1±0.5	*NS*
AST (IU/L)	56±33	41±36	NS
ALT (IU/L)	62±57	36±27	0.001

NS: not significant.

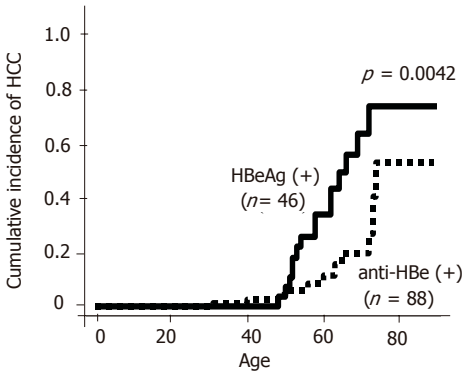

Figure 1 Cumulative incidence of HCC in patients with HBeAg or anti-HBe (Kaplan –Meier analysis and log-rank test). The incidence of HCC in both groups was increasing after the age of 50. The incidence of HCC was significantly higher in the patients with HBeAg positive (solid line) than those with anti-HBe positive (dot line) (P=0.0042).

±14 years (M:F = 34:14). The average age at HBeAg seroconversion was 40±12 years (range, 16-67 years). HBeAg seroconversion occurred spontaneously in 75% (36/48), by IFN in 18.8% (9/48) and by propagermanium in 6.2% (3/48) cases. HBV-DNA was detectable by TMA methods in 27.1% (13/48) patients. The average follow-up periods after HBeAg seroconversion were 10.9±5.4 years (range, 1-25 years). Six patients developed HCC during follow-up. All six patients were male and the average age of HCC development was 57±13 years (14.0±5.1 years after HBeAg seroconversion). The incidence of HCC evaluated by Kaplan–Meier analysis was significantly higher in patients with abnormal AST (>40 IU/L) level (P = 0.007, Figure 2A), suggesting that active hepatitis even after seroconversion may be one of the risk factors for HCC. However, there were no differences in ALT levels (Figure 2B). Low platelet count ($<10\times10^4/\mu L$) ($P<0.0001$) or low albumin level (Alb<30 g/L) (P = 0.009) was another risk factor for HCC, suggesting that HCC may develop in patients with advanced liver diseases at HBeAg seroconversion or with progressive liver diseases even after seroconversion (Figures 2C and D). Positive HBV-DNA (P = 0.014) increased the incidence of HCC as well (Figure 2E). The incidence of HCC tended to be non-significantly higher in the patients with HBeAg seroconversion by therapy as compared with the spontaneous seroconversion (Figure 3A). The cumulative incidence of HCC was significantly higher in the patients with HBeAg seroconversion after 40 years of age (Figure 3B). Multivariate proportional-hazards analysis demonstrated that low platelet counts ($<10\times10^4/\mu L$) was the only predictive factor for HCC (P = 0.032, hazard ratio = 21.6), whereas serum albumin and AST levels and HBV-DNA positivity could not be determined as predictive factors for HCC (Table 2). Furthermore, the incidence of HCC was not observed in the patients with both normal platelet counts ($>10\times10^4/\mu L$) and normal AST level (<40 IU/L) during follow-up in our study. In contrast, the incidence of HCC was annually increasing after HBeAg seroconversion in patients with either lower platelet counts ($<10\times10^4/\mu L$) or abnormal AST level (>40 IU/L) (Figure 4).

DISCUSSION

The present study demonstrated that low platelet counts ($<10\times10^4/\mu L$), low albumin level (<30 g/L), abnormal AST level (>40 IU/L), older age at HBeAg seroconversion (>40 years) and positive HBV-DNA were the predictive factors for HCC after HBeAg seroconversion. Multivariate proportional-hazard analysis demonstrated that platelet count was the only significant risk factor. These observations suggested that active hepatitis or progression of liver disease even after HBeAg seroconversion or advanced hepatitis at HBeAg seroconversion would be the predictive factors for HCC. In other words, patients without any of these factors after HBeAg seroconversion would be at low risk for HCC development.

In patients with chronic hepatitis C virus (HCV) infection, we should focus on patients with advanced

Table 2 Predictve Features of HCC

Variable	Hazard ratio	95%CI	*P*
Platelet counts ($<10^5$ *vs* $\geq10^5$/mL)	21.6	1.3 – 354.8	0.032

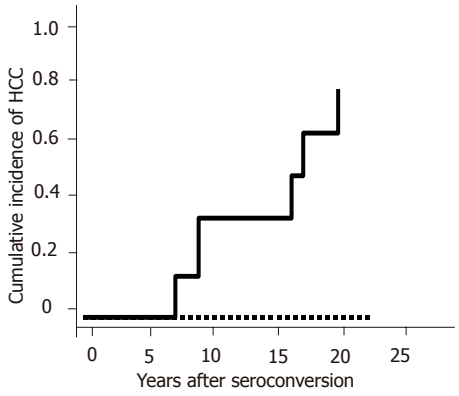

Figure 4 Cumulative incidence of HCC in patients with or without risk factors (Kaplan–Meier analysis and log-rank test). Solid line: either platelet counts<10×10^4/μL or AST>40 IU/L; dot line: both platelet counts≥10×10^4/μL, and AST<40 IU/L.

chronic hepatitis or cirrhosis as high risk group for HCC development and follow-up with tight observation for biochemical studies, tumor markers and image studies since HCC is usually accompanied with the progression of liver diseases. In patients with chronic HBV infection, however, HCC sometimes develops not only in liver cirrhosis, but even in mild hepatitis[9,10]. So, it is more difficult to select high risk patients for HCC in chronic HBV infection than that in HCV infection. Of course, positive HBeAg or reactivation after HBeAg seroconversion with active hepatitis is one of the risk factors for cirrhosis[7,8], HCC[3,11] or survival[12]. However, the cumulative incidence of HCC in our study was high even in anti-HBe-positive patients, especially in older patients (Figure 1). Therefore, we conducted this study to determine the predictive factors for HCC in patients with anti-HBe.

We found that the cumulative incidence of HCC was significantly higher in patients with abnormal AST (Figure 2A), suggesting that active hepatitis even after HBeAg seroconversion was one of the risk factors. This result was consistent with previous reports that progression to cirrhosis or HCC occurred in patients with HBeAg negative hepatitis without reversion to HBeAg[11,13]. Furthermore, the incidence of HCC was significantly reduced in HBeAg-negative chronic hepatitis or cirrhotic patients who maintained virological response by lamivudine[14] or interferon (IFN)[15,16]. These previous reports support our observation that therapy for transaminase control may reduce the risk of HCC development in our patients with abnormal AST level. On the other hand, the cumulative incidence of HCC was not statistically different in ALT levels. We, therefore, hypothesized that ALT elevation might be observed in patients with fatty liver as well as necroinflammatory liver disease.

Other risk factors for HCC development in anti-HBe-positive patients were lower platelet counts and low albumin level. Interestingly, multivariate proportional-hazards analysis showed that low platelet counts (<10×10^4/μL) was the only risk factor for HCC development, suggesting that HCC may develop in patients with progressive liver disease even after HBeAg seroconversion or advanced liver diseases before HBeAg seroconversion. Since multiple exacerbations usually occurred before HBeAg seroconversion, necroinflammation occurs more frequently in patients with delayed HBeAg seroconversion, which results in progression to liver cirrhosis or HCC[13]. Our results show that the cumulative incidence of HCC was significantly higher in patients with delayed HBeAg seroconversion (older than 40 years) are consistent with the previous reports. Furthermore, the cumulative incidence of HCC in our study was annually increasing in the patients with either low platelet counts (<10×10^4/μL) or abnormal AST (>40 IU/L) after HBeAg seroconversion, whereas no HCC was observed in patients with both normal platelet counts (≥10×10^4/μL) and normal AST (<40 IU/L) during follow-up (median follow-up period: 11±5 years).

In this study, we observed a relatively higher incidence of HCC in patients with anti-HBe as compared with the previous reports. This might be because our study was not a prospective study and we might have lost the patients with relative low risk of active hepatitis or fibrosis during follow-up. It is possible that there might be a bias, in which the patients with relative high risk (high AST or ALT) were accumulated in our study. Prospective and large-scale studies need to determine the predictive factors for HCC in patients with anti-HBe.

In conclusion, in anti-HBe-positive patients, lower platelet counts, lower albumin, abnormal AST and positive HBV-DNA are the predictive factors for HCC. In other words, anti-HBe-positive patients without any of these factors are at low risk for HCC. In the follow-up of anti-HBe-positive patients, those predictive factors, especially platelet counts, should be taken into account for determining the frequency of biochemical study or imaging studies. Moreover, to reduce the risk for HCC development, we should induce HBeAg seroconversion before progression to advanced liver diseases and control AST level within the normal range using lamivudine or IFN. These results may be supported by our clinical experiences. However, to our knowledge, there are no reports to clarify the high risk group in anti-HBe positive patients with known time of HBeAg seroconversion.

Abstract

AIM: To assess the clinical significance of Hepatitis B virus (HBV) DNA localization in the liver tissue of patients with positive HBsAg and negative viremia.

METHODS: HBV virological parameters of 33 HBsAg positive chronic hepatitis patients, including seromarkers and HBV DNA amplification in both sera and liver biopsies, were evaluated.

RESULTS: Ten patients had negative viremia and positive HBV DNA in their liver biopsies. Most of them had HBeAg-negative/HBeAb-positive chronic hepatitis. Their liver biochemical and histopathological profiles were different from the viremic patients. Their disease pattern was designated as "hepatitis B *in situ*".

CONCLUSION: Hepatitis B *in situ* is a consequential entity which can be missed in clinical practice. It is a new clinical pattern of chronic HBV infection that considers HBV in liver biopsy and adds a new indication for antiviral therapy.

Key words: Hepatitis B *in situ*; Antiviral therapy; HBV DNA; Chronic hepatitis

INTRODUCTION

Hepatitis B virus is a virus that infects 350 million people worldwide with a clinical spectrum of acute hepatitis, the healthy carrier state, cirrhosis, and hepatocellular carcinoma. The outcome of infection is the result of complicated viral-host interactions. As in other infections with non-cytopathic viruses, the immune response is thought to play a crucial role in disease pathogenesis. However, there are increasing evidences that varieties of viral mechanisms, some depending on the function of virally encoded proteins, have a profound impact on the infected hepatocytes, the liver microenvironment and host antiviral responses[1].

Occult HBV infection is characterized by undetectable HBsAg. Serum HBV DNA level is usually less than 10^4 copies/mL in these patients. Diagnosis requires a sensitive HBV-DNA assay[2]. To our knowledge, no data are available about the amount of HBV genomes in the liver of patients with chronic HBV infection. However, it has been reported that cases with suppressed HBV activity, despite the very low level of viremia, maintain a relatively high amount of intrahepatic viral genomes. This virus reservoir is likely involved in HBV reactivation, which is usually observed after stopping lamivudine treatment[3].

The detection of HBV genomes in nested PCR-based assays appears to be the most reliable methods for monitoring infection and assessing response to antiviral treatment[4]. The majority of patients with HBsAg in serum have HBV DNA present in serum as well. Some patients have HBsAg but no HBV DNA in serum. These are chronic carriers with normal transaminases[5]. On the other hand, HBV DNA can be detected in serum and liver by PCR in patients who have lost their HBsAg. In addition, hepatic HBV DNA can be detected in cirrhotic liver in the absence of serum HBV DNA[5,6]. HBV DNA can be treated as a sign of HBV activity[7], without ignoring the facts that HBV DNA levels fluctuate in patients with chronic HBV infection and that the correlation between serum HBV DNA levels and histologic activity is poor[8].

In this study, we evaluated the clinical significance of the localization of HBV in liver tissue of chronic HBV patients with negative viremia and elevated ALT.

PATIENTS AND METHODS

This prospective study included chronic liver disease patients who attended the out-patient clinic of the

Endemic Medicine Department, Cairo University during the period between September 2002 and July 2003. All patients with data suggestive of liver affection were evaluated, and those with positive HBsAg and elevated ALT were selected as the candidates for this study.

Exclusion criteria were HCV infection, advanced liver disease, alcohol consumption, autoimmune hepatitis, drug-induced hepatitis, hepatic schistosomiasis, evidence of acute hepatitis in the last 6 mo, presence of HDVAb, hepatocellular carcinoma, and advanced co-morbid conditions such as cardiac or renal disease.

Selected patients were subjected to clinical evaluation and laboratory investigations including viral serologic tests using enzyme immunoassay technique applying the Abbott System®. These assays included the detection of HBsAg, HBsAb, HBcAb (total), HBeAg, HBeAb, and HCVAb (total) by 3rd generation ELISA assay (Sorin®, Italy). Abdominal ultrasonography and liver biopsy were performed. The modified HAI score was used to stage and grade liver disease[9]. For the detection of hepatic total HBV DNA (integration plus CCC form), part of the liver sample was incubated at 56 °C for 3 h with 270 μL of phosphate buffer saline containing 160 μg of proteinase K (Promega, Madison, WI, USA) and 30 μL of 10 buffer. Serum HBV DNA was extracted by incubation at 56 °C for 3 h with 270 μL of serum plus 30 μL of 10×buffer containing 160 μg proteinase K. DNA extraction was purified by phenol: chloroform (300 μL, 1:1 V/V) extraction, ethanol/0.2 mol/L sodium acetate precipitation. Qualitative PCR testing for HBV in serum and liver tissue was carried out using nested PCR technique[10]. Total genomic DNA was extracted from serum or liver tissue using phenol/chloroform extraction after proteinase K digestion. Purified DNA (1–2 μg) was utilized as a template in the polymerase chain reaction using two rounds of amplification with nested primers as follows:
Outer primers: B1 5' AAGGTCTTACATAAGAGGAC 3' (nt 1 644–1 663), B2 5' CTAACATTGAGATTCCCGAG ATTGAGA 3' (nt 2 458–2 432);
Inner primers: B3 5' GGCTGTAGGCATAAATTGGTC-TG 3' (nt 1 781–1 803), B4 5' TTGCCTGAGTGCAGTA-TGGT 3' (nt 2 075–2 056).

The PCR reactions were performed in 50 μL reaction volume containing 10 μmol/L dNTPs, 50 pmol from each primer, and 2 U of Taq. The amplification protocol for the two nested rounds consisted of 35 cycles, each cycle contained a denaturation at 94 °C for 30 s, annealing at 52 °C for 1 min, and extension at 72 °C for 2 min, followed by a single cycle with final extension at 72 °C for 7 min. Positive samples infected with HBV DNA produced a amplified product of 295 bp in length.

Statistical analysis

Patients' data were tabulated, and then processed using the software SPSS for Windows 9 version 10.0®. Quantitative variables were expressed as mean±SD and compared using Student's *t* test. Qualitative variables were compared using Fisher's exact test. A $P<0.05$ was considered statistically significant.

RESULTS

Out of the 670 patients with chronic liver disease, 44 were seropositive for HBsAg. Eleven of the forty-four HBsAg seropositive patients were excluded because of normal liver enzymes. The study was then conducted on the remaining 33 patients (26 males and 7 females; mean age 32.8±12.0 years, range 18–60 years). Fifteen patients were originally from urban areas and 18 from rural areas (10 from Nile Delta, and 8 from Upper Egypt).

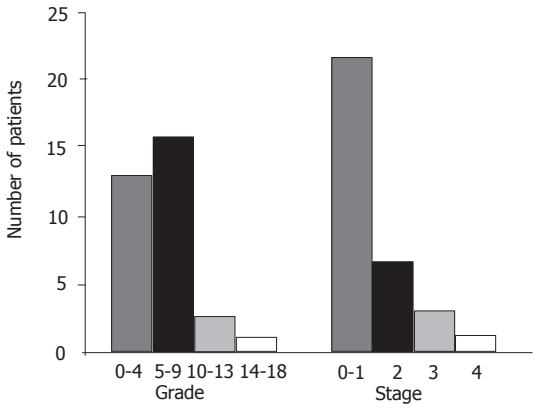

Figure 1 Histopathological grading and staging

According to the modified HAI grading and staging, histopathological findings are shown in Figure 1. Ground glass pattern of the hepatocytes was detected in 21 patients, steatosis was found in 14 patients, while cholestasis was detected in two cases.

HBV markers were spread into Poynard's table of classification of HBV infected patients[10]. Seventeen patients were fit with the "chronic carrier, pre-core mutant type", and six with the "chronic carrier, wild type" definitions. Ten patients remained uncategorized, showing a unique pattern (Table 1).

These 10 patients (group 1) were compared to the remaining 23 chronic hepatitis B patients (group 2) as shown in Tables 2 and 3. No statistically significant differences were observed regarding the liver biochemical or histological parameters. In this study, we found five possible permutations of the HBV seromarkers, which were grouped according to the HBV DNA results (Table 4). Among the HBcAb-negative patients, three patients were also negative for HBeAg and HBeAb. HBV DNA was detectable in

Table 1 Characteristics of patients uncategorized in Poynard (2000) classification

cAb: hepatitis B core antibody; eAg: hepatitis B envelope (e) antigen; eAb: hepatitis B antibody against envelope (e) antigen.

six patients with positive HBsAb (four with detectable viral DNA in both serum and liver tissue, while two with detectable viral DNA only in liver tissue). Although four of the HBeAg-negative cases had higher HAI score (10–18) compared to none of the HBeAg-positive chronic hepatitis cases, the two groups showed no significant difference in either biochemical or histological parameters.

DISCUSSION

HBV infection varies widely from high (>8%, e.g., Africa, Asia, and the Western Pacific) to intermediate (2–7%, e.g., Southern and Eastern Europe) to low (<2%, e.g., Western Europe, North America, and Australia) prevalence areas. Egypt lies in the intermediate prevalence region[10]. HBV DNA is a good marker of the level of viremia and can be correlated with serum transaminase levels. The majority of patients with HBsAg in serum have HBV DNA. However, some patients are positive for HBV DNA in serum even in the absence of HBsAg, while some others have HBsAg but not HBV DNA in serum[5]. The presence of HBV genome is associated with ongoing necroinflammation[8]. In the presence of HBeAg, the diagnosis of replicating chronic HBV can be made whatever the viral load is. In contrast, the interpretation of HBV DNA quantification is difficult in HBeAg-negative/HBeAb-positive patients (pre-core mutant HBV) who generally have lower replication levels than HBeAg-positive patients. Active HBV replication is associated with a significant risk of progression to chronic hepatitis B complications[11]. The presence of HBV DNA is the single most important indication to start antiviral therapy[12]. This work aimed at evaluating the clinical significance of localizing HBV DNA in the liver in case of negative viremia. Patients with HBsAg and elevated ALT were selected among patients who presented at the outpatient clinic of the Tropical Medicine Department, suffering from a variety of chronic liver diseases.

Of 670 patients, the prevalence of HBsAg-positive patients among those with chronic liver disease was 6.6% (44/670). This figure represented both the carriage rate and the infection rate among chronic liver disease patients, whatever the causes were. The prevalence of HBV chronic hepatitis among chronic liver disease patients was 4.9% (33/670). The prevalences of HBV infection in Egypt have been found to be variable among different studies, ranging from 3.2% to 21%[13–19], depending on the number of patients. The higher figures studied the prevalence among cirrhotic patients, the lowest figures were found among school children in certain villages. Thirty-three patients eligible for the present study were considered to have chronic hepatitis B. NASH was not totally excluded. Fourteen liver biopsies showed prominent steatosis. The prevalence of steatosis in Egypt is expected to be quite high. It is known that 35% of the Egyptians are considered obese[20]. Moreover, high comorbid factors are recorded among Egyptians, such as diabetes, pollution, etc. It is worth mentioning that none of our 33 patients had a BMI >29 kg/m^2, and we had two diabetic patients.

In this study, the histopathological results showed that most of our patients had relatively mild disease, with an HAI score between 0 and 9, and a fibrosis score between 0 and 2. Conversely, the HBsAb-positive patients had a higher HAI score as compared with the HBsAb-negative patients. This might be explained by a stronger reaction to HBV infection in the former subgroup. The co-existence of both HBsAg and HBsAb has been previously described, and it is thought that HBsAb in such a situation is unable to neutralize the virus[21]. It has also been postulated that infection with multiple types of HBV is another explanation for this finding[22]. Most of our patients (78.8%) were HBeAg-negative chronic hepatitis B. It is known that the core promoter mutants are predominant in Egypt[23]. Compared to the HBeAg-negative chronic hepatitis B, the HBeAg-positive patients had a milder disease histopathologically, which was in agreement with previous reports[23–25]. We observed that the detection of HBV viremia was more in HBeAg-positive patients, which is expected, because of the formerly documented strong correlation between HBV DNA and HBeAg[26]. Characteristically, five patients (15.2%) were negative for both HBeAg and HBeAb, and five patients were negative for HBcAb. Three patients were negative for all seromarkers except HBsAg. These unusual patterns of serological profile can be explained either by mutations or viral DNA integration. Absence of cytotoxic T-lymphocyte (CTL) recognition of epitopes in HBeAg, HBsAg, and other viral proteins contributes to viral persistence. Failure of antigen presentation to CD4 helper T cells, failure of CD4

proliferating responses, immune modulation by secreted proteins, viral mutation, and integration of viral DNA into the cellular genome are all mechanisms involved in viral persistence[27]. Three patients had undetectable HBV DNA in either serum or liver tissue. This might be explained by an enhanced immunological response to HBV DNA, and extraordinarily low viral DNA copy number[28], or by the integration phenomenon affecting the primer orientation used in PCR technique[29]. Another explanation stands on HBV infection being a dynamic process, so that some of these patients might have been in the immune clearance phase[23]. Five patients had negative HBV DNA in the liver tissue, but positive in serum. This can be explained by the liver being a vast size organ, and hence, substantial viremia can result even if each cell produces only a few numbers of virions per day. This hypothesis has been proposed by Branch *et al*.[31] on HCV infection. In our opinion, it can also be applied on HBV infection if the viral genome is present in a very low level to be detected by biopsy. Ten patients (30.3%) did not fulfill any of the clinical criteria identified in literature. They could not classically fit in the Poynard's 2002 classification. They had one common serological profile, which is, detection of HBV DNA in the liver tissues but not in the sera (negative viremia). The disease burden as evidenced by hepatic biochemical profile and the spectrum of HAI and fibrosis was not different in this group of patients from those with the classic chronic HBV infection. This group has been named in this study as "hepatitis B *in situ*". Seven out of the eighteen patients, showing a classic unequivocal pattern of HBeAg-negative chronic hepatitis, had hepatitis B *in situ*. This implies that the reliance on mere testing of serum HBV DNA would have missed viral replication in such condition. On the other hand, HBeAg-positive hepatitis showed viremia in most cases.

In conclusion, a significant number of patients with chronic hepatitis B fail to show viremia, yet HBV DNA can be detected in their liver tissues. Hepatitis B *in situ* is a term used to describe the detection of total HBV DNA (Integrated plus CCC form) in liver tissue of patients with positive HBsAg and negative viremia. It is particularly frequent in the HBeAg-negative variety of chronic hepatitis B. The bearing of "hepatitis B *in situ*" on the liver is no less than the viremic form; serious sequelae are thus liable to take place. The recognition of this form of the disease may have its impact on the choice of therapy, since such patients should not be denied the chance to receive antiviral treatment.

Abstract

AIM: To assess the impact of transjugular intrahepatic portosystemic shunt (TIPS) on pulmonary gas exchange and to evaluate the use of TIPS for the treatment of hepatopulmonary syndrome (HPS).

METHODS: Seven patients, three of them with advanced HPS, in whom detailed pulmonary function tests were performed before and after TIPS placement at the University of Alabama Hospital and at the Hospital Clinic, Barcelona, were considered.

RESULTS: TIPS patency was confirmed by hemodynamic evaluation. No changes in arterial blood gases were observed in the overall subset of patients. Transient arterial oxygenation improvement was observed in only one HPS patient, early after TIPS, but this was not sustained 4 mo later.

CONCLUSION: TIPS neither improved nor worsened pulmonary gas exchange in patients with portal hypertension. This data does not support the use of TIPS as a specific treatment for HPS. However, it does reinforce the view that TIPS can be safely performed for the treatment of other complications of portal hypertension in patients with HPS.

Key words: Portal hypertension; Transjugular intrahepatic portosystemic shunt; Pulmonary gas exchange; Hepatopulmonary syndrome

INTRODUCTION

Transjugular intrahepatic portosystemic shunt (TIPS) has been used increasingly in patients with cirrhosis complicated by bleeding varices and refractory ascites[1]. Recently, TIPS has also been proposed as a potential treatment for pulmonary vasodilatation associated with cirrhosis, the so-called hepatopulmonary syndrome (HPS)[2-7]. However, both hemodynamic and metabolic effects of TIPS have been widely studied, little data exists on the effects of TIPS on pulmonary gas exchange in patients with portal hypertension.

HPS occurs when intrapulmonary vasodilatation causes abnormal pulmonary gas exchange in the setting of liver disease[8]. The abnormalities in pulmonary gas exchange result from microvascular dilatation and involve varying degrees of ventilation-perfusion imbalance, oxygen diffusion limitation (diffusion-perfusion defect), and increased intrapulmonary shunting[9]. Although the natural history of HPS is poorly understood, pulmonary gas exchange abnormalities are generally progressive, even in the setting of clinically stable hepatic dysfunction[10]. Currently, liver transplantation is the only therapeutic approach that can resolve HPS. However, perioperative mortality remains high (16-38% within 1 year) and appears to be greatest in those with more advanced HPS[11,12].

HPS has been described most commonly in patients

with cirrhosis of the liver, although it has also been reported in patients with severe acute hepatitis and in non-cirrhotic portal hypertension[13-15]. These findings suggest that portal hypertension plays an important role in the development of intrapulmonary vasodilatation and in the occurrence of HPS. TIPS, by correcting portal hypertension[1], could improve HPS. Indeed, TIPS may be an attractive alternative therapeutic option in selected patients with advanced HPS who are not transplant candidates or in whom liver function is well preserved, particularly if HPS is of sufficient severity to increase transplant mortality or if the waiting time for transplantation is expected to be prolonged. However, the small number of case reports published to date have had variable clinical features and results, and the majority TIPS placement was performed for an acute indication other than HPS[2–7]. Therefore, it is difficult to determine if TIPS specifically improves HPS. In addition, TIPS is known to further exacerbate the hyperdynamic circulation present in patients with cirrhosis and portal hypertension, a fact that might trigger or increase pulmonary vasodilatation and adversely effect pulmonary gas exchange[16-19].

Accordingly, in the present study, we aimed to assess the impact of TIPS on pulmonary gas exchange in patients with portal hypertension and to evaluate the use of TIPS for the treatment of HPS.

MATERIALS AND METHODS

Patients submitted to TIPS treatment at the University of Alabama Hospital and at the Hospital Clínic, Barcelona, were reviewed and the characteristics of patients in whom pulmonary function was evaluated in a period of less than 6 mo before TIPS placement and no more than 1 year after, were included. In three of these patients, TIPS was placed specifically for the treatment of HPS. The diagnosis of HPS was made on the basis of established criteria: the presence of an increase of alveolar-arterial oxygen difference ($AaPO_2$ >15 mmHg); with or without hypoxemia; and evidence of pulmonary vascular dilatation by means of contrast-enhanced echocardiography and/or nuclear isotope lung perfusion scanning, in the context of liver disease[8-10]. The presence of mild intrinsic cardiopulmonary disease was not considered as an exclusion criterion for the diagnosis of HPS[20,21].

Before TIPS placement, all patients underwent measurements of forced spirometry, plethysmography, and single-breath carbon monoxide diffusing capacity (DL_{CO}) after correcting appropriately for hemoglobin concentration. Arterial blood gases were collected while breathing room air in the upright position. The $AaPO_2$ was calculated according to the alveolar gas standard equation using 0.8 as the standard respiratory exchange ratio. Arterial blood gases were repeated after a 20-min period of 100% oxygen breathing in an upright position in patients with HPS.

The TIPS procedure was similar in both institutions and has been previously described[1]. After TIPS, patients underwent close follow-up with US-Doppler and hemodynamic evaluation of TIPS patency. Clinical and biochemical evolution, pulmonary gas exchange analysis, and systemic and pulmonary hemodynamics after TIPS placement were recorded for at least 1 mo following TIPS.

RESULTS

Pulmonary gas exchange was assessed before and after TIPS placement in seven patients. Three patients had HPS and the specific indication for TIPS in each of these patients was treatment of HPS. The remaining four patients had no HPS, but one of them had mild hypoxemia due to a moderate obstructive ventilatory pattern, and the indication for TIPS in these patients was variceal bleeding in three and refractory ascites in one. Demographic and clinical data are summarized in Table 1. TIPS substantially reduced the portal pressure gradient (PPG) (from 15±2 to 5±2 mmHg). In each case, the PPG immediately after TIPS was below 12 mmHg. In addition, during follow-up, TIPS patency, defined as a PPG <12 mmHg, was confirmed by hemodynamic evaluation. The clinical course of pulmonary function in patients without HPS was stable during all the study period. Pulmonary function tests and gas exchange data before and at least 3 mo after TIPS placement in patients with normal gas exchange prior to placement are shown in Table 2. As shown, TIPS neither influenced arterial blood gases nor pulmonary function tests in these patients.

Individual data of patients with HPS are shown in Table 3. All patients had advanced HPS as evidenced by PaO_2<60 mmHg with low $PaCO_2$ values; only Patient #2 responded favorably to 100% oxygen administration. Patients #1 and #2 had a mild restrictive ventilatory pattern possibly related to a coexistent diffuse interstitial

lung disease (Patient #1) and unilateral pleural fibrosis (Patient #2), respectively. Pulmonary angiography excluded the presence of arterio-venous communications. Ventilation-perfusion (V_A/Q) studies in these two patients, using the multiple inert gas elimination technique[22], was consistent with HPS, showing increased intrapulmonary shunt (43% and 11% of cardiac output) with a mild to moderate degree of V_A/Q mismatch, characterized by areas with low V_A/Q units (6.4% and 0.1% of cardiac output). All three patients exhibited a very severely reduced diffusing capacity (<25% predicted). Transient improvement in arterial oxygenation was observed in only one patient early after TIPS placement (Patient #1) but this was not maintained 4 mo later despite TIPS patency. In the other two patients, no improvement in gas exchange was observed early after TIPS and progressive deterioration in arterial oxygen saturation was evident at 4 mo in Patient #2 and at 4 wk in Patient #3 after TIPS. Patient #1 was excluded for liver transplantation because of the potential coexistence of diffuse interstitial pulmonary disease and severe hypoxemia with a poor response to 100% oxygen breathing. He died of progressive deterioration of pulmonary, hepatic, and renal function. Patient #2 was transplanted, 8 mo after TIPS placement. At the time of liver transplantation, he had persistent severe oxygenation abnormalities. Ten months after orthotopic liver transplant (OLT), pulmonary gas exchange was markedly improved with normal arterial oxygenation and contrast-enhanced echocardiography confirmed resolution of intrapulmonary vasodilatation. Patient #3 was excluded for liver transplantation due to severe hypoxemia. Subsequently, she developed progressive hypoxemia 4 wk after TIPS and died of multisystem organ failure one week later.

Table 2 Pulmonary gas exchange before and after TIPS placement in patients without HPS (mean±SD)

DISCUSSION

Portal hypertension is characteristically associated with a hyperkinetic circulation reflected by an increased cardiac output and splanchnic and peripheral vasodilatation[23]. A number of mechanisms contribute to these hemodynamic changes including increased bioavailability of vasodilators, such as nitric oxide[23]. HPS is most commonly observed in the setting of portal hypertension and likely appears to result from a disequilibrium between vasodilator and vasoconstrictor factors in the pulmonary microcirculation. Increased production of nitric oxide has also been proposed as one major determinant of pulmonary vascular dilatation in human HPS[24]. However, whether the same mechanisms that drive the splanchnic and peripheral vasodilatation are operative in the pulmonary microvasculature in HPS is still unknown.

Since HPS is associated with the presence of portal hypertension, portal pressure reduction through TIPS placement may be a useful therapeutic alternative. Till date, six case reports have evaluated the effects of TIPS on gas exchange in HPS[2–7]. Surprisingly, five demonstrated some

FEV_1: forced expiratory volume at 1 s; FVC: forced vital capacity; TLC: total lung capacity; DL_{CO}: single-breath carbon monoxide diffusing capacity; PaO_2: partial pressure of arterial oxygen; $PaCO_2$: partial pressure of arterial carbon dioxide; $AaPO_2$: alveolar to arterial oxygen partial pressure gradient; PAP: mean pulmonary artery pressure; PVR: pulmonary vascular resistance; SVR: systemic vascular resistance; Q_T: cardiac output; PP: portal pressure; IVCP: inferior vena cava pressure; PPG: portocaval pressure gradient.

degree of improvement in oxygenation. However, short-term (<1 mo) duration of follow-up in two patients[2,3] and the presence of coexistent hepatic hydrothorax in the third one[4] limit the evaluation of the utility of TIPS for hypoxemia in these cases. In two other reports[5,6], with a longer follow-up (>7 mo), arterial desaturation improved after TIPS and in one of these, a 11 year-old female with biliary atresia, gas exchange improvement was associated with a remarkable reduction in intrapulmonary shunt[6]. In the sixth report[7], TIPS failed to improve arterial hypoxemia in one patient. Altogether these reports suggest that portal pressure reduction *per se* does not consistently improve pulmonary gas exchange in HPS.

Portal pressure reduction after TIPS is also associated with an exacerbation of the hyperdynamic circulatory state, an effect that persists for at least 3 mo following TIPS placement[16-19]. During this time, pulmonary vascular resistance may also decline[17,18,25]. The mechanisms by which TIPS accentuate the hyperdynamic circulation are not well understood but may involve porto-systemic shunting of vasoactive substances through the TIPS which alter NO production[17,26-28]. The net result could enhance pulmonary vasodilation, thereby resulting in the development and/or worsening of HPS. In two of our patients with HPS who underwent TIPS, we confirmed obviously decreased systemic and pulmonary vascular resistance early after placement. Despite these hemodynamic changes, arterial oxygenation did not significantly deteriorate. In addition, in our four other patients without HPS who underwent successful TIPS, no changes in gas exchange were shown following TIPS placement. These findings complement and extend the findings of prior reports and support that the exacerbation of the hyperdynamic state following TIPS placement is not associated with arterial oxygenation worsening.

The portal pressure gradient (PPG) was reduced below 10 mmHg in each of our patients who underwent TIPS for HPS. Despite this, none of them had a sustained improvement in arterial blood gases. One patient did have a transient improvement in arterial oxygenation early after TIPS placement. Conceivably, one explanation for this improvement could be improved ventilation-perfusion matching induced by a rise in cardiac output resulting in increased blood flow, selective redistribution to the upper lobes of the lung, where vasodilatation is typically less severe in HPS. A similar mechanism may have been operative in the study by Selim *et al.*[4] where oxygenation improved after TIPS in association with a rise in cardiac output despite significant persistent intrapulmonary shunting. Alternatively, the increased cardiac output may improve PaO_2 through increased mixed venous PO_2, other things being equal. Our study and patients were different from prior case reports in that our group represented patients who specifically underwent TIPS for HPS. In four of the six prior reports, another acute indication for TIPS was present, including variceal bleeding and hepatic hydrothorax. The presence and resolution of other major complications of portal hypertension could have influenced favorably arterial blood gases in these cases. In addition, our patients had more severe gas exchange abnormalities than those in prior studies and it is unknown whether or not the severity of pulmonary vasodilatation may modulate the response to TIPS. Finally, our findings are clearly different from the report by Paramesh *et al.*[7], where TIPS placement resulted in a sustained and dramatic improvement in both pulmonary vasodilatation and arterial oxygenation. However, this case involved a child with biliary atresia and whether pathophysiologic mechanisms and responses to portal decompression in this setting are applicable to adults with other causes of liver disease is unknown[7].

In summary, our findings suggest that treatment with TIPS in patients with portal hypertension has no deleterious effects on pulmonary gas exchange, despite coexisting exacerbation of the hyperdynamic circulatory state. However, portal decompression with TIPS as a specific therapy for HPS is ineffective. This data supports the use of TIPS in patients with HPS for the treatment of other accepted indications for TIPS, but not as a specific therapy to improve arterial oxygenation defects in HPS.

Abstract

AIM: To investigate the incidence and localizations of lymphoid follicles (LFs) in early colorectal neoplasms in human beings.

METHODS: From July 1992 to September 1999, a total of 1 324 early colorectal neoplasms were removed endoscopically or surgically at our hospital; 1 031 (77.9%) were available for analysis in this study. Localization of LFs was defined histologically: as submucosal LFs, if located under the muscularis mucosa; and as intramucosal LFs, if located across or over the muscularis mucosa.

RESULTS: Histologically, the materials included 903 intramucosal neoplasms and 128 submucosal cancers. Overall incidence of LFs was 27.2% (280/1 031). The incidence of LFs was significantly higher in females (33.6% *vs* 24.9%, $P = 0.0064$), the right-sided colon (32.2% *vs* 25.6%, $P = 0.0403$) and in flat or depressed type lesions (34.6% *vs* 25.2%, $P<0.0001$) as compared to males, left-sided colon and protruding type lesions, respectively. The incidences of intramucosal neoplasms and submucosal cancers were 24.3% and 43.8%, respectively ($P<0.0001$). Localizations of LFs (intramucosal LF/submucosal LF) in depressed, flat, and protruding types were 1/24, 14/36, and 131/74, respectively.

CONCLUSION: The incidence of LFs in early human colorectal neoplasms significantly differs by gender, location, macroscopic type, and histology. Moreover, localization significantly differs by macroscopic type.

Key words: Lymphoid follicle; Early colorectal neoplasm; Carcinogenesis

INTRODUCTION

Several reports have investigated the association between lymphoid aggregates and colonic tumors in rodents[1-4]. The results indicate that colonic crypts overlying lymphoid follicles (LFs) show a significantly higher proliferative activity. These results also showed that the risk of carcinoma increased in the colonic mucosa on LFs compared to mucosa without LFs. Consequently, it was considered that factors from LFs promote carcinogenesis in the epithelium in rodents. Rubio *et al*.[5] also investigated the incidence of LFs in early stage adenomas and adenocarcinomas in Swedish and Japanese patients, showing that 38% of 174 consecutive non-polypoid adenomas and flat incipient adenocarcinomas had subjacent LFs. Moreover, they observed a higher incidence of LFs in non-polypoid neoplasms as compared to polypoid neoplasms in rats[6].

Recently, advances in endoscopic techniques and equipment have enabled much smaller flat and depressed colorectal neoplasms to be detected[7-11]. We have also microscopically encountered LFs and found that their incidence and localization tended to be different according to their macroscopic features in early colorectal neoplasms. In this study, we, therefore, aimed to investigate the incidence and localization of LFs revealed in early human colorectal neoplasms.

MATERIALS AND METHODS

Subjects

From July 1992 to September 1999, a total of 1 324 early colorectal neoplasms, including adenoma with high-grade

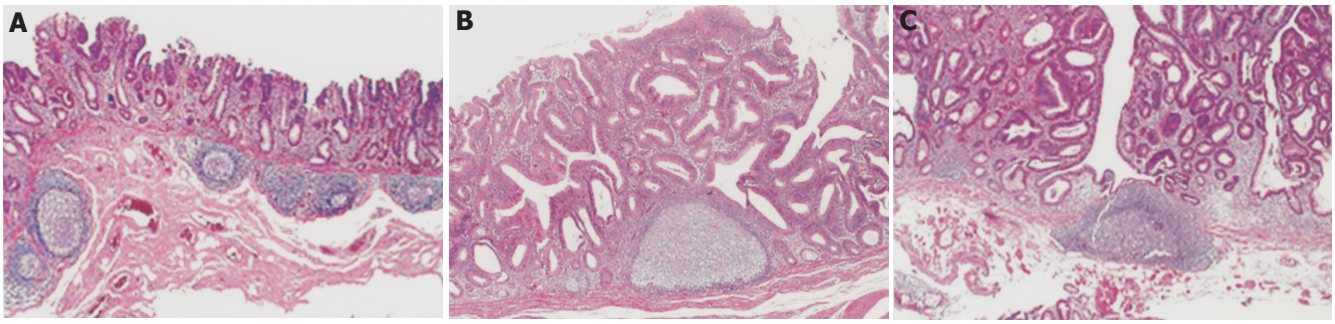

Figure 1 Localizations of LFs in early colorectal neoplasms. **A:** Submucosal LF in intramucosal carcinoma; **B:** intramucosal LFs in adenoma with moderate atypia; **C**: intermucosal LFs in adenoma with moderate atypia.

atypia, intramucosal cancer and submucosal invasive cancer, were removed endoscopically or surgically in our hospital. Of the 1 324 lesions, 293 (22.1%) were excluded from this study because the histology had been damaged by endoscopic procedures and they were judged inappropriate for analysis. The lesions of patients with familial polyposis, hereditary non-polyposis colorectal cancer, and inflammatory bowel disease were also excluded.

Location

The locations of the lesions were categorized into two groups at the splenic flexure: right-sided colon (including the cecum, ascending colon, and transverse colon); and left-sided colon (including descending colon, sigmoid colon, and rectum).

Macroscopic type

Macroscopically, colorectal lesions were classified into three groups according to the criteria of the Japanese Research Society for Cancer of the Colon and Rectum (JRSCCR): depressed (D) type; flat (F) type; and protruding (P) type.

Evaluation

Histological examinations of the available lesions were performed with hematoxylin-and-eosin (HE) staining. The pathological definitions of the lesions were as established by the JRSCCR. We defined a lymphoglandular complex with an enlarged germinal center as a LF. The localizations of LFs were classified into two groups: LFs located beyond the muscularis mucosa were defined as "submucosal LFs" (Figure 1A); and LFs located across or above the muscularis mucosa were defined as "intramucosal LFs" (Figures 1B and C). The presence and localization of LFs were investigated histologically.

Statistical analysis

Using χ^2 test and Fisher's exact probability test, we compared the clinicopathological characteristics and the incidence and localization of LFs in early human colorectal neoplasms. Correlations between lesion size and the presence or absence of LFs in each macroscopic type were evaluated by using Spearman's rank correlation. A value of $P<0.05$ was considered statistically significant.

RESULTS

The details of the clinicopathological characteristics of the subjects are shown in Table 1. A total of 1 031 lesions, including 903 intramucosal neoplasms and 128 submucosal cancers, were investigated histologically. Endoscopically, 60 were depressed type, 157 flat type, and 814 protruding type.

Incidence of LFs

LFs were present in 280 of the 1 031 lesions, an overall incidence of 27.2%. The incidence of LFs was significantly higher in females (89/265, 33.6%) compared to males (191/766, 24.9%) ($P = 0.0064$). The incidence of LFs was markedly higher in the right-sided colon (32.2%, 79/166) than in the left-sided colon (25.6%, 201/786, $P = 0.0403$). In addition, the incidence of LFs in submucosal cancers (43.8%, 56/128) was significantly higher than in intramucosal neoplasms (24.3%, 224/903, $P<0.0001$). The incidences of LFs in submucosal cancers with or without lymph node metastasis were 8.9% (5/56) and 8.3% (6/72), respectively, showing no significant correlation between the presence of LFs and lymph node metastasis in submucosal cancers. LFs were present in 41.7% (25/60) of D type, 31.8% (50/157) of F type, and 25.2% (205/814) of P type lesions. The incidence of LFs in F and D type (34.6%, 75/217) was significantly higher than in P type (25.2%, 205/814) ($P<0.0001$, Table 1).

Localization of LFs

Of the 280 lesions with LFs, 146 were classified as intramucosal and 134 as submucosal. In addition, the localizations of LFs (intramucosal/submucosal) were also different according to macroscopic types: 1/24 in D, 14/36 in F, and 131/74 in P types (Table 2). The D and F type lesions harboring LFs also showed a significantly higher incidence of submucosal LFs as compared to the P type lesions ($P<0.0001$).

Correlation between the presence of LFs and tumor size

The mean tumor sizes of the early colorectal neoplasms with or without LFs in each macroscopic type were 12.3±6.3 and 8.0±5.7 mm in D type, 14.8±10.6 and 8.6±5.1 mm in F type, and 17.9±12.0 and 12.8±8.3 mm in P type, respectively,

Table 1 Correlations between clinicopathological characteristics and the presence or absence of lymphoid follicles

		LF[1] present (%)	LF absent (%)	*P*
Total cases	1 031	280 (27.2)	51 (72.8)	
Gender				
Male	766	191 (24.9)	575 (75.1)	
Female	265	89 (33.6)	176 (66.4)	0.0064
Location				
Right - sided colon	245	79 (32.2)	166 (67.8)	
Left - sided colon	786	201 (25.6)	585 (74.4)	0.0403
Size (mean)(mm)				
Depressed + Flat	10.3 ± 3.4	13.9 ± 6.3	8.5 ± 5.3	
Protruding	14.1 ± 9.6	17.9 ± 12.0	12.8 ± 8.3	0.0095
Macroscopic type				
Depressed + Flat	217	75 (34.6)	142 (65.4)	
Protruding	814	205 (25.2)	609 (74.8)	0.0133
Histology				
Intramucosal neoplasias	903	224 (24.8)	679 (75.2)	
Submucosal cancer	128	56 (43.8)	72 (56.2)	<0.0001

[1]Lymphoid follicle.

Table 2 Localizations of the lymphoid follicles in each macroscopic types

	Intramucosal LF[1] (%)	Submucosal LF (%)	Total
Depressed	1 (4)	24 (96)	25
Flat	14 (28)	36 (72)	50
Protruding	131 (64)	74 (36)	205

[1]Lymphoid follicle

which showed that the mean tumor size in each macroscopic type with LFs was obviously larger compared to the macroscopic type without LFs ($P<0.0001$), and the mean tumor sizes of D and F types with LFs were markedly smaller than that of P type ($P = 0.0095$).

DISCUSSION

We believe that this study is the first report to describe the incidence and localization of LFs subjacent to early colorectal neoplasms in human beings. Rubio *et al*.[5,6] concluded that there appeared to be a genuine association between LFs and non-polypoid adenomas, not only in rodents but also in human beings; however, they did not mention depressed type lesions. Recently, with advances in endoscopic instruments and techniques, concerns have arisen about depressed and flat type early colorectal neoplasms that have increasingly been found worldwide[7-11]. To clarify the characteristics of these depressed and flat type lesions, we investigated the incidence of LFs not only of protruding, but also of depressed and flat type lesions.

Our present results showed that the incidence of LFs differed according to the macroscopic features of early colorectal neoplasms, being especially high in depressed type lesions (41.7%). We also observed that the localizations of LFs seen in early colorectal neoplasms were different according to macroscopic type: 96% (24/25) of depressed and 72% (36/50) of flat lesions-associated LFs were located under the muscularis mucosa (submucosal LF), while 36% (74/205) of protruding lesions harboring LFs were located over or across the muscularis mucosa (intramucosal LF). To the best of our knowledge, no other reports on the localization of LFs in early colorectal neoplasms have been published as yet.

Depressed lesions are known to demonstrate invasive tendencies despite their smaller size[7-9]. Furthermore, flat lesions are reported to be 10 times more likely to contain high-grade dysplasia than protruding ones[12]. In this study, the depressed or flat lesions were found to have a significantly higher incidence of LFs and submucosal LFs compared to the protruding lesions. Based on reports of the aggressive growth patterns of depressed and flat lesions, we speculate that the differences in incidence and location of LFs between flat or depressed and protruding lesions might reflect the host physical defense against neoplasms in human beings; that the submucosal LFs might prevent depressed or flat lesions from downward growth; and that LFs might act against the upward growth of protruding lesions. However, the results from experimental colon cancer studies indicated that aggregates of LFs might promote the development of adenocarcinomas[1-4]. On the other hand, studies in experimental animals have also shown that the intestinal lymphoid system plays an important role in the immunologic defense mechanisms; that is, antigenic stimuli result in germinal center formation, subsequently antibody production, and finally enlargement of the follicles[13]. *In vivo*, the presence of tumor-infiltrating lymphocytes is associated with improved prognosis in colorectal cancers, as does the presence of high level DNA microsatellite instability[14-15]. Carcinomas with lymphoid stroma in various organs are also reported to be associated with better prognosis[16]. Thus, these results suggest LFs in early colorectal neoplasms play an important role in defense rather than promotion.

In our study, the incidence of LFs was markedly higher in submucosal invasive cancers than in intramucosal lesions, and it was also more frequently observed in depressed or flat lesions and in larger sizes of each macroscopic type. We observed significant correlations

among the incidence of LFs and the invasive tendencies and size of early colorectal lesions. Mortality rates for colorectal cancer in Japan tend to be lower in females than males. Our results also showed a significant higher incidence of LFs in females compared to males (33.6% *vs* 24.9%). Taking these results together, we suggest that LFs in early colorectal neoplasms are signs of a possible early physical defense event against neoplastic cells.

Submucosal cancers are reported to show lymph node metastasis in 3.6–16.2%[17-20]. However, in this study, we could not find a significant difference between the presence of LFs and lymph node metastasis in submucosal cancers. This might be due to the small numbers of submucosal cancers (8.6%, 11/128) harboring lymph node metastasis. Another explanation is that LFs may have defense only against the process of tumor invasion but not that of metastasis.

In conclusion, significant differences exist in the incidence and localization of LFs in early colorectal neoplasms in human beings. We suggest that LFs in early colorectal neoplasms might be considered as a sign of the host physical defense against neoplastic cells. Further studies, including experimental and clinical analyses, will be necessary to confirm this phenomenon.

Abstract

AIM: To evaluate the effect of MSX2 on gemcitabine-induced caspase-3 activation in pancreatic cancer cell line Panc-1.

METHODS: Using V5-tagged MSX2 expression vector, stable transfectant of MSX2 was generated from Panc-1 cells (Px14 cells). Cell viability under gemcitabine administration was determined by MTT assay relative to control cell line (empty-vector transfected Panc-1 cells; P-3EV cells). Hoechst staining was used for the detection of apoptotic cell. Activation of caspase-3 was assessed using Western blotting analysis and direct measurement of caspase-3 specific activities.

RESULTS: MSX2 overexpression in Panc-1 cells resulted in decreased gemcitabine-induced caspase-3 activation and increased cell viability under gemcitabine treatment in Px14 cells.

CONCLUSION: MSX2 exerts repressive effects on gemcitabine-induced apoptotic pathway. This novel apoptosis-regulating function of MSX2 may provide a new therapeutic target for pancreatic cancer.

Key words: MSX2; Caspase-3; Gemcitabine

INTRODUCTION

Pancreatic cancer is known as a cancer with poor prognosis. Surgical resection of pancreatic cancer is available only in 15-20% of all patients[1], while medical approaches, such as chemotherapy or radiation, have no cure. The resistance of pancreatic cancer to chemotherapeutic agents is one of the serious problems in clinical situation. Gemcitabine (2',2'-difluoro-2'-deoxycytidine) is a widely used chemotherapeutic agent for unresectable pancreatic cancer treatment, and its administration triggers apoptosis in pancreatic cancer cell line[2]. On the other hand, previous report showed that acquired gemcitabine resistance was accompanied by altered expression of apoptosis regulatory genes[3]. The mechanisms how cancer cells evade apoptotic signals are beginning to come to light, but its upstream regulators are not fully understood as yet.

We have previously demonstrated that overexpression of homeobox gene MSX2 accelerated proliferation of pancreatic cancer cell lines, combined with epithelial-mesenchymal transition (EMT)-like phenotypic changes *in vitro* (Satoh *et al*., submitted). In addition, forced expression of MSX2 increased anchorage-independent growth of pancreatic cancer cells, indicating enhanced aggressive biological behavior. Recent studies have demonstrated that MSX2 is a downstream target of the Wnt signaling pathway in several cancer cell lines[4,5]. The upregulation of Wnt signaling is reported in various cancer cell lines, and its target genes are closely related to cancer cell growth and survival[6–9]. At this point of view, we hypothesized that MSX2 might affect apoptotic signaling pathway, which leads to the chemoresistance of pancreatic cancer cells.

In this study, we generated MSX2-overexpressing pancreatic cancer cell line Px14, and this cell line revealed resistance to the gemcitabine treatment. When cells were treated with gemcitabine, the caspase-3 activation was significantly upregulated in empty vector-transfected control cells, but not in Px14 cells compared to basal control cells. Taken together, MSX2 might act as a negative regulator of apoptosis in this cell line. This new upstream regulator of apoptotic signaling pathway may provide a novel therapeutic target of chemotherapy-resistant pancreatic cancer.

MATERIALS AND METHODS

Cell line and cell culture

Panc-1, a human pancreatic cancer cell line, was maintained in Dulbecco's modified Eagle's medium (DMEM)

supplemented with 100 mL/L fetal bovine serum (FBS), and incubated at 37 °C in a humidified atmosphere containing 50 mL/L CO_2 in air.

Chemical substances

Gemcitabine (Gemzar; Eli Lilly Co., Indianapolis, IN, USA) was dissolved in phosphate buffered saline (PBS) at various concentrations of 0.1, 1, 10, 100 μg/mL and 1 mg/mL as stock solutions. In cell culture, vehicle and these stock solutions were used in 1:100 dilutions.

Plasmids, gene transduction and expression

Expression vector, pcDNA3.1-MSX2V5, was generated as described previously (Satoh *et al*. submitted). Panc-1 cells were plated in six-well plates and cultured until reaching a subconfluent state. Cells were transfected with 1 μg of pcDNA3.1-V5His (empty vector) or pcDNA3.1-MSX2V5 using FuGENE6 transfection reagent (Roche Diagnostics, Basel, Switzerland) in normal growth medium. Three days later, cells were plated on 10-cm dishes and cultured until reaching a confluent state. After G418 selection, clones were subjected to Western blot analysis with a specific anti-V5 antibody (Invitrogen, Carlsbad, CA, USA).

Cell proliferation and cell viability assays

For cell proliferation assay, 6 000 cells were seeded per well in triplicate in 96-well plates in normal growth media. After 24-h (d1) and 72-h (d3) incubation, cell proliferation assay was performed using cell proliferation ELISA, BrdU (5-bromo-2-deoxyuridine) kit (Roche Diagnostics) according to the manufacturer's instructions. Cell proliferation ratio at d3 was normalized by that of d1. For cell viability assay, 10 000 cells were seeded per well in triplicate in 96-well plates in normal growth media. After 24-h incubation, cells were incubated with gemcitabine at various concentrations. After 48-h incubation, cell viability was measured by using 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay. Cells were treated with MTT solution at a concentration of 0.5 mg/mL for 2 h, and then solubilized in dimethylsulfoxide (DMSO). Color reaction was measured by a spectrometer at a wavelength of 570 nm. Each experiment was repeated at least twice.

Detection of apoptotic cells

Apoptosis was determined by staining with Hoechst. Cells were plated at 1×10^4 on culture slide (Becton Dickinson, Franklin Lakes, NJ, USA) and allowed to adhere to the slide overnight. Gemcitabine (1 μg/mL) was added and incubated for an additional 24 h. The cells were fixed with 40 g/L paraformaldehyde for 20 min, followed by Hoechst 33342 (Calbiochem-Novabiochem, La Jolla, CA, USA) staining in these cells for 30 min. Then the cells were analyzed under a fluorescence microscope (Leica, Cambridge, UK). Between the incubations, the specimens were washed thrice with PBS. Chromatin condensation, nuclear shrinkage, and nucleosomal fragmentation were considered to be morphological markers of apoptosis.

Measurement of caspase-3 activities

APOCYTO Caspase-3 Colorimetric Assay Kit (MBL, Nagoya, Japan) was used for the detection of caspase-3 activity following the manufacturer's protocol. The subconfluent state cells in 10-cm dishes were harvested after 24-h incubation with gemcitabine (1 μg/mL), and subjected to caspase-3 activity detection.

Western blotting analysis

Cells were lysed by the addition of lysis buffer containing 150 mmol/L NaCl, 50 mmol/L Tris–HCl, 10 mL/L Nonidet P40 and 5 g/L sodium deoxycholate. Cell lysates were cleared by centrifugation at 16 000 *g* at 4 °C for 15 min. Cleared lysates were boiled for 5 min at 100 °C after the addition of 5× sample loading buffer containing 1 mol/L Tris–HCl (pH 6.8), sodium dodecyl sulfate, glycerol, and bromophenol blue. Samples were electrophoresed at 200 V on 125 g/L polyacrylamide gels and transferred to nitrocellulose membranes (Bio-Rad, Hercules, CA, USA), blocked with 50 g/L nonfat dry milk, and then incubated with primary antibodies, such as anti-caspase-3 antibody (BD610322), anti-v5 antibody (R960-25, Invitrogen) and anti-α-tubulin antibody (sc-8035, Santa Cruz Biotechnology, Santa Cruz, CA, USA). Horseradish peroxidase-conjugated anti-mouse antibody (NA931, Amersham, Buckinghamshire, UK) was used as secondary antibody. Reactive bands were detected using ECL™ Western Blotting Detection Reagents (Amersham).

Statistical analysis

The unpaired *t*-test and one-way ANOVA were used for statistical comparison. Calculations were made with the help of Microsoft Excel computer software (Microsoft, Redmond, WA, USA). $P<0.05$ was considered statistically significant.

RESULTS

Forced MSX2 expression in human pancreatic cancer cell line Panc-1

To evaluate whether MSX2 expression correlates with gemcitabine resistance in pancreatic cancer cells, we generated MSX2 stable transfectant cell line. As described previously (Hamada *et al*., submitted), V5-tagged MSX2 expression vector was transfected in Panc-1 cells. MSX2-expressing clone (Px14) was selected and subjected to further analysis (Figure 1A). Panc-1 cells transfected with empty vector were maintained with the culture media containing G418, and used as control cell line (P-3EV). BrdU incorporation assay showed no significant difference in cell growth between two cell lines, but there was a tendency of slightly increased proliferation ratio in Px14 cells ($P = 0.074$, Figure 1B) relative to control cells (P-3EV cells), which was compatible to our previous report (Satoh *et al*., submitted).

Decrease of gemcitabine sensitivity in Panc-1 cells by MSX2 overexpression

Gemcitabine administration at a concentration of 10 μg/mL

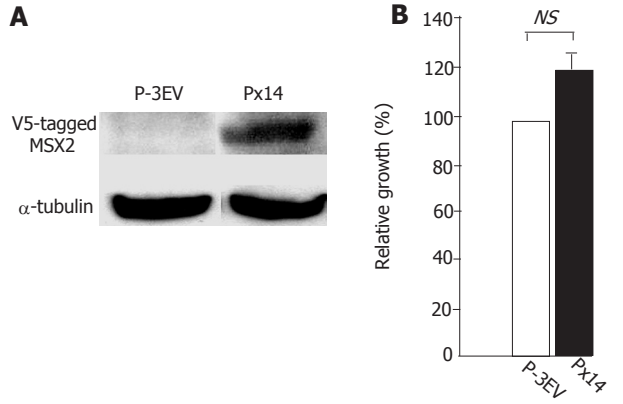

Figure 1 A: Western blotting analysis of V5-tagged MSX2 expression in Px14 cells; **B:** detection of cell proliferation of P-3EV and Px14 by BrdU incorporation assay. No significant difference was observed in these two cell lines, but slight increase of proliferation ratio was observed in Px14 cells (unpaired *t*-test, $n = 3$).

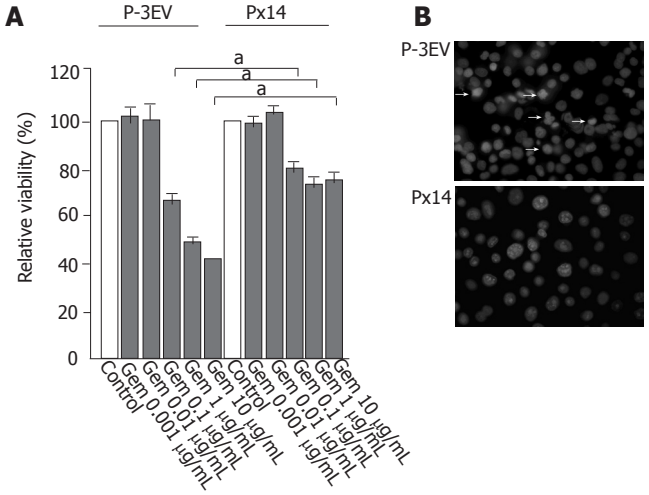

Figure 2 A: Cell viability of P-3EV and Px14 cell lines after 24 h of gemcitabine treatment at various concentrations. Gemcitabine reduced cell viability in a dose-dependent manner. At a concentration of 0.1 μg/mL or above, Px14 cells exhibited higher viability relative to P-3EV cells (one-way ANOVA, $n = 3$, $^aP<0.05$ *vs* others); **B:** Hoechst staining of P-3EV and Px14 cell lines. After 24 h of gemcitabine treatment at a concentration of 1 μg/mL, apoptotic changes (nuclear chromatin condensation and nuclear fragmentation) were obviously observed in P-3EV cells (arrow), but not in Px14 cells.

for 48 h decreased the viability of P-3EV cells by 60%, whereas that of Px14 cells only by 30% (Figure 2A). Px14 cells also depicted gemcitabine resistance at concentrations of 1 and 0.1 μg/mL (Figure 2A). Since Px14 cells were thought to be resistant to gemcitabine cytotoxicity, we analyzed gemcitabine-induced morphological alteration in P-3EV cells and Px14 cells. Gemcitabine-treated P-3EV cells at a concentration of 1 μg/mL for 24 h showed obvious apoptotic characteristics such as nuclear fragmentation and chromatin condensation, while these morphological changes were unremarkable in Px14 cells (Figure 2B).

Gemcitabine-induced caspase-3 activation in P-3EV cells and Px14 cells

Gemcitabine treatment led P-3EV cells to apoptotic state,

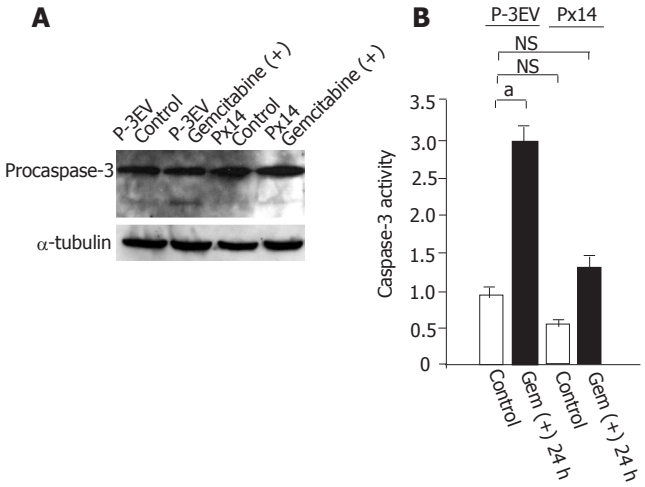

Figure 3 A: Western blotting analysis for caspase-3 activation. Cells were harvested 24 h after gemcitabine (1 g/mL) or vehicle administration. In P-3EV cells, active caspase-3 (cleaved form) was detected after gemcitabine treatment (arrow), whereas in Px14 cells, cleaved form of caspase-3 was undetectable with or without gemcitabine; **B:** direct caspase-3 activity measurements by APOCYTO Caspase-3 Colorimetric Assay Kit. Gemcitabine (1 μg/mL) treatment significantly enhanced caspase-3 specific activity in P-3EV cells, but not in Px14 cells. No significant differences in caspase-3 activities were detected between vehicle-treated P-3EV cells and Px14 cells, even after gemcitabine treatment (one-way ANOVA, $n = 3$, $^aP<0.05$ *vs* others).

thus we examined caspase-3 activation in P-3EV and Px14 cells. Gemcitabine administration at a concentration of 1 μg/mL clearly induced active (cleaved) form of caspase-3 in P-3EV cells, but not in Px14 cells (Figure 3A). Caspase-3 activation is a critical event in apoptosis induction; therefore, we hypothesized that gemcitabine resistance in Px14 cells might be due to suppressed caspase-3 activity. To evaluate this hypothesis, we conducted direct measurements of caspase-3 activities in P-3EV cells and Px14 cells, with or without gemcitabine treatment. The basal activities of caspase-3 in these cells were not significantly different (Figure 3B). However, gemcitabine treatment at a concentration of 1 μg/mL significantly increased caspase-3 activity in P-3EV cells but not in Px14 cells as compared with its basal activity in control cells.

DISCUSSION

Even in pancreatic cancer cells, apoptotic signal does exist, but the signal is considered to be overwhelmed by inhibitor of apoptosis[10]. In our experiment, gemcitabine treatment induced apoptotic changes in P-3EV cells, whereas this effect was attenuated by MSX2 overexpression. Studies have shown that the ability of evasion from apoptosis is one of the critical steps for tumor progression. For example, interference of X-linked inhibitor of apoptosis (XIAP) expression in MDA-MB-231 mammary cancer cell line increases sensitivity to several chemotherapeutic agents[11]. The expression level of survivin in pancreatic cancer tissue is significantly associated with the reduction of the apoptotic index of tumor cells[12] and is also reported to be correlated with the prognosis of patients[13],

indicating that anti-apoptotic effectors directly affect clinical outcomes.

MSX2 overexpression enhanced cell proliferation in pancreatic cancer cell line BxPC-3 (Satoh K *et al.*, submitted), and tended to stimulate the Panc-1 cell growth in the current study, indicating that MSX2 enhances the proliferation effect rather than the pro-apoptotic effect in pancreatic cancer cells. Association of MSX2 with cell proliferation has also been shown in facial mesenchyme[14] and in skeletogenic mesenchyme[15], suggesting that the downstream targets of this homeobox gene may include regulators of cell proliferation. In addition, MSX2 itself and/or BMP-induced MSX2 has shown to lead the pancreatic cancer cells to epithelial-mesenchymal transition (EMT) state (Satoh *et al.*, Hamada *et al.*, submitted), indicating the enhancement of malignant phenotype of pancreatic cancer cells by MSX2. In this study, we clearly demonstrated that forced expression of MSX2 in pancreatic cancer cells produced the resistance to gemcitabine-induced apoptosis via the suppression of caspase-3 activity, which is an additional new aspect of MSX2 to accelerate the pancreatic cancer cell malignancy. Although further detailed investigations would be required to clarify how MSX2 inhibits caspase-3 activation in pancreatic cancer cells, the involvement of this gene in the development of gemcitabine resistance provides us some clues for further understanding of the cancerous cell nature and a novel therapeutic target.

Abstract

AIM: To compare the prevalence of *Helicobacter pylori (H pylori) Ig*G and *Ig*A antibodies between adult subjects, with defined gastric diseases, nondefined gastric disorders and those representing the population.

METHODS: Data on *H pylori Ig*G and *Ig*A antibodies, determined by enzyme immunoassay, were analyzed in 3 252 subjects with DGD including 482 patients with gastric ulcer, 882 patients with duodenal ulcer, 1 525 patients with chronic gastritis only and 363 subjects with subsequent gastric cancer, 19 145 patients with NoDg and 4 854 POPUL subjects. The age-adjusted prevalences were calculated for 1- and 20-year age cohorts.

RESULTS: The prevalences of *Ig*G antibodies were equally high (89-96%) in all 20-year age cohorts of the DGD groups, whereas the prevalences of *Ig*G antibodies were lower and increased by age in the POPUL and NoDg groups. The prevalences of *Ig*A antibodies were also higher in the DGD groups; among them CA (84-89%) and GU groups (78-91%) showed significantly higher prevalences than DU (68-77%) and CG patients (59-74%) (OR 2.49, 95%CI 1.86-3.34 between the GU and DU groups). In the CA, GU, and DU groups, the *Ig*A prevalences showed only minor variation according to age, while they increased by age in the CG, POPUL, and NoDg groups ($P \leqslant 0.0001$). The *Ig*A response, but not the *Ig*G response, was associated with an increased risk of CA (OR 2.41, 95%CI 1.79-3.53) and GU (OR 2.57, 95%CI 1.95-3.39) in comparison with CG patients.

CONCLUSION: An *Ig*A antibody response during *H pylori* infection is significantly more common in CA and GU patients as compared with CG patients.

INTRODUCTION

Helicobacter pylori (*H pylori*), the causative agent of chronic gastritis[1], is also the most important risk factor for peptic ulcer disease[25] and distal gastric cancer[4,5]. The presence of *H pylori* antibodies signify this chronic infection and their prevalence increases with age in all populations, mainly due to the birth of cohort phenomenon[6,7]. The optimal serological tests for *Ig*G antibodies to *H pylori* show a sensitivity and a specificity of over 95%[8-10]. Antibodies of the *Ig*A class are usually detected in combination with elevated *Ig*G antibodies in approximately two-thirds of infected subjects[8,11,12]. They are diagnostically useful in the 2-7% of *H pylori* patients who do not have elevated *Ig*G levels[7,8,12-15]. *Ig*A antibodies have been shown to be a sensitive indicator of an increased risk for gastric cancer[14]. In this context, it may be important that subjects with CagA antibodies have more often *H pylori* antibodies of the *Ig*A class as compared with those who are CagA antibody-negative[15], since CagA-positive infections have been associated with an increased risk of both peptic ulcer disease and gastric cancer[16,17].

In the present study, we analyzed the prevalences of *H pylori* antibodies determined in our laboratory from 1986 to 2000 in clinical samples taken from patients with endoscopically verified or undefined gastric disorders and

in samples collected from the Finnish population.

MATERIALS AND METHODS

Study subjects

Serum samples for this study were obtained from 1986 to 2000 from the following patient groups: 3 252 patients with defined gastric diseases (DGD), including 482 patients with an endoscopically confirmed gastric ulcer (GU) (mean age 60.79 years, SD±12.59 years), 882 patients with an endoscopically confirmed duodenal ulcer (DU) (mean age 53.80 years, SD±13.64 years), 1 525 patients with a histologically verified chronic gastritis (CG) (mean age 50.58 years, SD±15.95 years) and 363 subjects with subsequent gastric cancer (CA) (mean age at the time of the serum sampling 57.23 years, SD±10.91 years). Sera from GU, DU, and CG patients were collected on the day of the endoscopy, those from CA patients between 2 wk to 24 years before the diagnosis of cancer was made (reported in part earlier[5,14]). In the GU, DU, and CG groups, patients who had prior successful eradication therapy were excluded from the study. In addition, serum samples were obtained from 4 854 subjects participating in a population study in Vammala, Finland (POPUL) (mean age 41.73 years, SD±20.60 years), reported in part earlier[7] and from 19 145 patients whose sera were sent by general practitioners, Municipal Health Centers or Hospitals to our diagnostic laboratory for *H pylori* antibody tests without any information on possible gastric disorders (NoDg) (mean age 51.47 years, SD±16.97 years).

Ethics

The study was approved by the Ethics Committee for Epidemiology and Public Health of the Helsinki and Uusimaa Hospital district.

Laboratory assessment

H pylori *Ig*G and *Ig*A antibody titers were determined by in-house enzyme immunoassays[8,10].The antigen used was an acid glycine extract from *H pylori* strain NCTC 11637. During the study period, the sensitivity and specificity of the *Ig*G test were 95-99% and 93-97%, respectively, and those of the *Ig*A test were 64-67% and 92-98%, respectively, as determined in patients in whom the presence of *H pylori* infection had been verified by culture and histology of gastric biopsies[8,10].

Statistical analysis

The trend in changes in the prevalences of *Ig*G and *Ig*A antibodies by age was studied using the linear trend test. The comparisons of prevalences of *Ig*A and *Ig*G antibodies between the groups were analyzed using the logistic regression model adjusting for age based on 1-year age cohorts. For an overview, the prevalences were determined for 20-year age-adjusted cohorts (15-34, 35-54, 55-74, and 75-94 years), each including at least 50 subjects. The association of *Ig*A and *Ig*G responses with the risk of serious complications (CA, GU, and DU) was analyzed using a logistic regression model by comparing the number of subjects in each antibody response and complication category to that in CG patients, who are regarded to present the basic disease caused by *H pylori*. Statistical analyses were carried out using the SPSS 12.0 software package (SPSS Inc., Chicago, IL, USA). $P<0.05$ was considered statistically significant.

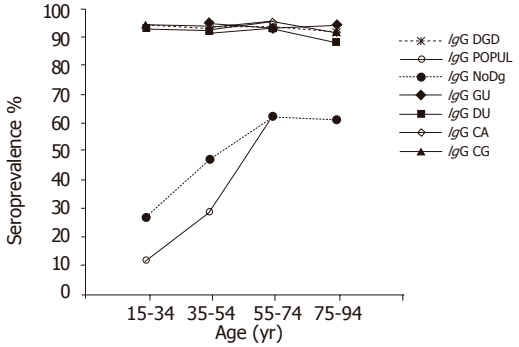

Figure 1 Prevalence of *H pylori* *Ig*G antibodies by 20-year age cohorts in the Finnish population and patients with different gastric disorders. (Only cohorts including at least 50 subjects are shown).

RESULT

Of the 27 251 subjects, 13 939 (51.2%) were positive for *H pylori* antibodies. Of the antibody-positive subjects, 61.8% were positive for both *Ig*G and *Ig*A antibodies, 34.9% for *Ig*G antibodies only and 3.3% for *Ig*A antibodies only.

IgG antibody prevalences

Among the subjects in the DGD groups, 88.6-95.7% had *H pylori* antibodies of the *Ig*G class in all 20-year age cohorts (Figure 1). In contrast, among the subjects representing the POPUL and NoDg groups, significantly lower seroprevalences were observed (OR 19.73, 95%CI 16.15-24.10 and OR 14.11, 95%CI 12.28-16.21, respectively) (Figure 1). Furthermore, the prevalence was seen to increase by age from 12% in the youngest cohort to 63% in the 55-74-year-old cohort in the POPUL group ($P<0.0001$; trend test), and from 27% to 62%, respectively, in the NoDg patients ($P<0.0001$; trend test). The prevalence of *Ig*G antibodies was significantly higher in the NoDg patients than in the POPUL group (OR 2.18, 95%CI 2.00-2.36) (Figure 1).

Within the DGD group, the prevalences did not differ between the GU, DU, CG, and CA groups, nor did they show any significant variation by age (trend test).

IgA antibody prevalences

The prevalence of *Ig*A antibodies group in all age cohorts was significantly higher in the DGD group than in the POPUL (OR 9.61; 95%CI 8.20-11.26) and NoDg groups (OR 5.00; 95%CI 4.59-5.44) (Figure 2). Within the DGD group, the highest prevalences were found in the GU and CA groups in all 20-year cohorts (77.7-90.7% and 84.3-88.6%, respectively) (Figure 2) without a significant difference between these two groups (OR 1.09, 95%CI

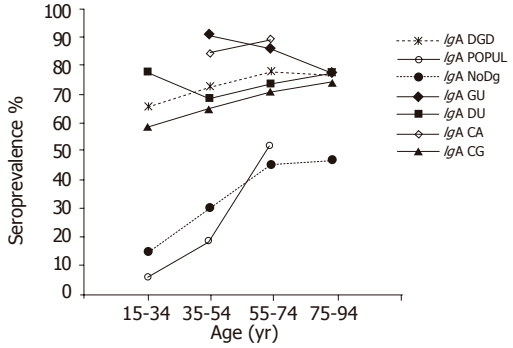

Figure 2 Prevalence of *H pylori IgA* antibodies by 20-year age cohorts in the Finnish population and patients with different gastric disorders. (Only cohorts including at least 50 subjects are shown.)

0.75-1.58). Although the GU patients showed a small decrease of *Ig*A-positive subjects by increasing age ($P = 0.016$; trend test), the prevalence was markedly higher than in DU (68.4-77.4%, OR 2.49; 95%CI 1.86-3.34) and CG patients (58.7-74.2%, OR 2.57, 95%CI 1.95-3.39). In the DU patients, the *Ig*A prevalence showed no significant trend by age (trend test), whereas a significantly increased trend by age was found in CG patients ($P = 0.0001$; trend test); the overall prevalences did not differ significantly between these two groups (OR 1.13; 95%CI 0.95-1.35) (Figure 2, Table 1).

In the subjects representing the POPUL and NoDg groups, the prevalence of *Ig*A antibodies increased by age from the lowest rates (6.5% and 15.1%, respectively) to significantly higher rates in the 55-74-year-old cohorts (52.1% and 45.6%, respectively; $P<0.0001$; trend test) (Figure 2). The overall prevalence of *Ig*A antibodies was higher in the NoDg patients than that in the POPUL group (OR 1.93, 95%CI 1.73-2.10).

Association of IgG and IgA responses with the risk of CA, GU, and DU in comparison with CG

*Ig*A response was more common in CA and GU groups as compared with CG patients (OR 2.41, 95%CI 1.79-3.53 and OR 2.57, 95%CI 1.95-3.39, respectively); however, this difference was not significant in DU patients (Table 1). The number of *Ig*G responders in CA and GU groups did not differ significantly as compared with the CG patients (Table 1), whereas it was even slightly lower in DU patients as compared with the CG patients (OR 0.72, 95%CI 0.55-0.99).

DISCUSSION

In the present study, we analyzed, according to age cohorts, a large body of serological data collected during a 15-year period. DGD subjects with gastric disorders known to be associated with *H pylori* infection showed a high and rather a constant prevalence of *H pylori Ig*G antibodies in all the 20-year age cohorts. Based on the prevalence of *Ig*A antibodies, the DGD group could be divided into two categories: in GU-CA-category, the age-adjusted *Ig*A prevalences ranged from 78% to 91%; whereas in DU-CG-category, the age-adjusted *Ig*A prevalences remained significantly lower. With the exception of CG patients, the *Ig*A antibody rates also remained rather constant throughout the age range. In contrast, the infected subjects in the POPUL and NoDg groups showed significantly lower *Ig*G and *Ig*A rates than those in the DGD group and that increased significantly by age. The CG patients formed a special intermediate group with overall *Ig*G and *Ig*A antibody prevalences at the same level as those of the DU patients, but with a significantly increasing trend by age in the prevalence of *Ig*A antibodies.

Table 1 Association of *H pylori Ig*A and *Ig*G antibodies with the risk of CA, GU or DU in comparison to CG

Subjects	*Ig*A		*Ig*G	
with	OR	95%CI	OR	95%CI
CG	1		1	
CA	2.41	1.79–3.53	1.28	0.81–2.02
GU	2.57	1.95–3.39	0.69	0.46–1.03
DU	1.13	0.95–1.35	0.72	0.55–0.99

The importance of the *Ig*A response increases when considered in connection with our earlier findings showing the association of *H pylori* antibodies of the *Ig*A class with a CagA-positive infection[15], as well as with other reports showing an increased risk of peptic ulcer disease and gastric cancer in CagA-positive infection[16,17]. The present results imply that an *Ig*A response during *H pylori* infection might be regarded as an indicator of an increased risk not only for gastric cancer[14] but also for gastric ulcer disease. In these comparisons, that we carried out using the data from patients with chronic gastritis as baseline values, we found that the higher *Ig*A response rate seen in DU patients did not reach significance.

By using the data obtained in prospective gastric cancer studies, we wanted to avoid the bias caused by severe atrophic gastritis, regarded as a precancerous process[18]. Severe atrophic gastritis may progress to a disease stage when *Helicobacters* first gradually decrease in number, then disappear and finally also *Helicobacter* antibodies, the longest lasting indicators of the infection, fall to a normal level[19]. In particular, in elderly subjects with non-cardia cancer, there may be several individuals who at the time of diagnosis may have lost all direct indicators of their burnt out *Helicobacter* infection.

Our large materials and the high sensitivity and specificity of our antibody tests also gave an opportunity to compare the prevalence of *H pylori* antibodies between the POPUL and NoDg groups. It is tempting to speculate that the higher *H pylori* prevalence in the two youngest cohorts (by 15% and 18% units in antibodies of *Ig*G class in the order of increasing age) in NoDg patients would preferentially reflect the strength of gastric symptoms driving patients to clinical consultations.

In conclusion, irrespective of age, practically all DGD subjects have *H pylori Ig*G antibody. The prevalence of *Ig*A antibodies highest in CA and GU patients, second highest in DU and CG patients, and lowest in the NoDg patients and POPUL subjects. An *Ig*A response is associated with serious sequelae of *H pylori* infection.

Abstract

AIM: To examine whether polymorphisms in SULT1A1 and GSTP1 genes contribute to colorectal cancer development and whether they are associated with clinicopathological variables are not well identified.

METHODS: We examined the genotypes of 125 colorectal cancer patients and 666 healthy controls in a Swedish population by using PCR-restriction fragment length polymorphism (RFLP).

RESULTS: SULT1A1 *2/*2 genotype (OR = 2.49, 95%CI = 1.48-4.19, P = 0.0002) and *2 allele (OR = 1.56, 95%CI = 1.16-2.10, P = 0.002) had an effect on colorectal cancer susceptibility, while GSTP1 genotype was without effect. However, GSTP1 G-type predicted a worse prognosis in the patients independently of gender, age, Dukes' stage, growth pattern, and differentiation (P = 0.03).

CONCLUSION: Polymorphism in SULT1A1 may predispose to colorectal cancer and GSTP1 may be a biological indicator of prognosis in the patients.

Key words: GSTP1; SULT1A1; Survival; Colorectal cancer; PCR-RFLP

INTRODUCTION

Sulfotransferase 1A1 (SULT1A1), a major sulfotransferase enzyme in human beings, is an important component in the detoxification pathway of numerous xenobiotics. The enzyme also plays an important role in the metabolism and bioactivation of many dietary and environmental mutagens, including heterocyclic amines implicated in carcinogenesis of colorectal and other cancers[1]. *SULT1A1* is polymorphic with the most common variant allele, *SULT1A1**2, where a G→A change occurs at nucleotide 638, resulting in an arg213→his213 change. This allele codes for an allozyme with low enzyme activity and stability compared to the *SULT1A1**1 variant. Therefore, *SULT1A1* genotype may influence susceptibility to mutagens following exposure to heterocyclic amines and other environmental toxins[1]. However, regarding the results of the *SULT1A1* polymorphism in relation to colorectal cancer risk was inconsistent[2-4].

Glutathione *S*-transferase P1 (GSTP1) plays a central role in the inactivation of toxic and carcinogenenic electrophiles[5]. The A to G polymorphism at nucleotide 313 in the *GSTP1* gene results in an isoleucine to valine change at residue 105, which reduces the catalytic activity of the enzyme. The polymorphism of lower activity allele of *GSTP1* was related to several types of cancers including bladder, testicular, and lung cancer, but not to colorectal cancer[5-10].

There was no study on the polymorphisms of *SULT1A1* and *GSTP1* in patients with colorectal cancer in comparison with healthy controls in Sweden; we, therefore, investigated the polymorphisms in this population in order to clarify whether the polymorphisms were related to colorectal cancer risk, and further to analyze whether the polymorphisms had any clinicopathological significance. We analyzed genomic DNA of normal colorectal mucosa from 125 colorectal cancer patients and of blood samples from 666 healthy controls by using PCR-restriction-fragment length polymorphism (RFLP).

MATERIALS AND METHODS

Materials

Normal colorectal mucosal samples and colorectal cancer tissue were obtained from 125 patients with primary colorectal adenocarcinomas diagnosed at the Department of Pathology, Vrinnevi Hospital, Norrköping, Sweden, during the period between 1990 and 2001. All patients were Caucasians. Patients' gender, age, tumor site, Dukes' stage and the grade of differentiation were obtained from their surgical and pathological records and reviewed by two authors. Normal colorectal mucosa was taken from the distant resection margin and the corresponding tumor tissue from the colorectal cancer. The patients with colon cancers in Dukes' stage C/advanced tumor received chemotherapy (the influence on survival was less than 20%), and some patients with rectal cancers received adjuvant preoperative radiotherapy (the treatment has a marginal influence on survival). The patients were followed up until the end of October 2003, and 32 deaths due to the cancer had been registered.

Control population comprised 666 individuals from the same residential area as the patients. The individuals had neither gastrointestinal diseases nor history of tumors. DNA samples were extracted from the peripheral leukocytes.

Methods

DNA extraction Genomic DNA was isolated from frozen normal colorectal mucosa and tumor from colorectal cancer patients by a modified proteinase K digestion and phenol/chloroform extraction technique. In brief, the tissue (about 200 mg) was cut into small pieces and dissolved in a cell lysis buffer (40 μL of 20% SDS, 40 μL of 10 mg/mL proteinase K, 400 μL TEN buffer, 0.1 mol/L NaCl, 10 mmol/L Tris-HCl, 1 mmol/L EDTA, pH 8.4). Samples were kept in a shaking water bath at 55 °C overnight. The digestive step was repeated by the addition of half of the volume of the cell lysis solution (above), until the sample solution turned completely clear. DNA was extracted with phenol, phenol/chloroform and chloroform, precipitated with ice-cold ethanol, washed with 70% ethanol, and redissolved in double distilled water. The amount of purified DNA was measured by a DU 640 spectrophotometer (Beckman, Fullerton, USA), and the DNA concentration was calculated. Genomic DNA from the controls was extracted from peripheral leukocytes by means of the Wizard Genome Purification Kit (Promega Inc., Madison, USA) according to the manufacturer's instructions.

PCR-RFLP Two sets of primers were used respectively for determining the polymorphisms of the *SULT1A1* (A1VIIF: GTT GGC TCT GCA GGG TCT CTA GGA GAG and 1A1VIIR: CCC AAA CCC CCG TAC TGG CCA GCA CCC) and *GSTP1* (P105F: ACC CCA GGG CTC TAT GGG AA and P105R: TGA GGG CAC AAG AAG CCC CT). PCR reactions were performed in a total volume 20-80 μL of a solution containing PCR buffer (2 mmol/L $MgCl_2$, 50 mmol/L KCl, 10 mmol/L Tris-HCl, pH 8.4, 1.2 μL DMSO (only for SULT1A1)), 0.2 mmol/L each of dATP, dCTP, dGTP, and dTTP (Pharmacia Biotech, Uppsala, Sweden) and 0.4-1.0 U of Taq DNA polymerase (Sigma Chemical, St. Louis, USA). The reaction started with 94 °C for 3 min, followed by 35-39 cycles consisting of denaturation (at 94 °C for 0.5-3 min), annealing (SULT1A1: at 63 °C for 1 min and GSTP1: 55 °C for 0.5 min), and extension (at 70-72 °C for 0.5-5 min). PCR products were checked by electrophoresis on a 1.5-2% agarose gel (Invitrogen Life Technologies, Groningen, The Netherlands) with 0.2 μg/mL ethidium bromide. A negative control (PCR without template) was included in each set of PCR reactions. All PCR reactions were repeated at least three times for confirmation and to ensure reproducibility.

Hae II (New England BioLabs) was applied to identify *SULT1A1* genotypes[11] and Alw26I (New England Biolabs, Hertfordshire, UK) for *GSTP1* genotypes[8]. The PCR products were digested with the restriction enzymes and separated in a 3.5% agarose gel or in a 4% of 3:1 NuSieve GTG agarose (BioWhittaker Molecular Applications, Rockland, ME, USA)/agarose, stained with ethidium bromide to visualize the bands.

Genotyping and grouping Genotyping and grouping of genotypes in the present study were based on their effect on carcinogenic metabolism and commonly used classifications in previous other studies. For *SULT1A1,* three genotypes of *1/*1, *1/*2, and *2/*2 were classified[2,11-13]. To analyze the relationship of *SULT1A1* genotype with clinicopathological factors, we combined *SULT1A1**1/* with *1/*2 as one group *vs* *SULT1A1**2/*2 group. The polymorphisms of *GSTP1* were confirmed to be A/A, A/G, and G/G. *GSTP1* A type was referred to A/A, and G type was referred to both A/G and G/G[6,14,15].

Statistical analysis

The χ^2 method was used to test the frequencies of genotypes/allele in colorectal cancer patients with the control population and various clinicopathological variables. McNemar's method was used for testing the differences of the genotype/allele frequency in normal colorectal mucosa and tumor tissue. The odds ratio (OR), an estimate of the relative risk, with 95% confidence intervals (CI) was computed to assess the relationship of the genotypes/allele to the risk of colorectal cancer. Cox's Proportional Hazard Model was used to test the relationship between the polymorphisms and the survival of patients. Survival curves were computed according to the Kaplan-Meier method. All *P* values cited were two-sided and *P* values <0.05 were judged as statistically significant.

RESULTS

We examined the polymorphisms of *SULT1A1* in 109 colorectal cancer patients and 666 healthy individuals. As shown in Table 1, the frequencies of *SULT1A1* *2/*2

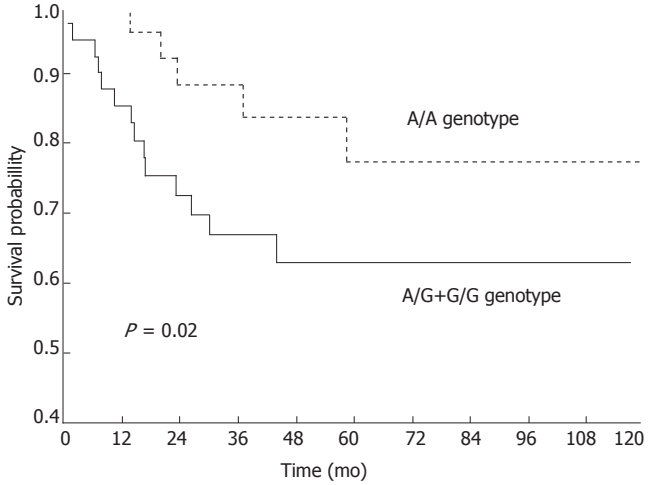

Figure 1 Colorectal cancer patients with G-type genotype (A/G+G/G) of the *GSTP1* gene had a worse prognosis than those with A/A genotype (A/A) ($P = 0.02$).

Table 1 Polymorphisms of SULT1A1 and GSTP1 in colorectal cancer patients and healthy controls

Gene	Patients (%)	Controls (%)	Odds ratio (95%CI)	*P*
SULT1A1				
*1/*1	43 (39)	266 (40)	1.0	
*1/*2	27 (25)	303 (45)	0.55 (0.32–0.94)	
*2/*2	39 (36)	97 (15)	2.49 (1.48–4.19)	0.0002[1]
Allele *1	113 (52)	835 (63)	1.0	
Allele *2	105 (48)	497 (37)	1.56 (1.16–2.10)	0.002
GSTP1				
A/A	59 (47)	127 (50)	1.0	
A/G	51 (41)	101 (40)	1.09 (0.67–1.76)	
G/G	15 (12)	27 (10)	1.20 (0.56–2.55)	0.63[2]
A allele	169 (68)	355 (70)	1.0	
G allele	81(32)	155 (30)	1.10 (0.78–1.54)	0.57

[1]SULT1A1: *2/*2 *vs* *1/*1+*1/*2, [2]GSTP1: G type (G/G+A/G) *vs* A type (A/A).

genotype (36% *vs* 15%, OR = 2.49, 95%CI = 1.48-4.19, $P = 0.0002$) and *2 allele (48% *vs* 37%, OR = 1.56, 95% CI = 1.16-2.10, $P = 0.002$) in the patients were significantly higher than in the controls. The *SULT1A1*2/*2* was still related to the risk for developing colorectal cancer when we did age-matched analyses of case-control, age ≤70 ($P = 0.04$), ≤80 ($P<0.0001$) and >70 years ($P<0.0001$). The status did not change when the tests were performed in different tumor sites (proximal or distal) in comparison with the control group ($P>0.05$).

The genotypes and allele frequency of the *GSTP1* gene were determined in 125 patients and 255 healthy controls. *GSTP1* G type was referred to both A/G and G/G. As shown in Table 1, there was no significant difference between the patients and controls based on G type (53% *vs* 50%, OR = 0.90, 95%CI = 0.57-1.41, $P = 0.63$) or allele frequency (32% *vs* 30%, OR = 1.10, 95%CI = 0.78-1.54, $P = 0.57$), neither in the subgroups of the age and tumor location ($P>0.05$).

The patients with *GSTP1* G-type genotype had a worse prognosis than those with *GSTP1* A (A/A) type genotype ($P = 0.02$, Figure 1). Even in multivariate analysis, the genotype was still related to survival, independent of gender, age, tumor location, Dukes' stage, growth pattern, and differentiation ($P = 0.03$, Table 2). Besides, there was no relationship of genotype/allele frequency with any of the clinicopathological variables studied in the patients ($P>0.05$).

Table 2 Multivariate analysis of GSTP1, gender, age, site, Dukes' stage, growth pattern, and histological type in relation to survival in colorectal cancer

Variable	Number	Cancer death Rate ratio	95%CI	*P*
GSTP1 genotype				
A/A	14	1.0	–	0.03
A/G+G/G	26	5.3	1.26–19.53

Histological type				0.02
Non-mucinous	27	1.0	–	
Mucinous	13	7.1	1.39–32.07	

In order to check whether there was a difference between normal colorectal mucosa and tumor regarding the two polymorphisms, we isolated DNA from the tumors in the same patients and analyzed the genotype/allele frequencies of *SULT1A1* and *GSTP1* polymorphisms by using the same protocol. Neither genotype nor allele frequency of the polymorphisms in the tumors differed from that of the polymorphisms determined in normal mucosal samples ($P>0.05$).

DISCUSSION

In the present study, we demonstrated that the patients with colorectal cancer, comparing with the controls, had significantly higher frequencies of *SULT1A1*2/*2* genotype (36% *vs* 15%) and *2 allele (48% *vs* 37%), indicating that *SULT1A1*2/*2* allele was related to colorectal cancer risk. Our results supported previous findings in colorectal, esophagus, breast and lung cancer studies, where *SULT1A1* *2/*2 genotype was associated with an increased risk for the tumor development[2,16-18]. It has been observed that a G to A transition at nucleotide 638 in *SULT1A1* gene causes an Arg213 to His substitution associated with a low SULT activity. Thus, these results suggest that low activity of SULT1A1*2 allozyme lacks a protection against dietary and/or environmental chemicals involved in the carcinogenesis of colorectal cancer.

It has been demonstrated that individuals with *GSTP1* G/G alleles had a lower catalytic activity compared with individuals with *GSTP1* A/A. An intermediate activity was reported for heterozygotes[19,20]. In the present study, the frequencies of genotype and allele in the control (50% for A/A, 40% for A/G, 10% for G/G, and 70% for A allele) and in the patients (47%, 41%, 12%, and 68%, respectively) were similar to the frequencies raised by other studies in Caucasian controls (40-52%, 39-48%, 7-11%, and 67%, respectively) and colorectal cancer patients (37-49%, 42-55%, 8-12%, and 70%, respectively)[7,8,10,14,21]. We failed to find any evidence supporting an association between the allelic variants of *GSTP1* and susceptibility to colorectal cancer or certain clinicopathological factors including gender, age, tumor location, Dukes' stage and differentiation, which is supportive to previous findings[6,7,9,21].

Interestingly, we found that patients with *GSTP1* G-type had a worse prognosis than the patients with *GSTP1* A-type, even after adjustment for gender, age, tumor location, Dukes' stage, and differentiation. A study in breast cancer found that a significantly higher proportion of breast cancer patients with a *GSTP1* G-type had more frequency of p53 mutations and loss of heterozygosity at the TPp53 gene locus, compared with *GSTP1* A-genotype[22]. It has been widely accepted that altered p53 predicts a poor prognosis in breast cancer patients, although there is not a direct evidence of *GSTP1* in relation to survival in their study. It seems that *GSTP1*, through the A→G polymorphism, may reduce its effect on the inactivation of toxic and carcinogenic electrophiles[5]. In contrast, Stoehlmacher *et al*.[21] demonstrated that the *GSTP1* A→G polymorphism was associated in a dose-dependent fashion with increased survival of patients with advanced colorectal cancers receiving 5-FU/oxaliplatin chemotherapy. They suggest that the effect of certain chemotherapeutic drugs might be altered when enzymes that could enhance the elimination of these drugs show a reduced activity. The opposite results related to survival in colorectal cancer patients may be due to different characteristics of patients included in the two studies. We included all Dukes' stages with a proper stratification (A = 12, B = 46, C = 34, and D = 17); among them, the cases with colon cancers in Dukes' stage C or advanced tumors received chemotherapy, and some patients with rectal cancer received adjuvant preoperative radiotherapy. All patients in their study had a metastasis and received 5-FU/oxaliplatin combination chemotherapy. Furthermore, we had a longer follow-up period than theirs (median month: 33 *vs* 10.9). Comparing with their data, we have more Caucasians (100% *vs* 72%) and older patients (median: 73 *vs* 60 years).

In conclusion, our results suggest that *SULT1A1* may predispose to colorectal cancer, and *GSTP1* may be used as a prognostic factor to predict the patients' survival.

ACKNOWLEDGMENT

Abstract

AIM: To screen the immunogenic membrane proteins of *Shigella flexneri* 2a 2457T.

METHODS: The routine two-dimensional polyacrylamide gel electrophoresis (2-DE) and Western blotting were combined to screen immunogenic proteins of *S. flexneri* 2a 2457T. Serum was gained from rabbits immunized with the same bacteria. Immunogenic spots were cut out from the polyacrylamide gel and digested by trypsin in-gel. Matrix-assisted laser desorption/ionization time of flight-mass spectrometry (MALDI-TOF-MS) was performed to determine the molecular weight of peptides. Electrospray ionization (ESI-MS/MS) was performed to determine the sequences of the interesting peptides.

RESULTS: A total of 20 spots were successfully identified from Coomassie brilliant blue stained gels representing 13 protein entries, 5 known antigens and 8 novel antigens. A hypothetical protein (YaeT) was detected, which might be a candidate target of vaccine.

CONCLUSION: Membrane proteins of *S. flexneri* 2a 2457T were successfully observed by 2-DE. Several known and novel antigens were identified by mass spectrum.

INTRODUCTION

The genus *Shigella* spp. is a group of Gram-negative enteric bacilli which cause bacillary dysentery in human beings, accounting for 20% of the 4.6 million diarrhea-associated deaths among children[1]. Though the LPS can induce a good immune response in human beings, the role of proteins (especially the membrane proteins) in conferring immunity to shigellosis is at best speculative. Considering outer membrane proteins of *Shigella* spp. function as a dynamic interface between the cell and its surroundings, it is possible to develop new antigens from them. Due to the methodology limitations of protein separation and identification, it is difficult to identify the immunogenic proteins in bands on 1-D gel. With the improvement of 2-DE in recent years much valuable information is available and immunoproteomics has been built around 2-DE and routine immunologic technologies.

S. flexneri 2a is the dominant serotype causing shigellosis in China. Our laboratory has finished a two-dimensional electrophoresis reference map and a proteomic database of *S. flexneri* 2a 2457T[2], but only a few of membrane proteins can be identified in that database. In order to develop new protective antigens against *S. flexneri* and to understand their immune mechanism, we applied immunoproteomic technologies in screening new antigens of *S. flexneri* 2a 2457T.

MATERIALS AND METHODS

Bacterial strains and growth conditions

S. flexneri 2a 2457T was aerobically cultured in LB overnight at 37 °C. Overnight cultures were diluted 1:100 and shaken at 250 r/min. Growth was stopped at the early stationary phase at an A_{600} of 3.3.

Membrane protein preparation

Cells were harvested and centrifuged for 15 min at 2 000 r/min (Sigma 3K12, No. 12150; St. Louis, MO, USA) at 4 °C. The pellet was washed thrice for 10 min at 2 000 r/min with low-

salt washing buffer (3 mmol/L KCl, 1.5 mmol/L KH_2PO_4, 68 mmol/L NaCl, 9 mmol/L NaH_2PO_4)[3]. Proteins were extracted using the ReadyPrep™ protein extraction kit (Membrane I) (BioRad, USA). Integral membrane proteins were separated from hydrophilic proteins using the nonionic detergent Triton X-114.

Two-dimensional electrophoresis

Eighteen-centimeter immobilized pH gradient (IPG) strips (pH ranges, 4-7) (Amersham Pharmacia Biotech, Sweden) were used. Isoelectric focusing (IEF) was conducted for 60 000 Vh (IPGphor, Amersham Pharmacia Biotech). Vertical slab SDS-PAGE (12.5%) was run at 30 mA/gel for the second dimension. Gels were stained with Colloidal Coomassie Blue[4]. Image analysis was performed with Image-Master 2D Elite Version 3.1.

Preparation of antisera against 2457T

S. flexneri 2a 2457T was aerobically cultured in LB overnight at 37 °C. Rabbits were immunized six times with culture solution intravenously at intervals of 5 d. The doses were (5, 7.5, 10, 15, 20, 20)×10^8 CFU, respectively. Eight days after the last immunization, blood was collected from the tested animals and the sera were separated. Antibody titers 1:5 120 was measured by microaggalutination test and ELISA.

Immunoblot assay

After two-dimensional electrophoresis, the gels were electroblotted onto Hybond™ECL™ nitrocellulose membrane (Amersham Pharmacia Biotech) using a semi-dry transfer unit (Hoefer™ TE 77, Amersham Pharmacia Biotech, Sweden). Before immunodetection, the membranes were stained for 10 min with 5 g/L Ponceau S in 10 mL/L acetic acid and the positions of some selected spots were marked by clean needles. Western blotting was performed as previously described[5]. Then antigen-antibody complexes were detected with peroxidase-labeled goat anti-rabbit IgGs and substrate.

In-gel protein digestion and MALDI-TOF-MS protein identification

In-gel protein digestion was performed as previously described[6]. All MALDI-MS measurements were performed on a Bruker Reflex. III MALDI-TOF-MS (Bruker Daltonik, Bremen, Germany) operating in reflectron mode.

Nanospray ESI-MS/MS

The peptide solution after in-gel protein digestion was desalted with ZipTip C18™ pipette tips (Millipore, Bedford, MA, USA). Electrospray ionization (ESI-MS/MS) was carried out with a hybrid quadrupole orthogonal acceleration tandem mass spectrometer (Q-TOF2) (Micromass, Manchester, UK)[2].

Peptide mass fingerprinting

Peptide mass fingerprinting searches were performed using the program Mascot developed by Matrix Science Ltd (http://www.matrixscience.com). For protein identification, peptide mass searches against the database of 2457T by Mascot licensed in-house and the searches against the NCBInr database with free access on the internet were done. A peptide mass accuracy of 0.3 Da was defined.

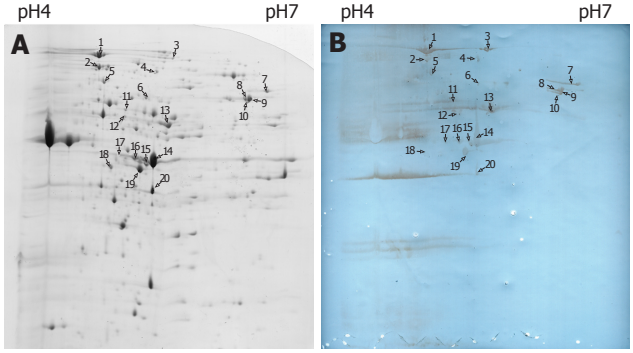

Figure 1 A: Two-dimensional electrophoresis profile of *S. flexneri* 2a 2457T membrane proteins, stained with Colloidal Coomassie Blue; **B:** Western blot of membrane proteins of *S. flexneri* 2a 2457T. Gel equal to Figure 1A was electroblotted onto nitrocellulose membrane using a semi-dry transfer unit.

RESULTS

The sample was prepared on the basis of the separation of membrane proteins by temperature-dependent phase partitioning using Triton X-114 detergent. Proteins anchored to the membrane or containing one or two transmembrane domains were efficiently partitioned to the detergent-rich phase. In order to solubilize the protein thoroughly, thiourea was used. In pH 4-7 gradient 2-DE map, 148 spots were cut and 111 spots were successfully identified by MALDI-TOF-MS presenting 82 protein entries. Twenty-five proteins were not observed/identified in our previous work[2]. The majority of these 25 proteins (data not shown) were hydrophobic and associated with the membrane. The relative abundance of membrane-associated proteins identified in this study was higher than that in our previous study[2].

On the basis of the established immunoproteomic map of soluble proteins of *S. flexneri* 2a 2457T (unpublished), we described a group of spots in a 2-DE map of immunogenic proteins from hydrophobic proteins in this study. Five hundred micrograms of protein sample was used to perform the 2-DE. One of the parallel gels was electroblotted onto nitrocellulose membrane and the other was stained with Coomassie brilliant blue G-250. We successfully identified 20 immunoreactive spots from Coomassie brilliant blue stained gels using sera from immunized rabbits, which represented 13 protein entries, 5 known antigens and 8 novel antigens. The 20 spots were marked on the 2-D gel and corresponding blotting membrane (Figure 1). Table 1 lists all the identified proteins. ESI-MS/MS was used to confirm the protein marked as spot 1. Figure 2 shows the result of ESI-MS/MS identification.

Table 1 List of immunoreactive proteins of membrane proteins

Spot ID	Gene symbol	Protein common name	NCBI GI identifier	Cellular role
1	YaeT	Hypothetical protein	gi|30061734	Cell envelope
2	DnaK	Chaperone Hsp70; autoregulated heat shock protein	gi|30061584	Protein fate

DISCUSSION

Known antigens

Our results are in accordance with other studies[7-11].The outer membrane protein 3a (II*; G; d) is a precursor of OmpA, a major and highly conserved outer membrane protein of Gram-negative bacteria. Due to its high copies per cell[12], multiple charged isoforms[13] and its strong immunogenecity, identification of OmpA was performed several times during the immunoproteomics analysis. All these proteins were observed in our other works (unpublished).

Novel antigens

Besides the above confirmatory findings, the study detected several new immunoreactive proteins (AtpA, OppA, MglB, LpdA, ClpB, Gnd, Pgm, YaeT). AtpA, LpdA, Gnd, and Pgm are components of the energy metabolism system. ATP synthesis/hydrolysis occurs in the ATP synthase F1 sector which lies at the surface of cytoplasmic membrane. LpdA codes for an outer membrane lipoamide dehydrogenase that is highly immunogenic. It is an *in vivo*-induced antigen in *Mycobacterium tuberculosis*[14]. Since LpdA is a functional subunit of both pyruvate dehydrogenase (aceEF) and alpha-ketoglutarate dehydrogenase (sucAB), a lpdA mutant of *H. influenzae* can be significantly attenuated[15]. Gnd is an important component of pentose phosphate pathway. Phosphoglucomutase (pgm) is associated with virulence of *Brucella abortus* because the deltapgm strain is unable to assemble the O side chain in the complete LPS. Vaccination with the deltapgm strain induces effective protection[16]. The periplasmic oligopeptide binding protein OppA is part of the oligopeptide transport system. In addition to the function mentioned above, it also plays a role in mediating the adhesion or interactions of bacteria to different substrates, tissues or environments[17-19]. OppA and periplasmic galactose-binding protein MglB also display some chaperone-like functions, suggesting that they are probably involved in protein folding and protection against stress in periplasm[20]. ClpB is also a heat shock protein. The proteins described above have not been reported as antigens and may serve as candidate markers for bacterial infection though they are unlikely to be protective.

A hypothetical protein (YaeT) detected is of high homology to Oma90 of *S. flexneri* M90T (serotype 5)[21]. We also detected this protein in another study (unpublished), which is verified by ESI-MS/MS. Since it has an enhanced expression in a murine model and exhibits strong homology to genes encoding *Haemophilus influenzae* D15 and *Pasteurella multocida* Oma87, its role in Shigella infection and immunoreaction is worthy to be clarified.

Abstract

Primary splenic cyst is a relatively rare disease, and the majority of cases are classified as epithelial cysts. Three cases with nonparasitic splenic cysts are presented: two epithelial and one pseudocyst. All cases had an atypical symptomatology, consisted mainly of fullness in the left upper abdomen and a palpable mass. Preoperative diagnosis was established with ultrasonography and computerized tomography. Two cases with large cysts located in the splenic hilum were treated with open complete splenectomy. The most recent case, a pseudocyst, was managed laparoscopically with partial cystectomy. All cases did not have any problems or recurrence during follow-up. Laparoscopic partial cystectomy is an acceptable procedure for the treatment of splenic cysts, because it cures the disease preserving the splenic tissue. Complete splenectomy is reserved for cases in which cyst excision cannot be done otherwise.

Key words: Spleen; Epithelial cyst; Surgery; Laparoscopy

INTRODUCTION

Splenic cysts are unusual in everyday surgical practice. They can be parasitic (hydatid), caused by the parasite *Echinococcus granulosus*, or nonparasitic[1,2]. Non-parasitic cysts are classified as primary (true, epithelial), lined by an epithelial cover (epidermoid, dermoid, and mesothelial) or endothelial cover (hemangioma, lymphangioma), and secondary (pseudocysts, non-epithelial), which are usually of post-traumatic origin[3,4].

Primary splenic cysts comprise 30-40% of the total and are encountered more commonly in children and young adults[5,6]. Most of the cysts are asymptomatic, and they are incidental findings during abdominal ultrasonography. The number of diagnosed splenic cysts seems to rise because of the increased use of abdominal imaging techniques[7].

Laparotomy with splenectomy has been the method of choice for the treatment of primary splenic cysts[5,8]. Today, performance of more conservative surgical procedures has been advised, especially in children and young adults, in order to avoid overwhelming postsplenectomy infection[4,8]. Herein, we present three cases with non-parasitic splenic cysts, their diagnostic evaluation and surgical management.

CASE REPORTS

Case 1

A 15-year-old girl was admitted to our Department with a chief complaint of abdominal fullness. An elastic, hard mass of approximately 15 cm in diameter was palpable in the left upper abdomen. A chest X-ray showed a mild elevation of the left hemidiaphragm. Ultrasonography of the upper abdomen showed a giant cystic lesion with irregular echoic patterns. Computerized tomography confirmed the splenic localization of the cyst and demonstrated almost total displacement of the remaining splenic parenchyma.

At laparotomy, a huge splenic cyst of approximately 15 cm of maximal diameter was revealed, located in the middle of the splenic parenchyma, displacing it towards the splenic poles. First, reduction of the cyst with intraoperative drainage of 1 000 mL of serous fluid was done. However, due to the cyst location, preservation of the spleen was considered impossible, and complete splenectomy followed. The aspirated cystic fluid showed no evidence of malignancy. Histology report revealed that the cyst wall consisted of dense fibrous tissue, covered by stratified squamous or cuboid epithelium. Thus, the diagnosis of a primary epidermoid splenic cyst was established. The postoperative clinical course of the patient was satisfactory and was discharged on postoperative d 7. She received a pneumococcal vaccine and chemoprophylaxis with oral penicillin at a dose of 1 500 000 IU twice daily, for a period of 6 months. Today, the patient is in excellent condition, 8 years after surgery.

Case 2

A 27-year-old woman presented with mild dyspeptic symptoms, an atypical pain and a sensation of fullness in the epigastrium. Past medical history was negative,

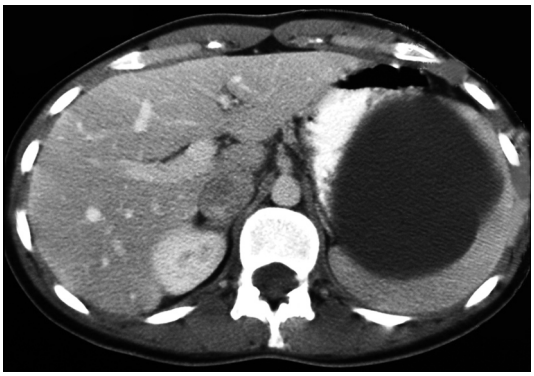

Figure 1 Plain abdominal CT scan showing the splenic localization of a large cyst displacing the remaining splenic parenchyma, the so-called "beak-sign".

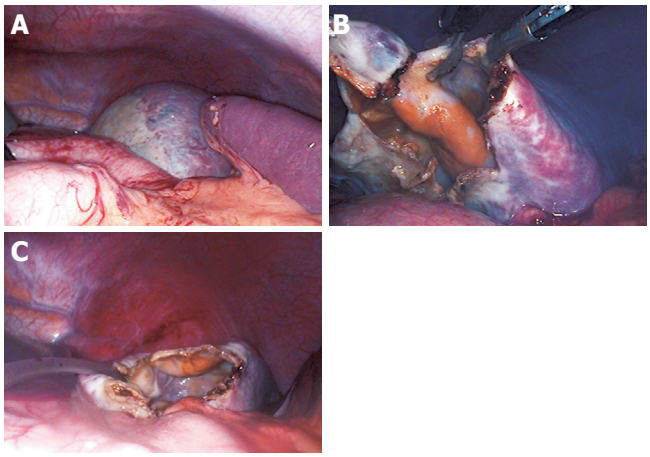

Figure 2 Laparoscopic view of the cyst. Most parts of the cyst are covered with a thin layer of splenic tissue; only a small portion in the upper pole of the spleen displays a "white roof" **(A)**. The cyst was punctured and evacuated and a 3 cm× 3 cm portion of the cyst was excised using the monopolar scissor **(B)**. A drainage tube was inserted in the remaining cavity **(C)**.

and physical examination revealed a 6-7 cm palpable mass in the left upper quadrant of her abdomen. All laboratory tests were normal, and serological tests gave no evidence of parasitic infection with *Echinococcus granulosus*. Plain abdominal films of the abdomen were negative. Ultrasound and computerized tomography of the abdomen showed a solitary cystic mass in the splenic hilum with a maximum diameter of 8 cm, displacing the splenic parenchyma (Figure 1). Endoscopic examination of the upper gastrointestinal tract did not reveal any significant findings.

The diagnosis of a splenic cyst was confirmed and the patient was subjected to exploratory laparotomy. On exploration, there was a medium-sized splenic cyst located in the hilum, which made splenectomy inevitable. Postoperative recovery was uneventful. Histological examination of the specimen showed a normal splenic parenchyma and an epidermoid splenic cyst with a fibrous wall lined by epithelial cells. The patient had no problems after surgery and she received pneumococcal vaccine and oral penicillin for 6 months. Today she is in good clinical condition, 4 years postoperatively.

Case 3

A 24-year-old female presented with an asymptomatic lump in the left hypochondriac region, since 2 years. The patient did not have any specific symptoms except for a mild abdominal discomfort and a sensation of fullness in her left upper abdomen. She had a negative medical history. On physical examination, a cystic mass was palpable under the left costal margin, which was moving according to the respiratory movements. The routine hematological and biochemical tests were normal. Casoni's skin test and complement fixation test for hydatid disease were negative. A clinical diagnosis of cystic splenomegaly was made and the patient was subjected to radiological investigations. Ultrasonography of the upper abdomen revealed a single unilocular spherical cystic lesion in the anterior surface of the spleen. Computerized tomography confirmed the ultrasound findings of a subcapsular cystic lesion with an almost 10 cm of maximal diameter within the spleen with attenuation value near that of water with a non-calcified wall.

With a preoperative diagnosis of a splenic cyst, the patient was subjected to laparoscopy. Before starting with the procedure, a thorough video-guided inspection of the peritoneal cavity was performed. After focusing on the left upper quadrant, the greater omentum was pulled down, and the cyst was clearly visible in the upper pole of the spleen (Figure 2A). The cyst roof was punctured and about 700 mL of yellowish (serous) fluid was aspirated and sent for culture and cytological examination. A 3 cm ×3 cm portion of the collapsed cyst wall was then excised with monopolar scissors, paying attention to remove the cyst wall segment free of splenic parenchyma (Figure 2B). Thus, there was minimal blood loss and unroofing of the cyst wall was accomplished. The specimen was extracted through a 10-mm port and sent for histological examination. The tip of an elastic drainage tube was left inside the remaining cavity (Figure 2C). The postoperative course was uneventful. The patient resumed oral diet on the first postoperative day, and was discharged on the second postoperative day after the drain was removed.

Bacteriological cultures of the fluid were negative. Cytological examination of the fluid showed a few lymphocytes and histiocytes. Histological examination of the cyst wall revealed the presence of dense cytopenic connective tissue without any epithelial lining, and confirmed the diagnosis of a splenic pseudocyst. The patient is in good clinical condition, one year after surgery, and on follow-up tomographic scan had no evidence of recurrence.

DISCUSSION

Benign true non-parasitic splenic cysts cannot be clinically distinguished from other types of splenic cysts. They have an inner lining of epithelial cells and are usually of congenital etiology[3,6]. Pseudocysts have an inner lining of connective tissue and are usually secondary to blunt trauma or hemorrhage in the splenic parenchyma, but

they may also be of infectious and degenerative origin[9,10]. Both types of splenic cysts do not produce any specific symptoms, until they reach a significant size. Large cysts may cause atypical pain and heaviness in the left hypochondriac region, due to distension of the capsule or space-occupying mechanisms within the abdominal cavity, or they may present as a palpable mass[3,5,9]. Indeed, in our patients, symptomatology was atypical with a sensation of fullness and a palpable mass in the left upper abdominal quadrant, as well as mild dyspeptic symptoms. Symptoms secondary to pressure on surrounding organs, such as nausea, vomiting, flatulence, and diarrhea may gradually appear. Also, pressure in the cardiorespiratory system may cause pleuritic pain or dyspnea, and irritation of the left diaphragm may cause persistent cough[10]. Occasionally splenic cysts may present with complications, such as infection, rupture and hemorrhage[9,11].

When a lump is detected in the left upper quadrant of the abdomen, it is necessary to exclude any disease associated with splenomegaly, mononucleosis, fever of unknown origin, hemolytic anemia, chronic leukemias, collagen vascular disease, and liver diseases[12]. Serological studies are useful in excluding most of the above-mentioned diagnosis. In our cases hematological, biochemical, and serological investigations were negative. Angiography is useful in differentiating a splenic cyst, which is usually avascular, from solid malignant tumors (lymphoma, sarcoma), which usually have neoplastic vasculature in a disorganized pattern[10,13]. Ultrasonography is able to see that the cysts are either anechoic or hypoechoic and they have a smooth thin wall[14], whereas solid tumors are either isoechoic or hypoechoic. In addition, computerized tomography and magnetic resonance imaging may give most of the necessary information, regarding the morphology of the cyst, the composition of the cystic fluid, the location in the spleen, the position of the cyst and its relationship with the surrounding tissues[5,7,10]. Calcifications of both the primary and secondary cysts are frequently found, which are useful in diagnosing cysts from other causes of splenomegaly[5]. In our cases, ultrasonography and computerized tomography had preoperatively set the diagnosis of solitary unilocular noncalcified splenic cysts.

Due to the increased risk of complications in splenic cysts with a diameter larger than 4-5 cm should be managed surgically[9,11,15], because conservative options, such as percutaneous aspiration or sclerosis, do not result in long-term control[5,8,16]. There are different types of surgical treatment according to the patient's age and the size, location and nature of the cyst. The classical approach to splenic cysts has been open complete splenectomy[5,8,17]. However, there was a trend towards more conservative surgery after the 1970s, because of the appearance of overwhelming life-threatening septicemia, especially in children who underwent splenectomy[5,10,18]. Indeed, the spleen plays an important role in hematopoiesis, immune function, and protection against infections and malignancies[5,19]. Today the optimal treatment options are partial splenectomy, total cystectomy, marsupialization, or cyst decapsulation (unroofing), accessed either by open laparotomy or laparoscopy[5,11,19,20,21].

Partial splenectomy preserves more than 25% of splenic parenchyma, which is the minimal splenic tissue to preserve immunologic protection without increasing the risk of recurrence[5,20]. Partial splenectomy can be performed safely with the laparoscopic approach[4,11,20,21]. This procedure is recommended, if the cyst is located in the poles of the spleen, or if the cyst cavity is deep, due to the higher risk of recurrence[5,8]. Incision of the splenic capsule and hemostasis is performed with the ultrasonic or the monopolar scissors[5,11]. A more conservative option could be a partial cystectomy (unroofing) of the cyst. However, it has yet to be determined how much of the cyst wall should be resected, and whether unroofing should be partial or radical. It is supported that as much of the cyst wall as possible should be resected to prevent reclosure of the cyst[11,15].

Marsupialization of the cyst is another conservative option recommended for superficial splenic cysts, and can be performed safely with the laparoscopic method. This approach reduces the duration of the operation and carries no risk of recurrence[5,8]. In general, the laparoscopic management of splenic cysts offers the benefits of minimally invasive surgery: minimal postoperative pain, faster recovery, shorter hospital stay, and reduced morbidity and recovery[21].

However, any type of conservative procedure is difficult to perform, if the cyst is very large, is located in the splenic hilum, or is covered completely by the splenic parenchyma (intrasplenic cyst), or if there are multiple cysts (polycystic cases): in these cases, a complete splenectomy should be performed either using the open or the laparoscopic appro ach[1,21,22,23].

In all our cases, the cysts were of significant size and had produced clinical manifestations. Therefore, surgical treatment was absolutely indicated. Our first and second cases have been treated earlier, when laparoscopic splenectomy was not performed routinely in our center. In both the cases, we had to treat large cysts located in the splenic hilum, whereas the splenic parenchyma consisted of a rim of tissue pushed to the periphery. Therefore, both indications were met, location and dimension, and a successful open complete splenectomy was accomplished. In both cases the cysts were proved to be true epithelial cysts.

In the third case, there was a large subcapsular cyst located in the lower pole of the spleen, and thus a laparoscopic cystectomy looked as a feasible option. A partial cystectomy was done using the monopolar scissors followed by placement of a drainage tube in the remaining cavity. In this case, histology revealed a cyst without an epithelial lining (pseudocyst), and thus recurrence is not expectable[15,24]. Since there was no history of trauma, this cyst was probably of degenerative origin. We conclude that laparoscopic partial cystectomy is considered as an adequate procedure in cysts devoid of epithelial lining[24], as was our third case. No neoplastic growth has been found in any of our cases.

In conclusion, splenic cysts larger than 5 cm or symptomatic ones should be treated surgically, trying to preserve as much of splenic parenchyma as possible. If the cyst is very large and almost completely covered by splenic parenchyma, or if it is located in the splenic hilum, complete splenectomy is recommended, because of the risk of intractable bleeding from the spleen. Partial cystectomy (unroofing) could be an acceptable procedure in the majority of other cases. The laparoscopic approach seems to be a safe procedure, having all the benefits of minimally invasive surgery.

Abstract

We report a case of secondary pouchitis, defined as a mucosal inflammatory lesion in the ileal reservoir provoked by pouch-related complication following total colectomy and pouch anal anastomosis, which was successfully treated by salvage surgery. A 20-year-old woman with ulcerative colitis developed acute severe bloody diarrhea following proctocolectomy, ileal pouch-anal anastomosis and diverting ileostomy. She was diagnosed as having a secondary pouchitis mainly caused by a peripouch abscess and partly concerned with the abnormal pouch formation. The remnant rectum and ileal pouch were excised and ileal pouch-anal anastomosis and diverting ileostomy were constructed. The postoperative course was uneventful with no sign of pouchitis. Salvage surgery may be indicated to treat secondary pouchitis when caused by surgery-related complications.

Key words: Ulcerative colitis; Ileal pouch-anal anastomosis; Secondary pouchitis; Salvage operation

INTRODUCTION

Restorative proctocolectomy with ileal pouch-anal anastomosis (IPAA) is the current treatment of surgical choice for ulcerative colitis and for selected familial adenomatous polyposis[1,2]. One of the main long-term complications after IPAA is inflammation of the pouch (pouchitis). Symptomatic inflammation of the ileal pouch develops in 7-40% of patients who undergo IPAA[3-6]. The etiology of pouchitis is probably a multifactorial event involving genetic, immune, microbial, and toxic mediators, but is poorly understood. Heusten first identified "secondary pouchitis" caused by surgical complication specific to the ileal reservoir and pouch anal anastomosis[7]. Most cases of pouchitis are primary with an acute course and show a good response to medical therapy, but patients with secondary pouchitis underlying surgical complications need surgical management because medical treatment alone is ineffective. In this report, we described a case of secondary pouchitis due to a peripouch abscess, blind loop formation, which had no response to medical treatment, and so we selected a surgical procedure suitable to the disease state.

CASE REPORT

This case was about a 20-year-old woman who had been diagnosed as having an ulcerative colitis when she was 12 years old. She had been controlled in remission with medical therapy (prednisone and 5-aminosalicylic acid), but on July 2001, she relapsed to severe colitis and was admitted in another hospital. She was treated there with intravenous fluids, broad spectrum parenteral antibiotics, systemic steroids (prednisone 60 mg/d), and granulocytapheresis (GCAP). Despite this conservative therapy, her condition deteriorated and she had underwent laparoscopic total colectomy, ileal pouch-anal anastomosis and diverting ileostomy.

About 3 mo after the primary operation, she had episodes 10 times a day of continuous severe bloody diarrhea. Colonoscopy showed inflammatory mucosa spontaneously bleeding from the anal verge to the ileal J pouch; and was diagnosed as severe pouchitis. She received metronidazole in the form of enemas, but did not respond.

On admission to our hospital, she was not pale, afebrile with a pulse rate of 90 beats/min, and had an anal bloody mucus discharge of 5-10 times per day. Laboratory studies showed that all parameters were almost normal. Culture analysis of the bloody mucus discharge showed multiplication of streptococcus agalactiae and Gram-negative rods. Pouchoscopy showed easy bleeding, inflammatory mucosa with ulcer formation, apical bride formation in the ileal J pouch and edematous colonic mucosa with inflammation from the anal verge to the anastomosis (Figure 1). A pouchogram showed an about

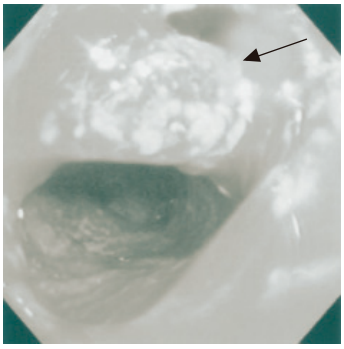

Figure 1 Pouchoscopy shows inflamed hemorrhagic mucosa. An apical bridge is seen (arrow head).

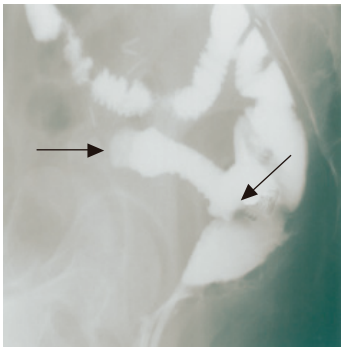

Figure 2 Pouchography shows a blind loop 10 cm in length (arrow head) and apical bridge formation (arrow).

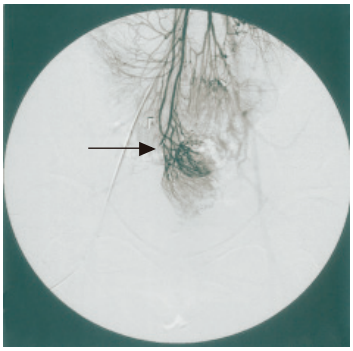

Figure 3 Superior mesenteric arteriography shows a marginal disconnection of the arcade (superior mesenteric artery–ileocolic artery) (arrow).

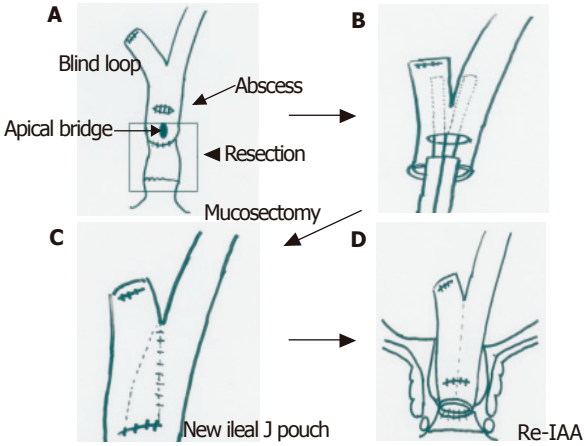

Figure 4 A: Mucosectomy and ileal pouch excision; **B:** side to side anastomosis of blind loop by linear stapler; **C:** reconstruction of a new ileal pouch; **D:** re-ileal pouch anal anastomosis.

10-cm blind loop formation of the ileal J pouch and apical bridge formation (Figure 2). Since we assumed that the operative procedures had not causally affected the outcomes, conservative therapy using metronidasole enemas, steroid enemas, and leukocytapheresis was undertaken for 1 mo.

However, no improvement of clinical symptoms or endoscopic findings was obtained. We attempted to re-evaluate using more extensive examinations. Abdominal CT showed that bilateral ovarian cysts but no remarkable intrapelvic abscess was recognized. Superior mesenteric arterial angiography showed that the ileal J pouch was supplied from the superior mesenteric artery (SMA) and the ileocolic artery (ICA), but that the arcades of these arteries were divided (Figure 3). These findings suggested that the pathogenesis of the disease was secondary pouchitis, due to abnormal formation of the ileal J pouch constructed apical bridge and blind loop or/and ischemic change of the pouch.

On 27 February 2002, she underwent laparotomy. At laparotomy, adhesion in the intra-abdominal space was recognized, but no ascites was seen. From the dentate line, rectal mucosectomy and ileal J pouch excision was performed at first. A peripouch abscess was recognized on the posterior wall of the pouch, and was tightly adhesive to the sacrum. Pouch mucosa on the site of the abscess had erosion and was partly deficient. We diagnosed secondary pouchitis due to a late peripouch abscess. We undertook abscess drainage, excision of the remnant rectum and ileal J pouch including the apical bridge. Side to side anastomosis of the blind loop was performed using a linear stapler into the site of the wall deficiency. After re-ileoanal anastomosis was performed, a covering ileostomy was constructed (Figures 4A-D).

There was a sustained clinical improvement in the patient after this re-operation without any complications. She was discharged on March 25, 2002. Three months later, ileostomy closure was performed. She remains well, with no sign of pouchitis, and has complete continence with bowel movements, 5 times per day.

DISCUSSION

Pouchitis is a term coined by Kock[8] that described the reservoir ileitis that developed in a number of patients with ulcerative colitis who underwent continent ileostomy operations. In 1980, proctocolectomy with ileal reservoir and anal anastomosis was described by Parks[9] and this operation, when performed for ulcerative colitis,

also produced pouchitis in a number of patients. The causes of the pouchitis have been poorly understood. Possible causes advanced include fecal stases resulting in bacterial overgrowth and infection[10], ischemia[11], oxygen free radical injury[12] and deprivation of short chain fatty acids[13].

Data on incidence and prevalence of pouchitis in the literature shows great disparities[14,15]. One reason for this disparity is related to the varying durations and modes of follow-up, the lack of a commonly accepted definition of pouchitis, and the lack of valid scoring for estimating the severity of inflammation[16-20]. Another reason is that pouchitis caused by surgical complication is not widely recognized. Heuschen[7] coined the term "secondary pouchitis" caused by surgical complication specific to the ileal reservoir and pouch-anal anastomosis. These surgical complications can cause clinical symptoms, such as an elevated frequency of defecation, hematochesia, fever, and malaise, which are very similar to those of idiopathic pouchitis. Nonspecific medical treatment of these symptoms as with primary pouchitis appears to be totally inadequate.

In our case, the patient had inflammatory changes in ileal J pouch mucosa with a defunctioned pouch. Pouch formation was abnormal with an apical pouch bridge[21] and an about 10-cm blind loop of the ileal pouch. Furthermore, medical treatment such as with metronidazole, topical steroids in the form of enemas, and GCAP were not effective. SMA angiography could suspect ischemic changes of the pouch mucosa because of the dividing of the arcades of SMA and ICA. However, a resected specimen (remnant rectum and ileal pouch) near the abscess formation showed extensive erosion and diffuse thickening. So we diagnosed that this secondary pouchitis was mainly caused by a peripouch abscess and was partly concerned with the abnormal pouch formation.

Moreover, crucial elements in our salvaged surgery were the initial resection of the peripouch abscess and the damaged portion of the pouch, and then the reconstruction of the pouch and re-IAA; thus improving hopes of curability.

In conclusion, salvage surgery might be indicated as a first choice treatment for secondary pouchitis caused by surgery-related complications. A surgical procedure suitable for the state of the disease should be selected after instituting a comprehensive series of examinations[22].

Abstract

The clinical diagnosis of classic Crohn's disease (CD) of the small bowel is based on a typical history, tender right lower quadrant fullness or mass, and characteristic radiographic findings of the terminal ileum. Appendicitis may as well present with chronic or recurrent symptoms and this presentation may be confused with CD. We herein describe the case of a young teenage girl with a presumptive diagnosis of CD, who was ultimately diagnosed as having chronic nongranulomatous appendicitis. The literature on the subject is reviewed.

Key words: Chronic appendicitis; Crohn's disease; Diagnosis; Terminal ileitis; Adolescent

INTRODUCTION

Crohn's disease (CD) is a chronic transmural inflammation, which may involve any part of the alimentary tract from mouth to the anus. CD typically affects the ileum, colon, or perianal region[1]. The clinical diagnosis of classic CD of the small bowel is based on a typical history, tender right lower quadrant fullness or mass, characteristic radiographic findings of the terminal ileum and endoscopic findings. Although granulomas are regarded as the characteristic feature of CD, their absence does not rule out the diagnosis[1]. Only half of the documented cases of CD reveal epithelioid granulomas in surgical specimens[1]. CD can involve the appendix by extension from the terminal ileum or the cecum and present as an acute or subacute appendicitis. About 25% of patients with ileal CD and 50% of those with colonic Crohn's disease have appendiceal involvement[2]. A clinical picture similar to acute appendicitis is not an uncommon presentation of Crohn's disease.

Among the inflammatory diseases of the right lower quadrant that may mimic CD, acute appendicitis is the most common and potentially the most dangerous one. The principal distinguishing features of acute appendicitis are its onset without any pre-existing history of chronic bowel symptoms and the change in the location of pain and tenderness from epigastrium to the right lower quadrant (RLQ)[1]. Appendicitis, however, may present with chronic or recurrent symptoms and this presentation may be confused with CD. Although an entity of recurrent attacks of RLQ pain, apparently self-limiting, is not infrequently encountered, the entity of chronic or recurrent appendicitis is controversial[3-7]. Nevertheless, it is probably an authentic clinical and pathologic entity[3-15]. Intermittent bouts of obstruction of the appendiceal lumen with spontaneous remission may be the cause[4]. True chronic inflammation of the appendix is difficult to define as a pathologic entity, although occasionally granulation tissue and fibrosis associated with acute and chronic inflammation of the appendix are demonstrated, suggesting an organizing acute appendicitis[16]. In the pediatric population, children with cystic fibrosis can develop chronic appendicitis due to mucous engorgement of the lumen. The occurrence of chronic appendicitis in otherwise healthy children is nevertheless debatable[6].

Herein, we have described the case of a young teenage girl with a presumptive diagnosis of CD, who was ultimately diagnosed as having chronic non-granulomatous appendicitis. The literature on the subject has been reviewed.

CASE REPORT

A 17-year-old girl presented to our pediatric emergency room because of persistent RLQ abdominal pain. She had been previously healthy. Three weeks prior to admission, she was admitted to another hospital for severe RLQ pain. A computerized tomography (CT) scan of the abdomen with barium contrast showed a bowel conglomerate in the cecal area and a stricture of the distal ileum. A presumptive diagnosis of CD was made and the patient was discharged

Table 1 Laboratory values

	1st admission	2nd admission	3rd admission	4th admission	Normal values
HB	12	12.4	13.2	13.8	11.5–16.5 g/dL
WBC	8.0	17.7	5.7	9.1	4.0–11.0×109/L
PLT	322	197	371	309	150–400×109/L
ESR	NA	20	53	6	0–20 mm/h
CRP	2.4	27	0	0.28	0–1 mg/L
ALB	3.7	3.6	4.4	4.8	3.2–5 g/dL

ALT	18	46	61	15	10–40 U/L
GGT	10	16	105	47	7–33 U/L

HB: hemoglobin; WBC: white blood cells; PLT: platelets; ESR: erythrocyte sedimentation rate; CRP: C reactive protein; ALB: albumin; AST: aspartate aminotransferase; ALT: alanine aminotransferase; GGT: gamma-glutamyl transpeptidase.

Figure 1 Upper gastrointestinal and barium follow-through study showing a stricture of an ileal loop without involvement of the terminal ileum (arrow).

Figure 2 Abdominal CT with contrast media showing a bowel conglomerate in the cecal area and a stricture of the distal ileum (arrow).

on 5-ASA, antibiotics and steroids. Colonoscopy, performed a week later, showed no gross pathology and the treatment was discontinued. Biopsy samples from the colon and terminal ileum were normal.

She was admitted to our Pediatric Department because of the continuation of RLQ abdominal pain, recurrent non-bilious vomiting and a 6-kg weight loss over 2 wk.

Physical examination revealed a well-looking young girl with 45 kg body weight and 167 cm height. Diffuse tenderness of the abdomen and right flank was noted. Rectal examination revealed no masses, normal stools and no localized tenderness.

Laboratory results are shown in Table 1 (1st admission). Abdominal ultrasound (US) was normal; a gynecological US showed a left ovarian cyst and a tubular structure in the RLQ. An upper gastrointestinal and barium follow-through study showed a stricture of an ileal loop without involvement of the terminal ileum. This finding was considered to be compatible with CD (Figure 1). Gastroscopy showed gastritis with hemorrhagic areas in the body and antrum. A quick urease test for *H pylori* was negative. Biopsies from the antral mucosa showed remodeling of the foveolar layer, regeneration, atypia, and mild chronic inflammation. Biopsies from the small bowel, gastric corpus and esophagus were normal.

Despite the absence of characteristic histological findings of CD, the clinical presentation and the radiological findings were thought to be compatible with CD and therefore oral steroids and omeprazole were prescribed with resolution of symptoms.

Four weeks later, she was readmitted because of a 24-h history of abdominal pain mainly over the RLQ, fever of 39 °C and non-bilious vomiting.

Physical examination revealed a sick-looking girl having 37.8 °C temperature, 47.5 kg body weight and severe diffuse tenderness over the right lower abdomen. Laboratory results are shown in Table 1 (2nd admission). Abdominal X-ray was normal. Abdominal US showed a thickened bowel loop located over the RLQ. A repeat CT of the abdomen with contrast media showed a bowel conglomerate in the cecal area and a stricture of the distal ileum similar to the findings previously demonstrated. No signs of appendicitis or periappendicular abscess were noted (Figure 2). After 5 d of intravenous treatment with steroids, ciprofloxacin, and metronidazole, the patient's symptoms and clinical signs improved and she was discharged on oral steroids and azathioprine.

For the following 2 mo, the patient was asymptomatic. She was gradually weaned from steroids and maintained on azathioprine. She was then readmitted because of abdominal pain and non-bilious vomiting for 10 d. She had no fever or diarrhea, her appetite was poor and had a 1 kg weight loss. Her physical examination revealed severe diffuse tenderness over the right abdomen. Laboratory results are shown in Table 1 (3rd admission). Budesonide was started and the azathioprine dose was decreased due to abnormal liver enzymes. She was discharged after a clinical improvement but readmitted a week later due to vomiting and epigastric and RLQ pain for 4 d. Laboratory results are shown in Table 1 (4th admission). Gastroscopy showed a mild inflammation with normal antral and duodenal biopsies. A diagnostic laparoscopy showed a phlegmonous appendicitis and an appendectomy was performed. No other abnormality was noted and the ileum appeared to be normal. Histological examination of the appendix and terminal ileum showed periappendicular inflammation and normal small bowel. No granulomata were found. A diagnosis of chronic appendicitis mimicking CD was made. Follow-up of 4 years showed a healthy asymptomatic girl.

DISCUSSION

Controversy and skepticism surround the diagnoses of chronic and recurrent appendicitis[3-6]. Nevertheless, a sufficient histological and radiological evidence to support that this entity exists[3-16].

Chronic appendicitis is defined as lower abdominal pain lasting for 3 wk with radiological and pathological findings of appendicitis. Recurrent appendicitis is defined as recurring episodes of right lower abdominal pain with radiological or pathological finding of appendicitis[17].

Five to ten percent of patients suffering from acute appendicitis describe prior episodes of RLQ pain resolving spontaneously. USG studies have demonstrated a spontaneous resolution of acute appendicitis, in as many as 1 in 13 patients suffering from symptoms of acute appendicitis. The recurrence rate, however, was 38%, mostly in the year following the initial episode[9]. The CT diagnosis of acute appendicitis includes distended or thickened appendix with or without appendicolith, greater than approximately 5-7 mm in size. The wall of the inflamed appendix is circumferentially thickened and may appear as a "halo" or "target." CT findings of periappendiceal inflammation would also support the diagnosis of appendicitis[4,18]. Moreover, CT findings of appendices in patients suffering from prolonged (more than 3 wk) abdominal pain as well as recurring episodes of abdominal pain are identical to those of patients suffering from acute appendicitis[17]. None of these findings were present in the CT done in our patient. It is important to mention that advances in CT with high-resolution techniques have yielded a sensitivity as high as 100% and specificity as high as 98% for the diagnosis of acute appendicitis[18]. The yield of CT in the diagnosis of CD is not good.

Mattei *et al*.[14] reviewed a series of seven patients matching the criteria of chronic or recurrent appendicitis and concluded that recurrent and chronic appendicitis should be considered in the differential diagnosis of recurrent or non-resolving lower abdominal pain. Barber *et al*.[3], in their retrospective study encompassing 1 084 patients who had inflamed appendices removed, found that 6.5% of them had attended the emergency ward prior to their operation for symptoms compatible with recurrent appendicitis. Our patient had clinical and radiological findings compatible with Crohn's ileitis, without evidence of acute or chronic appendicitis on US and CT. It has been suggested that these modalities can aid diagnosis in questionable situations[1]. Although there was no histopathological evidence of CD at biopsy, the clinical manifestations, the radiological findings and the response to treatment supported the diagnosis.

Consideration was also given to the diagnosis of isolated CD of the appendice, an uncommon chronic appendicitis with histological findings (granulomas) resembling a CD[2]. This rare presentation of CD is confined to the appendice and progression to systemic disease is rarely noted. The reluctance to intervene surgically in a patient with a suspected CD is another barrier to diagnosis.

Considering the data presented, chronic or recurrent appendicitis seemed to be the probable diagnosis. It must be considered in every case of unexplained long-standing or recurrent abdominal pain over RLQ. The great improvements in laparoscopic techniques should be valuable in those cases where endoscopical, histological and radiological findings do not provide a definitive answer.

World Journal of Gastroenterology ISSN 1007-9327

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG,* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc*., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Published jointly by
The WJG Press and Elsevier Inc.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297×210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures and Figure Legends. Neither the Editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and Elsevier Inc., and may not be reproduced by any means, in whole or in part without the written permission of both the Authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations.

Online submission
Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com for assistance. If you submit manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission
Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4(297×210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

World Journal of Gastroenterology
Apartment 1066 Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors originating from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page
Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be involved. Titles should be concise and informative (removing all unnecessary words), emphasize what is NEW, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initials and/or first name, middle name or initial(s) and full family name.

Abstract
An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc*. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words
Please list 3-10 key words that could reflect content of the study.

Text
For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the body text or Figures and Tables, not both.

Illustrations
Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should add into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) and not RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126× 76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by Freehand and Illustrator, or TIFF from Photoshop. EPS files must be accompanied by a version in native file format for editing purposes. Scans of existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size at which they will appear when printed, not smaller. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...;C: ...; D: ...; E: ...; F: ...; G: ...

Tables
Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be involved under the tables. This part should add into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data which is not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used; Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or some other symbols with a superscript (Arabic

numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*. in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

References

Cited references should mainly be drawn from journals covered in the Science Citation Index (http://www.isinet.com) and/or Index Medicus (http://www.ncbi.nlm.nih.gov/PubMed) databases. Mention all references in the text, tables and figure legends, and set off by consecutive, superscripted Arabic numerals. References should be numbered consecutively in the order in which they appear in the text. Abbreviate journal title names according to the Index Medicus style (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=journals). Unpublished observations and personal communications are not listed as references. The style and punctuation of the references conform to ISO standard and the Vancouver style (5th edition); see examples below. Reference lists not conforming to this style could lead to delayed or even rejected publication status. Examples:

Standard jounal article (list all authors and include the PubMed ID [PMID] where applicable)

1 **Das KM,** Farag SA. Current medical therapy of inflammatory bowel disease. *World J Gastroenterol* 2000; 6: 483-489 [PMID: 11819634]

2 **Pan BR**, Hodgson HJF, Kalsi J. Hyperglobulinemia in chronic liver disease: Relationships between *in vitro* immunoglobulin synthesis, short lived suppressor cell activity and serum immunoglobulin levels. *Clin Exp Immunol* 1984; 55: 546-551 [PMID: 6231144]

Books and other monographs (list all authors)

4 **Sherlock S,** Dooley J. Diseases of the liver and billiary system. 9th ed. Oxford: Blackwell Sci Pub, 1993: 258-296

Chapter in a book (list all authors)

5 **Lam SK.** Academic investigator's perspectives of medical treatment for peptic ulcer. In: Swabb EA, Azabo S. Ulcer disease: investigation and basis for therapy. New York: Marcel Dekker, 1991: 431-450

Electronic journal (list all authors)

6 **Morse SS.** Factors in the emergence of infectious diseases. Emerg Infect Dis serial online, 1995-01-03, cited 1996-06-05; 1(1):24 screens. Available from: URL: http//www.cdc.gov/ncidod/EID/eid.htm

PMID requirement

From the full reference list, please submit a separate list of those references embodied in PubMed, keeping the same order as in the full reference list, with the following information only: (1) abbreviated journal name and citation (e.g. *World J Gastroenterol* 2003;9(11):2400-2403; (2) article title (e.g. Epidemiology of gastroenterologic cancer in Henan Province, China; (3) full author list (e.g. Lu JB, Sun XB, Dai DX, Zhu SK, Chang QL, Liu SZ, Duan WJ; (4) PMID (e.g. 14606064). Provide the full abstracts of these references, as quoted from PubMed on a 3.5 inch disk or CD-ROM in Microsoft Word format and send by post to The *WJG* Press. For those references taken from journals not indexed by *Index Medicus*, a printed copy of the first page of the full reference should be submitted. Attach these references to the end of the manuscript in their order of appearance in the text.

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean±SD and mean±SE.

Statistical expression

Express *t* test as *t*(in italics), *F* test as *F*(in italics), chi square test as χ^2(in Greek), related coefficient as *r*(in italics), degree of freedom as γ (in Greek), sample number as *n*(in italics), and probability as *P*(in italics).

Units

Use SI units. For example: body mass, m(B) = 78 kg; blood pressure, p(B)=16.2/12.3 kPa; incubation time, t(incubation)=96 h, blood glucose concentration, c(glucose) 6.4±2.1 mmol/L; blood CEA mass concentration, p(CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23,243,641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italicization

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc*.

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc*.

Biology: *Helicobacter pylori, H pylori, E coli, etc*.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the WJG Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

It is the policy of WJG to acquire copyright in all contributions. Papers accepted for publication become the copyright of WJG and authors will be asked to sign a transfer of copyright form. All authors must read and agree to the conditions outlined in the Copyright Assignment Form (which can be downloaded from http://www.wjgnet.com/wjg/help/9.doc).

Final check list for authors

The format is at: http://www.wjgnet.com/wjg/help/13.doc

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: http://www.wjgnet.com/wjg/help/10.doc

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Publication fee

Authors of accepted articles must pay publication fee.

Abstract

AIM: To review the cases reported in the literature, examined their clinicopathological features, and evaluated the efficacy of different therapeutic modalities for this rare condition.

METHODS: A search of the MEDLINE database revealed 16 cases of pericarditis carcinomatosa (PC) originating from GC reported in the literature between 1982 and 2005. Additional detailed data were obtained from the authors of these studies for subsequent clinicopathological investigation. We have also described about a case study from our own clinic.

RESULTS: The mean age of cases with pericarditis carcinomatosa originating from GC was 54 years. Females were diagnosed at a younger age (46.3 years) compared to males (58 years). The mean survival period after diagnosis was 4.5 mo. No statistical differences in the length of survival time were found between different therapeutic modalities, such as drainage, and local and/or systemic chemotherapy after drainage. However, three cases who underwent systemic chemotherapy survived for more than 10 mo. Cases that developed metachronous cardiac tamponade for more than 2 years after the diagnosis of GC generally survived for a longer period of time, although this was not statistically significant. Multivariate analysis revealed that low levels of carcinoembryonic antigen (CEA), and CEA and/or cancer antigen 19-9 (CA 19-9) were associated with longer survival.

CONCLUSION: Cases with low levels of CEA, and CEA and/or CA 19-9 should undergo systemic chemotherapy with or without local chemotherapy after drainage.

INTRODUCTION

Malignant pericardial effusion typically develops slowly and can spontaneously regress or remain stable. Some cases, however, may progress to cardiac tamponade[1]. Pericardial effusion can be caused by common primary malignancies that metastasize to the pericardium, such as lung cancer, lymphoma, breast cancer, and leukemia[2-4]. Cardiac tamponade due to pericarditis carcinomatosa (PC) originating from a primary gastric cancer (GC) is a rare condition. It is usually detected during the terminal stages of GC; however, it is also detected during cardiac emergencies. There are several reports of cardiac tamponade due to GC; however, most of them are only case reports. Due to the limited number of cases seen in a single institute, we performed a clinicopathological study of the cases of PC originating from GC reported in the literature, including a case from our hospital, and investigated the best therapeutic modality for this rare condition.

MATERIALS AND METHODS

A search of the MEDLINE database revealed 16 cases of PC originating from GC reported in the literature and meeting proceedings between 1982 and 2005 (Table 1)[5-15]. Cases in which PC was synchronous with GC and its recurrence were included. In addition, we asked the authors of these studies to review the available medical records to obtain more information about the cases.

A 36-year-old female patient, diagnosed with Kruckenberg's tumor, who consulted our clinic for further examination, was included in this case study. Endoscopic examination revealed GC of the antrum. The patient underwent distal gastrectomy with lymph node dissection. Histological examination showed that signet-ring cell carcinoma was mostly confined within the mucosal layer and had slightly invaded the muscular layer. Histology also showed lymph node metastases in a wide area with

Cases 11, 13 and 14 were cited from meeting proceedings.

massive permeation into the lymphatic vessels. The patient underwent postoperative chemotherapy of sequential methotrexate plus 5-fluorouracil. Twenty-seven and a half months after the operation, she developed nausea and laboratory data showed elevated levels of aspartate aminotransferase (95 IU/L), alanine aminotransferase (152 IU/L) and alkaline phosphatase (312 IU/L). An abdominal CT scan revealed massive pericardial effusion and left pleural effusion. The patient underwent pericardiocentesis and left pleural centesis. Cytological examination of the fluid revealed signet-cell carcinoma. After drainage, 10 mg of cisplatin was infused into the pericardial space. The pericardial effusion subsequently disappeared. She underwent injection chemotherapy into the pleural space (135 mg cisplatin) and systemic chemotherapy (cisplatin and sequential methotrexate plus 5-fluorouracil) until the pericardial effusion reappeared 9.5 mo later. Pericardiocentesis was performed again and 150 mg cisplatin was infused into the pericardial space. She also underwent systemic chemotherapy, however, died 13 months after the onset of PC.

Survival curves were generated using the Kaplan-Meier method and compared using the log-rank test. Multivariate Cox regression analysis was used to identify factors independently associated with mortality. For multivariate analysis, all factors were dichotomized: gender (male, female), time interval between diagnosis of gastric cancer and diagnosis of cardiac tamponade (<24 mo including synchronous cases, >24 mo), carcinoembryonic antigen (CEA) levels (<5.0, >5.0 ng/mL), cancer antigen 19-9 (CA 19-9, <40 U/mL, >40 U/mL), and systemic chemotherapy (done, not done). Using the Pearson's χ^2 test, differences in proportions were evaluated. $P<0.05$ was considered statistically significant.

RESULTS

The clinicopathological features of cardiac tamponade due to PC originating from GC are presented in Table 2. More than half of the patients were males, an occurrence similar to that generally seen in GC. The mean age of the 17 cases was 54 years (range, 33-69 years). Females diagnosed with cardiac tamponade tended to be younger (mean, 46.3 years; range, 33-65 years) as compared with the males (mean, 58 years; range, 42-69 years). Of the 17 cases, 14 died within 6 mo of diagnosis. Figure 1 shows the Kaplan-Meier survival curve for all the 17 cases. The mean survival after the diagnosis of PC was 4.5 mo (range: 1.0-14.0 mo). Histological data was obtained for 12 of the cases. Of these, 11 were of the less differentiated type. Eleven of the twelve cases also showed lymphatic permeation, and nine showed lymph node metastasis.

The different treatments used after the diagnosis of cardiac tamponade and the survival of the corresponding cases are shown in Table 3. Six cases underwent pericardiocentesis only, and the mean survival after the diagnosis of cardiac tamponade was 3.3 mo. Eleven cases underwent local infusion chemotherapy targeting the pericardial space and/or systemic chemotherapy following pericardiocentesis. The mean survival periods of the cases treated with local chemotherapy, systemic chemotherapy, and combined local and systemic chemotherapy were

The histological types, "T", "ly", "v", and "n", are defined in the General Rules for the Gastric Cancer Study by Japanese Research Society for Gastric Cancer[26]. sig: signet-ring cell carcinoma; por: poorly differentiated carcinoma; ud: undifferentiated carcinoma; and tub: tubular adenocarcinoma.

For T which represents depth of cancer invasion, 1: mucosal and submucosal layer; 2: proper muscular and subserosal layer; 3: expose to serosal layer; and 4: invasion to the adjacent organ.

For ly and v which represent lymphatic permeation and venous permeation, respectively, 0: none; 1: slight; 2: moderate; and 3: massive.

Table 3 Treatment and corresponding mean survival time after the diagnosis of cardiac tamponade

Modalities	*n*	Mean survival (mo)
Drainage only	6	3.3
Drainage+chemotherapy		
Local only	4	2.3
Systemic+local	4	8.4
Systemic only	3	5.0

Local: local infusion chemotherapy into pericardial space.

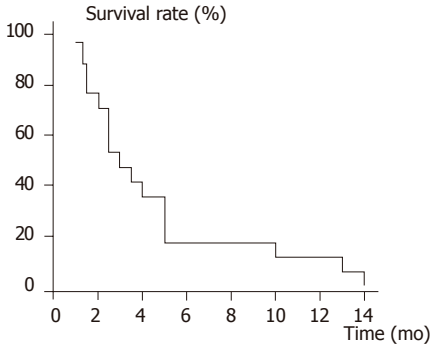

Figure 1 Kaplan-Meier survival curve of all cases (*n* = 17).

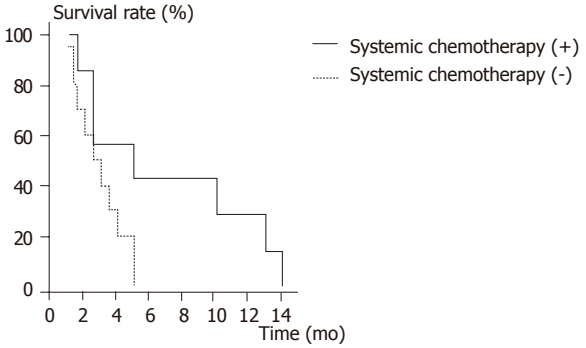

Figure 2 Kaplan-Meier survival curve according to administration of systemic chemotherapy. The cases treated with systemic chemotherapy were more likely to survive longer (*P* = 0.0579) than those who were not treated with systemic chemotherapy.

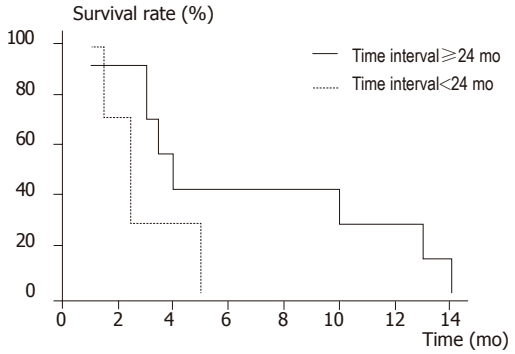

Figure 3 Kaplan-Meier survival curve according to time period between the diagnosis of gastric cancer and diagnosis of cardiac tamponade. The cases in whom cardiac tamponades were diagnosed for more than 24 mo after the diagnosis with gastric cancer were more likely to survive longer than those in whom cardiac tamponade was diagnosed for less than 24 mo after the initial diagnosis of gastric cancer. However, there was no statistical difference between the two groups (*P* = 0.1130).

2.3, 5.0, and 8.4 mo, respectively. All the three cases who had survived for more than 10 mo underwent systemic chemotherapy (two cases: local and systemic; one case: systemic only).

Statistical analyses of the prognostic factors are presented in Table 4. Cases treated with systemic chemotherapy tended to survive longer (6.9 mo) than those who were not treated with systemic chemotherapy (*P* = 0.0579; Figure 2). The mean survival period of the cases that developed cardiac tamponade within 2 years after the diagnosis of primary GC, including one synchronous case, was 2.9 mo. This was shorter than the cases in which the onset of cardiac tamponade occurred 2 years after the diagnosis of GC (6.9 mo). However, there were no statistical differences between the two groups (*P* = 0.1130; Figure 3). The mean

survival periods of cases with high levels (>5.0 ng/mL) and normal levels (<5.0 ng/mL) of CEA were 6.3 and 1.9 months, respectively (P = 0.0071; Figure 4). The mean survival periods of cases with high levels (>40 U/mL) and normal levels (<40 U/mL) of CA 19-9 were 2.8 and 7.4 months, respectively (P = 0.1074). The cases in which either CEA and/or CA 19-9 were elevated at the time of cardiac tamponade had shorter survival periods (2.6 mo) as compared with the cases without CEA and/or CA 19-9 elevation (8.6 mo) (P = 0.0244). Multivariate analysis also revealed that high levels of CEA and CEA and/or CA 19-9 were associated with poor survival (P = 0.029 and 0.049, respectively; Table 5).

DISCUSSION

Secondary tumors of the heart and/or pericardium are rarely diagnosed in clinical practice. However, it is not uncommon to find these during autopsy cases. Secondary cardiac metastases most frequently arise from primary lung tumors. Primary GC rarely metastasize to the heart, with 4.3-7.7%[16-19] reported from autopsy investigations.

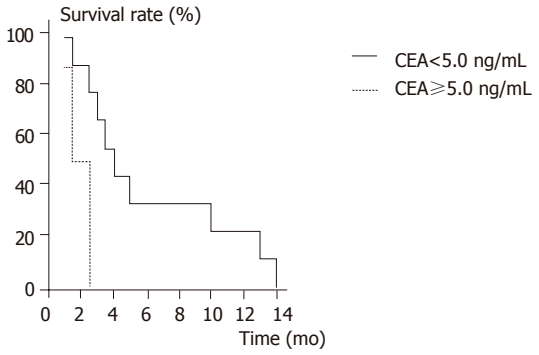

Figure 4 Kaplan-Meier survival curve according to CEA levels. The cases with normal CEA levels had a longer survival period as compared to those with high CEA levels (P = 0.0071).

We investigated 17 reported cases of cardiac tamponade due to PC originating from GC, and observed several characteristics specific to this condition. The mean age of the patients was 54 years, which was slightly younger than the average age reported for GC. Females tended to be diagnosed at a younger age than males. Histopathological results of 11 out of the 12 cases showed less differentiated tumors with massive lymphatic involvement. Raven[20] and Hanfling[21] reported that the hematogenous route was the most common metastatic pathway to the heart, while Warren and Gates[22] and Kline[23] believed that the cardiac lymphatic system was the major metastatic pathway to the heart. The fact that almost all cases showed massive lymphatic permeation suggested that the mechanism of pericardial metastasis might be through the lymphatic system.

There is no defined therapy for pericardial metastasis. Most reports describing therapeutic modalities for cardiac tamponade due to malignant pericarditis were based on cases in which lung cancer was the primary tumor. Drainage of the malignant effusion either by percutaneous pericardiocentesis or by pericardiectomy should be performed if this condition is diagnosed. The prognosis of cardiac tamponade caused by malignant pericarditis is grave and survival is limited. Fraser *et al*.[24] reported the prognosis of 21 cases and more than half of the 21 cases originated from lung cancer. Seven patients treated with pericardiocentesis and provided with supportive care had a median survival time of 3 wk. Eight patients treated with pericardiocentesis and either radiotherapy and/or intrapericardial or systemic chemotherapy had a median survival period of 3.5 mo. Six patients treated with pericardiocentesis and pericardiectomy with or without radio- or chemotherapy had a median survival period of 6 mo. Moreover, Appelqvist *et al*.[1] reported the prognosis of three cases of pericardiectomy. Among them, two cases had primary lung cancer, while the primary tumor was of unknown origin in the third case. The case who did not undergo treatment only survived for 5 wk, the case treated with radiotherapy survived for 7 wk, and the case treated with systemic chemotherapy survived for 9 mo[1].

To our knowledge, there are no reports investigating the different therapeutic modalities available for the treatment of cardiac tamponade originating from GC. Our review of the literature showed that the therapeutic modalities in 6 cases were only the drainage of malignant effusion, while the 10 cases underwent chemotherapy after the drainage. In addition, the chemotherapy treatment varied in the cases with the routes of administration of anti-cancer agents (e.g., intrapericardial infusion and/or systemic administration), the type of anti-cancer agents, and the dose of anti-cancer agents. More than half of the cases treated with local chemotherapy received various doses of cisplatin. We found that there were no complications caused by local chemotherapy in our review of the literature, and cisplatin was the most frequently used agent for local chemotherapy. The agents used for local chemotherapy should be less irritable to the heart. As the number of cases was limited, we were unable to determine which treatment was the most effective for this condition. However, we did find that cases treated with systemic chemotherapy tended to survive longer than those who were not ($P = 0.0579$).

The period of time from the diagnosis of gastric cancer to the onset of cardiac tamponade may influence prognosis. When the time period was less than 2 years, the survival was 2.9 mo, and if the time period was over 2 years, the survival increased to 6.9 mo. The cases with high levels of either of the tumor markers CEA or CA 19-9 had a shorter survival period than those with low levels of either of these markers.

Honda *et al*.[25] reported a case of cardiac tamponade originating from lung cancer, in which the malignant cardiac effusion was controlled by weekly paclitaxel therapy. Sakusabe *et al*.[15] also reported that weekly administration of paclitaxel was effective for the control of malignant pericardial effusion originating from GC. There are many reports demonstrating that malignant ascites arising from GC can be controlled by paclitaxel in patients diagnosed with peritonitis carcinomatosa of GC. We confirmed that the level of paclitaxel in malignant ascites remained effective until 72 h after systemic administration (submitted for publication). Paclitaxel may, therefore, be a promising agent for systemic chemotherapy, and should be considered for the treatment of malignant pericardial effusion.

In summary, we were unable to reveal which therapy was the best for extending the life expectancy in cases of PC originating from GC. However, the cases with systemic chemotherapy survived for a longer period of time compared to the cases treated with drainage only or with local chemotherapy. The cases that developed cardiac tamponade due to PC arising from GC more than 2 years after the diagnosis, and the cases in which the levels of CEA and CA 19-9 were not elevated may have a possibility of surviving for a longer period of time. Such cases should undergo chemotherapy following emergency pericardiocentesis. While a specific chemotherapeutic strategy has not yet been developed for these cases, the use of paclitaxel for systemic, and cisplatin for local chemotherapy may be promising for the treatment of cardiac tamponade caused by PC arising from GC.

Abstract

AIM: To investigate the usefulness of sucrose permeability test using serum in the diagnosis of gastric diseases, with special reference to early gastric cancer (EGC).

METHODS: A total of 63 subjects, including 11 patients with gastric ulcer, 20 patients with gastric cancer (13, early; 7, advanced) and 32 healthy controls, were studied. Blood and urine samples were collected repeatedly for 5 h before and after the sucrose loading. Sucrose levels were measured by a newly developed enzymatic method.

RESULTS: Serum sucrose levels started to increase 15 min after loading, and peaked at 60 min in the gastric disease groups. The levels for gastric ulcer, EGC and advanced gastric cancer (AGC) at 60 min were significantly higher than that in the healthy controls (26.9±2.4, 34.4±5.0, and 71.8±15.6 *vs* 7.9±0.7 mol/L, respectively, $P<0.01$). The cut-off level set at 15.4 mol/L (60 min) offered the best distinction between EGC patients and healthy controls; and the sensitivity and specificity were 92.3% and 93.8%, respectively, while those of the urine method were 76.9% and 93.8%, respectively.

CONCLUSIONS: The gastric permeability test using serum is reliable for the detection of EGC, and this test can provide results much earlier than the conventional urine method. This test may offer a useful alternative to more invasive tests for EGC.

Key words: Sucrose test; Gastric permeability; Early gastric cancer; Advanced gastric cancer; Gastric ulcer

INTRODUCTION

In 1993, Meddings *et al.*[1], proposed the sucrose permeability test as a new non-invasive test for evaluating gastroduodenal injury. This test is based on the principle that sucrose does not permeate the healthy gastric mucosa and is rapidly dissolved in the small intestine, whereas it permeates and is absorbed through sites of injury in the stomach, enters the bloodstream and is excreted into the urine. It is reported that this test is useful for diagnosing gastric ulcer or gastroduodenal injury caused by NSAIDs or steroids[2-6]. Furthermore, it has been demonstrated that sucrose permeability is elevated by infection with *H pylori* or celiac disease, reflecting mucosal injury associated with inflammatory cell infiltration; thus, the usefulness of this test in evaluating gastroduodenal injury has been established[4,7,8].

However, the conventional method is not practical for outpatients or for health screenings because urine must be collected for 5 h or longer after the sucrose loading. If the sucrose test could be done in a shorter period of time, its clinical usefulness would increase.

We recently developed a novel enzymatic assay that is sensitive enough to determine serum levels of sucrose accurately[9]. The changes of serum sucrose levels after ingestion in patients with gastric diseases, as in healthy subjects, are unknown. Therefore, the first aim of this study was to investigate the changes of serum sucrose levels in healthy subjects, patients with gastric ulcer and gastric cancer. The second aim was to identify the most suitable time to collect serum samples for the detection of gastric disease.

There are reports that gastric mucosal permeability is elevated in patients with advanced gastric cancer (AGC), but none regarding those with early gastric cancer (EGC). The third aim of this study was to evaluate the diagnostic value of the sucrose test using serum in patients with EGC.

MATERIALS AND METHODS

Patients

The subjects studied included: (1) 32 healthy volunteers (HV: 15 men and 17 women; mean age 51.0 years, range 35-65 years) without symptoms or a history of gastrointestinal disease, who had not been prescribed any medicine that might have affected the gastrointestinal system; and (2) a gastric disease patient group composed of 31 patients, including 11 with gastric ulcers (GU: 5 men and 6 women; mean age 55.5 years, range 24-80 years; mean long diameter 1.4 cm, range 0.8-2.0 cm), 13 with EGC (11 men and 2 women; mean age 73.5 years, range 61-87 years; depth of invasion Tis in 11, T1 in 2; mean long diameter 1.55 cm, range 0.8-3.5 cm), and 7 with AGC (3 men and 4 women; mean age 65.0 years, range 48-75 years; depth of invasion T2 in 3, T3 in 2, and unknown in 2; mean long diameter 7.7 cm, range 4.3 cm-whole stomach). The depth of invasion of the gastric cancer was judged by pathological exploration of the resected mucosal specimens and the surgical specimens (Table 1).

Table 1 Clinical data of subjects studied

	HV (n = 32)	GU (n = 11)	EGC (n = 13)	AGC (n = 7)
Age (yr)	51 (35-65)	55.5 (24-80)	73.5 (61-87)	65 (48-75)
Gender (M:F)	17:15	5: 6	11: 2	3: 4
Size (cm)	-	1.4 (0.8-2.0)	1.55 (0.8-3.5)	7.7 (4.3-whole stomach)
Invasive Depth	-	-	Tis:T1=11:2	T2:T3:unknown = 3:2:2

HV: healthy volunteers, GU: Gastric ulcers, EGC: early gastric cancers, AGC: advanced gastric cancers.
Tis = mucosa, T1 = submucosa, T2 = proper muscle and subserosa, T3 = serosa.

The gastric mucosa was resected in patients with EGC, when considered, on the basis of endoscopic diagnosis including endoscopic ultrasonography, to be an intramucosal lesion. In two cases of EGC that were judged to have invaded as far as the deep submucosa, and in five cases of AGC, surgery was performed, while the remaining two cases were treated non-surgically. Two cases in which the depth of invasion could not be determined histopathologically were diagnosed endoscopically as AGC. Patients with diabetes mellitus or reduced renal function were excluded.

Informed consent was obtained from every subject. This study was performed with the approval of the Ethical Committee of Chiba University School of Medicine, Japan.

Gastric permeability

After an overnight fast, patients and HV were given a solution composed of 100 g sucrose and 450 mL water for 15 min. Blood samples were collected before and at 15, 30, 45, 60, 75, 90, 120, 180, 240, and 300 min after the sucrose loading. The blood samples were immediately centrifuged and the sera were obtained. Simultaneously, urine was collected for over a period of 5 h after the sucrose loading and the amount of sucrose excreted during the 5-h period was obtained from the volume of urine and the concentration of sucrose. Sera and urine were stored at -20 °C until the assay.

Assay

Sucrose was phosphorylated by the action of sucrose phosphorylase. The subsequent reaction in the presence of phosphoglucomutase and glucose-1, 6-diphosphate formed glucose-6-phosphate. Finally, the sucrose of the monad formed the dyad thio-NADPH. The reaction was monitored by changes in absorbance at 405 nm. The details of the assay procedures are published elsewhere[9].

Statistical analysis

Data were expressed as mean±SE. Using ANOVA, the serum sucrose concentration before and after the administration of sucrose in each group was compared. Serum sucrose concentrations at each sampling time within each group and comparison by the urine collection method within each group were compared using Tukey's method. Comparison of diagnostic ability based on areas under the receiver operator characteristics (ROC) curve at each sampling point was carried out using Hanley's method[10]. Cut-off points based on the ROC curve at each time point were set to obtain sensitivity, specificity, and accuracy. The surface area of GC was calculated using the formula (1/4×π×long diameter×short diameter) on the assumption that the tumor was elliptical. The relationship between the surface area of EGC and the serum sucrose level was determined. A two-sided P value <0.05 was considered statistically significant.

RESULTS

Baseline serum sucrose concentrations were 2.4±0.4, 2.9±0.8, 1.4±0.7, and 1.6±1.4 μmol/L for the HV, GU, EGC and AGC, respectively, which showed no significant intergroup differences. The peak serum sucrose level for the HV was 8.5±0.8 μmol/L at 120 min after the sucrose loading. Serum sucrose levels for the GU, EGC and AGC, which increased 15 min after the sucrose loading (P<0.01), peaked between 45 and 120 min, and then gradually decreased (Figure 1). Serum sucrose levels for GU, EGC and AGC showed a significant difference from the HV (P<0.01) between 60 and 240 min. Between 15 and 300 min, serum sucrose levels for AGC showed a significant difference from those for EGC or GU (P<0.01). However, there was no significant difference between the serum sucrose levels for EGC and GU at any time point from 15 to 300 min.

The amounts of sucrose excreted into the urine in HV, GU, EGC and AGC were 50.5±4.4, 172.9±19.1, 165.1±27.2, and 464.5±78.9 mg, respectively, showing significantly higher values in GU, EGC and AGC as compared to the HV. In addition, the amount of sucrose excreted into the urine in AGC showed a significantly higher value than that

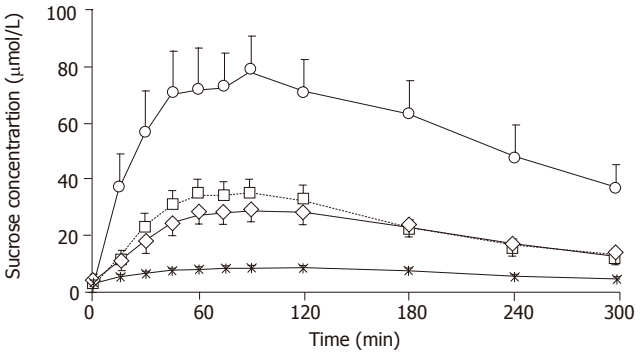

Figure1 Changes in serum sucrose level in HV, GU, EGC, and AGC groups (mean ±SE). The serum sucrose level in EGC group (□) showed a significant difference between 30 and 300 min after the sucrose loading as compared to the HV group (⁎) between 30 and 240 min (P<0.01) and 30 and 300 min (P<0.05). The serum sucrose level of AGC (○) patients showed a significant difference from HV (⁎) between 15 and 300 min after sucrose loading, GU (◇) and EGC (□) (P<0.01). GU patients (◇) showed a significant difference from the HV group ( ) between 45 and 240 min after sucrose loading (45 min, P<0.05; from 60 to 240 min, P<0.01). However, there was no significant difference in serum sucrose level in HV group from 15 to 300 min after loading as compared with either EGC (◇) or GU (□) group.

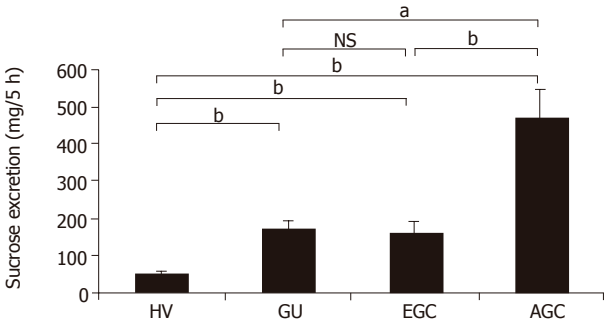

Figure 2 Amounts of sucrose excreted into urine in HV, GU, EGC and AGC groups (mean±SE). Even in the urine collection method, the amount of sucrose excreted in GU, EGC and AGC groups showed a significant difference (^bP<0.01) as compared with the HV group, and AGC group showed a significant difference (^bP<0.01) from both GU and EGC groups. However, no significant difference was seen in either EGC; NS: no significant difference.

in GU or EGC (Figure 2).

The diagnostic value of the sucrose test in gastric disease (GU, EGC and AGC) in relation to HV was compared between the serum method and the urine collection method using ROC curves (Figure 3). The areas under the curve (AUC) in the serum method at 15 and 60 min, and in the urine collection method were 0.876 (95%CI 0.783-0.968), 0.992 (95%CI 0.978-1.006), and 0.980

	AUC	SE	95% CI	
			Lower limit	Upper limit
Urine (5 h)	0.98	0.014	0.953	1.006
0 min	0.366	0.072	0.226	0.506
15 min	0.876	0.047	0.783	0.968
30 min	0.951	0.024	0.904	0.998
45 min	0.979	0.014	0.952	1.005
60 min	0.992	0.007	0.978	1.006
75 min	0.994	0.006	0.983	1.005
90 min	0.993	0.006	0.981	1.006
120 min	0.989	0.01	0.97	1.008
180 min	0.971	0.017	0.937	1.005
240 min	0.973	0.016	0.941	1.004
300 min	0.959	0.022	0.917	1.002

Figure 3 Receiver operator characteristics (ROC) curve and AUC of ROC curve. Comparison of the ROC curve of the sucrose test and AUC at each time point. There was no significant difference between the urine collection method and the serum method from 30 to 300 min. AUC: Area under the ROC curve; SE: standard error; CI: confidence interval.

(95%CI 0.953-1.006), respectively (Figure 3). Comparison of the AUC between the urine collection method and the serum method at every time point showed no significant difference. The diagnostic values of the urine collection method and the serum method were comparable from 30 min onward at each sampling time.

Cut-off points for the detection of gastric disease at each sampling time in the serum method were obtained from the ROC curves, and the diagnostic value of this method was also obtained. Similarly, cut-off points and diagnostic values were obtained by the urine collection method (Table 2). The cut-off points for the detection of gastric disease by the serum method over 60 min was 15.4 μmol/L and that of the urine collection method was 95 mg. Serum sucrose levels of the four studied groups at 60 min are shown in Table 3.

The sensitivity, specificity, and overall accuracy of the urine collection method for detecting gastric disease were 90.3%, 93.8%, and 92.1%, respectively, while those

	HV	GU	EGC	AGC
Mean (μmol/L)	7.6	26.9	34.4	71.8
SE (μmol/L)	0.7	2.4	5.0	15.6

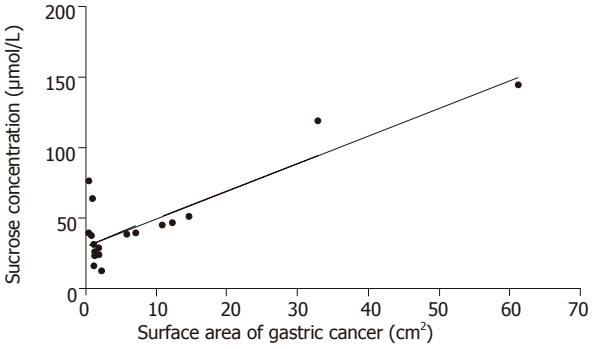

Figure 4 Relationship between serum sucrose level at 60 min and surface area of gastric cancer. The serum sucrose level at 60 min was closely correlated with the surface area of the gastric cancer (r = 0.83, P<0.01).

for the serum method (over 60 min) were 96.8%, 93.8%, and 95.2% (Table 4), indicating that the serum method was superior to the urine collection method, but not so significantly.

Sensitivity in detecting GU and AGC was 100% by using both the methods. Sensitivity in detecting EGC was 76.9% by the urine collection method, but 92.3% by the serum method (60 min), which was relatively high, but again without a significant difference.

There was a significant correlation between the surface area of GC and the serum sucrose level (60 min) (r = 0.83) (Figure 4).

DISCUSSION

The sucrose permeability test is a valuable noninvasive test for detecting gastroduodenal injury[1-8,11-13]. The conventional method involves measuring the amount of sucrose excreted into the urine for over a period of as long as 5 h following the administration of sucrose. If this test could be done more quickly, its clinical usefulness would increase greatly.

Vinet *et al*.[14] reported that the serum concentrations of sucrose after sucrose loading in volunteers whose stomachs had been injured by NSAIDs or alcohol clearly increased, and that this occurred only after 15-45 min. We considered that it might be useful in clinical practice to measure the sucrose concentration in the serum instead of the urine. However, the pattern of the changes of serum sucrose levels after sucrose ingestion either in healthy subjects or in patients with gastric diseases was unknown. Moreover, the appropriate time point for collecting serum samples was not known, nor was the usefulness of serum testing for detecting gastric diseases. We conducted this fundamental study for these reasons.

We took advantage of a novel enzymatic method that we had recently developed for measuring serum sucrose levels. Previously, the concentration of sucrose in biological fluids was measured by high-performance liquid chromatography (HPLC) with an electrochemical technique for detection[1-7,11], or by an enzymatic assay[8,14,15] in which invertase hydrolyzes sucrose to fructose and glucose, and then the glucose is measured using a hexokinase procedure with reduced nicotinamide adenine dinucleotide phosphate formation. But the invertase method is not applicable to serum samples because of interference by the glucose in the samples. The HPLC method is accurate and widely used, but is labor-intensive, costly, and time-consuming.

We collected blood specimens at 11 different sampling times from 63 individuals and examined the changes in serum sucrose and the time point appropriate for the detection of mucosal injury. There was no significant difference in diagnostic value between the urine collection method and the serum method at any determined time point between 30 and 300 min. Thus, it may be possible to detect a gastroduodenal injury using serum at any determined point between 30 and 300 min after sucrose loading. In particular, because the accuracy at 60, 75, 90, and 120 min was greater than 95%, which was higher than that for the urine collection method, it should be satisfactory to carry out sampling for the serum method only at 60 min in order to obtain more reliable results more quickly. On the basis of these results, we were able to shorten the sucrose test, and to increase its diagnostic accuracy.

All cases of GU were detected when the serum method was carried out for 60 min. Although GU is a benign disease, medical treatment is essential, and GU must be distinguished from cancer. In this respect, the high detection rate of GU by the serum method will not reduce the significance of this test for the screening of gastric cancer.

The average age of patients with GC in this study was higher than those of HV and GU patients, but there was no significant age-related difference in the sucrose level within each group (data not shown), because the inter-group age differences had little effect on the outcome.

Table 4 Sensitivity of sucrose permeability test for each gastric disease

Time (min)	Urine	15	30	45	60	75	90	120	180	240	300

AGC	100	100	100	100	100	100	100	100	100	100	100

[1]Cut-off points: Urine, as mg/5 h; serum, as μmol/L

We observed a significant relationship between the surface area of the gastric cancer and sucrose permeability even in cases without ulcer formation. This observation is exceedingly interesting and indicates some process of active absorption of sucrose through unhealthy gastric mucosa. This finding should be tested *in vitro*.

Using the conventional urine collection test for sucrose permeability, Kawabata *et al*.[11] reported an abnormally high sucrose permeability in 11 of 12 patients with advanced gastric cancer, which was significantly higher than that of a healthy control group. However, the diagnostic significance of this test for patients with early gastric cancer has not been elucidated. The results of our study clearly demonstrated that the sucrose test can detect not only AGC but also EGC.

When early gastric cancers are limited to the mucosal layer, they are frequently subjected to endoscopic submucosal dissection (ESD), and can be treated without conventional surgery[16,17]. In this study, 10 of the 11 patients who underwent ESD showed positive results with the sucrose test.

Gastric cancer is the second largest cause of cancer death throughout the world[18]. Contrast-enhanced upper gastrointestinal radiography has been widely used as the screening test for gastric cancer in Japan, but its diagnostic value regarding EGC is considered to be low[19]. The serum pepsinogen method is a new screening test for gastric cancer, but it was reported that the test failed to detect a considerable proportion of patients with advanced gastric cancer[19,20]. In this study, our results clearly demonstrated that the sucrose test on the serum had a higher sensitivity rate for EGC than any other non-invasive test reportedly used for screening purposes. Furthermore, the diagnostic sensitivity of the test for AGC was 100%.

In conclusion, the sucrose test conducted on the serum is a very promising screening test for gastric cancer. Since the serum method can be performed much more easily with an automatic analyzer, it can be used for mass screening of a large number of samples. Confirmatory large-scale prospective studies comparing this method with other methods used in mass screenings are still needed before definite recommendations can be made regarding the significance of the test in screening for gastric cancer, especially EGC.

Abstract

AIM: To investigate the effects of catalytically superior gene-directed enzyme prodrug therapy systems on a rat hepatoma model.

METHODS: To increase hepatoma cell chemosensitivity for the prodrug 5-fluorocytosine (5-FC), we generated a chimeric bifunctional SuperCD suicide gene, a fusion of the yeast cytosine deaminase (YCD) and the yeast uracil phosphoribosyltransferase (YUPRT) gene.

RESULTS: *In vitro* stably transduced Morris rat hepatoma cells (MH) expressing the bifunctional SuperCD suicide gene (MH SuperCD) showed a clearly marked enhancement in cell killing when incubated with 5-FC as compared with MH cells stably expressing YCD solely (MH YCD) or the cytosine deaminase gene of bacterial origin (MH BCD), respectively. *In vivo*, MH SuperCD tumors implanted both subcutaneously as well as orthotopically into the livers of syngeneic ACI rats demonstrated significant tumor regressions ($P<0.01$) under both high dose as well as low dose systemic 5-FC application, whereas MH tumors without transgene expression (MH naïve) showed rapid progression. For the first time, an order of *in vivo* suicide gene effectiveness (SuperCD>> YCD>>BCD>>>negative control) was defined as a result of a direct *in vivo* comparison of all three suicide genes.

CONCLUSION: Bifunctional SuperCD suicide gene expression is highly effective in a rat hepatoma model, thereby significantly improving both the therapeutic index and the efficacy of hepatocellular carcinoma killing by fluorocytosine.

Key words: YCD/YUPRT fusion; Cytosine deaminase; GDEPT; Suicide gene therapy; Hepatoma therapy

INTRODUCTION

Suicide gene therapy involves the transfer of genes into tumor cells to render them specifically sensitive to prodrugs that are relatively nontoxic to normal tissues. Cytosine deaminase (CD) enzyme is found in many bacteria, yeast and fungi, where it deaminates cytosine to uracil[1]. It also deaminates the relatively nontoxic prodrug 5-fluorocytosine (5-FC) to the highly toxic chemotherapeutic compound 5-fluorouracil (5-FU), used in the treatment of malignant tumors (Figure 1A)[2]. Transduction of the CD gene into tumor cells combined with systemic administration of 5-FC has been shown to have anticancer effects in various animal models[3-7]. Due to their inherent bystander effect, toxic 5-FU metabolites (Figure 1A) also reach non-transduced neighboring cells[8-10]. In contrast to the herpes simplex virus type 1 thymidine kinase/ganciclovir system, this bystander effect does not depend on gap junctional intercellular communication channels[11].

In this work, we focused on the optimization of the CD suicide gene system for hepatoma treatment. We

compared both *in vitro* and *in vivo* therapeutic efficiency of stable expression of: (1) a new bifunctional chimeric SuperCD suicide gene, composed of the yeast cytosine deaminase (YCD) suicide gene directly fused to a 5'-terminally deleted yeast uracil phosphoribosyltransferase (YUPRT) gene[12]; (2) YCD suicide gene; and (3) bacterial cytosine deaminase (BCD) suicide gene in the MH 3924A animal model[13].

MATERIALS AND METHODS

Retroviral vector construction

Genomic DNA of *Saccharomyces cerevisiae*, strain KFY159 (kindly provided by K.-U. Fröhlich, Physiologisch-Chemisches Institut, Eberhard-Karls-University, Tübingen, Germany), was employed to amplify YCD and YUPRT using polymerase chain reaction technique. YCD (*S. cerevisiae* gene FCY-1) was amplified with primers: 5'-G GGGTACCGCCACCATGGTGACAGGGGGAAT GGCAAG-3' (primer #1) and 5'-GGGCGGCCGCCT CACTCACCAATATCTTCAAA CCAATC-3' (primer #2). Alternatively, primer #3 (5'-GGGAATTCTCACC AATATCTTCAAACCAATC-3') was used as a reverse primer in combination with primer #1 to amplify the yeast FCY-1 gene. The latter YCD fragment was subsequently joined to a PCR product amplifying the yeast FUR-1 gene (YUPRT). While omitting the N-terminal domain, the remaining domains of the YUPRT open reading frame, enzymatically sufficient for efficiently transferring the phosphoribosyl residue to the deaminated 5-FC[14], were amplified with primers: 5'-CCGAATTCGGAACCATTTA AGAACGTC-3' (primer #4) and 5'-CCGCGGCCGCCTT AAACACAGTAGTATCTGTCACC-3' (primer #5). Both PCR fragments were purified for subsequent ligation as recently described elsewhere[15]. Subsequently, both YCD and YUPRT PCR amplification products were combined in a three-fragment ligation procedure employing a pUC-based cloning vehicle as a backbone. This intermediate construct was used to remove the *Eco*RI site between the YCD and YUPRT sequences and at the same time to generate the bifunctional SuperCD suicide fusion gene employing a site-directed mutagenesis using the Promega QuikChange method (Promega, Mannheim, Germany). With sense and anti-sense mutagenesis primers (sense sequence: 5'-ATGGTTTCCGAAGCCTCACCAATAT CT-3'), the two enzymatic moieties were joined in-frame, resulting in an Ala residue linking the two yeast ORFs (now with the YUPRT gene starting at the natural S38 codon). Subsequently, the following retroviral constructs were generated (Figure 1B): (1) pLXSN-BCD contains the *E. coli* cytosine deaminase (BCD) suicide gene under the control of the retroviral 5´LTR in basic retroviral vector pLXSN[16] (kindly provided by R.M. Blaese, NIH, Bethesda, MD, USA; originally denominated as pCD2)[17]; (2) pLXSN-YCD harboring the YCD suicide gene was generated by the insertion of the YCD PCR amplification product into basic vector pLXSN-GreeN (derivative of vector pLXSN, in which we exchanged the neo^r gene by a bifunctional EGFP/neo^r fusion gene); (3) pLXSN-SuperCD harboring the bifunctional SuperCD suicide fusion gene was generated by insertion of the YCD/YUPRT in-frame fusion fragment into basic vector pLXSN-GreeN.

Cell culture

Morris hepatoma (MH 3924A) cells were purchased from the German Cancer Research Center (DKFZ) Tumor Collection, Heidelberg, Germany, and maintained in DMEM supplemented with 50 mL/L fetal calf serum (FCS) in a humidified incubator containing 50 mL/L CO_2 at 37 °C.

Generation of stable BCD, YCD and SuperCD expressing Morris hepatoma 3924A cell lines

For the generation of suicide gene transducing retroviral particles, 5×10^5 PE501 ecotropic packaging cells were seeded on 60-mm diameter petri dishes. After 24 h, using lipofectAMINE reagent (Invitrogen), cells were transiently transfected with 3 μg of each retroviral vector DNA. Forty-eight hours later, the supernatant was employed for transduction of 3×10^5 naïve MH cells. Following G418 selection (600 μg/mL), resistant clones were analyzed for EGFP marker gene expression by fluorescence microscopy, followed by functional characterization of suicide gene expression in the sulforhodamin B (SRB) cytotoxicity assay. Cell clones exhibiting the highest cytotoxic effect were selected and named as MH BCD, MH YCD, and MH SuperCD.

Western blot analysis

Cells were lysed in SDS sample buffer and proteins were separated on 100 g/L SDS-PAGE and transferred to PVDF membranes[18]. Polyclonal rabbit antiserum directed against YCD (a generous gift from Transgene SA, Strasbourg, France), a polyclonal rabbit anti-BCD antibody (a generous gift from C. Richards, Glaxo-Wellcome, RTP, NC, USA)[19] and goat anti-rabbit IgG-horseradish peroxidase conjugates (BioRad, München, Germany) were used. Detection of reactive bands was facilitated using horseradish peroxidase-linked secondary conjugate and ECL detection reagents (Amersham Pharmacia, Freiburg, Germany).

SRB cytotoxicity assay

MH (naïve) as well as MH BCD, MH YCD, MH SuperCD cells were seeded in 24-well plates (1×10^4 cells/well). The next day 5-FC containing medium was added (a generous gift from Roche, Basel, Switzerland) and the cells were incubated for 4 d in order to allow untreated cells to reach confluence. Growth inhibition was evaluated by the SRB cytotoxicity assay[20] using a microtiter plate reader (Dynatech MR7000, Denkendorf, Germany) at 550 nm.

In vivo experiments

All animal experiments were performed in concordance with the laws of the German Government concerning the conduction of animal experimentation. Surgical and imaging procedures were performed under intraperitoneally applied anesthesia with ketamine hydrochloride (Ketanest,

Parke-Davis, Berlin, Germany; 100 mg/kg body weight) and xylazine hydrochloride (Rompun, Bayer, Leverkusen, Germany; 10 mg/kg body weight).

The subcutaneous MH naïve and MH SuperCD tumors were established by injecting 1×10^7 cells (in 70 μL PBS) at the dorsum of 6-wk-old male syngeneic ACI rats (Harlan Winkelmann, Borchen, Germany). Eleven days later the rats were randomized into two groups (3 rats/group), and were treated twice daily with ip injections of 5-FC (283 mg/kg body weight) or saline (0.9% NaCl) for 7 d. Tumor sizes were measured with calipers. Tumor volumes were calculated in cubic centimeter using the formula recommended by Carlsson *et al*.[21]: tumor volume (mm^3)=largest diameter (mm)×[smallest diameter (mm)]^2/2.

In order to monitor 5-FC serum levels by HPLC quantification, blood was taken via tail vein puncture on d 5 of the 5-FC application period. On d 8 of the treatment period, the animals were killed, and tumors were explanted and measured for tumor weight and volume. Tumor samples were analyzed for (1) the presence of SuperCD DNA and (2) the endurance of the SuperCD suicide gene functional activity. For PCR analysis, tumor sample DNA was extracted using DNeasy Tissue Kit (Qiagen, Hilden, Germany). MH SuperCD DNA was amplified using primers 5'-CGACCCCGCCTCGATCCTCC-3' (primer #6) and 5'-CTGCTGGGGAGCCTGGGGAC-3' (primer #7). PCR products were separated by electrophoresis on a 10 g/L agarose gel. For the functional testing of continuous suicide gene presence following the *in vivo* growth period of MH SuperCD tumors, tumor tissues were minced, placed into six-well plates and cultivated in DMEM medium containing 50 mL/L FCS, supplemented with 1% penicillin-streptomycin. Three days later, stably transduced MH SuperCD cells were selected by continuous addition of G418 (600 μg/mL). Two weeks later, the cells were analyzed for functional SuperCD gene activity employing the SRB cytotoxicity assay.

Orthotopic tumor implantation within the liver was performed as described elsewhere[13]. Twenty-one days later, tumor sizes were measured by magnetic resonance imaging (MRI). Subsequently, the rats were randomized into two groups (six rats/group) and were treated twice daily with ip injections of 5-FC (283 mg/kg body weight) or saline. On d 31, tumor sizes were again measured by MRI. Animals were killed, livers explanted and analyzed macroscopically for the presence of tumor tissue.

MRI measurements

Monitoring of tumor growth was performed by sequential MRI studies, using a 1.5 Tesla MR tomograph (VISION, Siemens, Erlangen, Germany). A turbospinecho sequence was applied to acquire T2 weighed images using the following parameters: 3.5 s repetition time, 96 ms echo time, field of view of 200 mm×100 mm. Fifteen slices with an in-plane resolution of 0.75 mm×0.75 mm, a slice thickness of 2 mm and a gap of 0.3 mm between the slices were acquired with six signal averages. Maximum areas of the tumors were determined by the identification of the tumor slice exhibiting largest diameters (main diameter *a* and minor diameter *b*), followed by the calculation of the respective area ($a/2\times b/2\times\pi$).

Statisticial analysis

Viability was explained by cell line, 5-FU concentration, and their interaction in analyses of variance. Square roots of counts were used as Box-Cox analyses and normal quantile-plots of residuals suggested so. Means and 95% confidence intervals were transformed back and divided by the fitted value of MH naïve cells. The *in vivo* experiment with four cell lines was analyzed by the analysis of covariance of logarithms of tumor sizes (considered censored at 30 mm² when below) with variable time factors, cell line and individual and different slopes for the cell lines. The hypotheses were: all four mean growth rates are equal, and mean growth rates of YCD and SuperCD cells are equal. As intra-individual comparison of cell lines was possible, all six possible combinations were implanted as in a balanced incomplete block plan. Sample size was planned to guarantee multiple power of more than 0.8 at effect size 30% and coefficient of variation 30%, while the multiple significance level was 0.05.

RESULTS

Through its toxic metabolites, 5-FU kills cells by binding to the thymidylate synthase, thereby causing a blockade of DNA synthesis as well as by directly interfering with the cellular RNA metabolism (Figure 1A). Because 5-FU is able to diffuse passively through cell membranes, it not only affects transduced cells, but also neighboring cells (so-called bystander cells). However, the conversion of 5-FU to 5-FUMP constitutes a rate-limiting step at least in some tumor cells[22]. In the context of suicide gene transfer, it is hypothesized that an additional encoding of the UPRT gene not only enhances tumor cell sensitivity to 5-FU, but also augments the sensitivity of tumor cells to 5-FC, when such cells are enabled to simultaneously express a CD gene (Figure 1A). Since also low tumor transduction efficiencies are recognized as a major limitation in liver tumor suicide gene therapy[23,24], 5-FC/CD/UPRT-based suicide gene systems could not only help to improve the effectiveness of 5-FC toxification, but also enhance the effectiveness of bystander killing, thereby helping to compensate for currently still low efficiencies of direct liver tumor suicide gene transfer. In this work, we therefore investigated whether hepatoma cell chemosensitivity for 5-FC could be enhanced by simultaneously addressing the two major steps of 5-FC metabolism. For this purpose, we first generated a so-called SuperCD fusion gene which combines the (1) enzymatic function of yeast CD (YCD) with (2) YUPRT-mediated phosphorylation of 5-FU to 5-FUMP (Figures 1A and B).

Construction of SuperCD/YCD/BCD suicide gene expressing retroviral vectors, and analysis of stably transduced Morris rat hepatoma cells

We employed genomic DNA of *S. cerevisiae* to amplify both yeast CD as well as yeast UPRT genes by PCR[22].

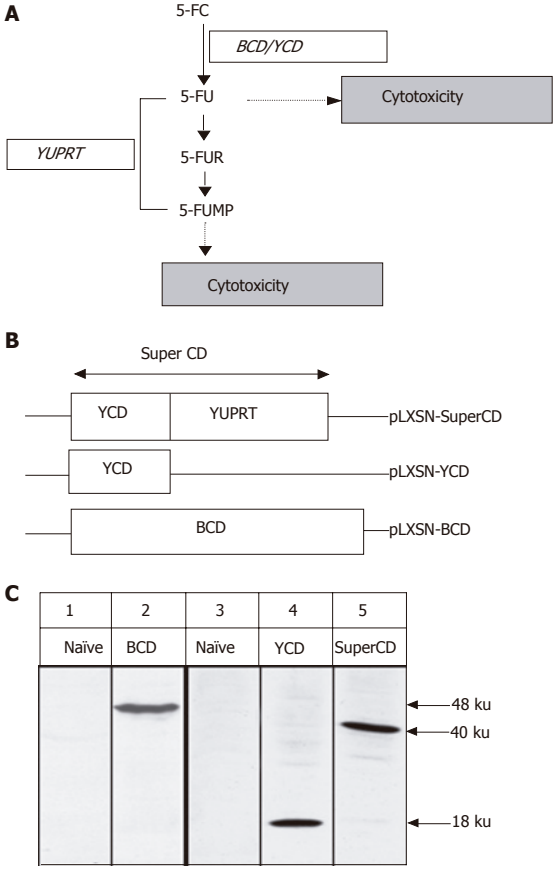

Figure 1 Mode of action of SuperCD (YCD::YUPRT) fusion. Panel **A**: Schematic representation of biological pathways resulting in cytotoxicity following cytosine deaminase/uracil phosphoribosyltransferase (UPRT)-mediated toxification of the prodrug 5-FC. 5-FC: 5-fluorocytosine; 5-FU: 5-fluorouracil; 5-FUR: 5-fluorouridine; 5-FUMP: 5-fluorouridine 5'-monophosphate; CD: cytosine deaminase; YUPRT: yeast uracil phosphoribosyltransferase. Panel **B**: Schematic representation of retroviral vectors used, in which suicide gene expression was placed under the retroviral 5' LTR. Panel **C**: Western blot detection of suicide gene expression in retrovirally generated stable SuperCD/YCD/BCD-expressing Morris hepatoma (MH) cell lines employing polyclonal rabbit antisera directed against BCD (lanes 1 and 2) and YCD (for detection of both SuperCD and YCD; lanes 3-5). Lane 1: MH naïve cells (negative control); lane 2: MH BCD cells, exhibiting a 48-ku band specific for BCD; lane 3: MH naïve cells (negative control); lane 4: MH YCD cells, exhibiting a 18-ku band specific for YCD; lane 5: MH SuperCD cells, exhibiting a 40-ku band specific for the YCD::YUPRT fusion, i.e. SuperCD. Numbers on the right hand side indicate the sizes of the expected proteins.

Subsequently, both genes were linked in-frame using a site-directed mutagenesis scheme, resulting in generation of a bifunctional suicide fusion gene which was named as SuperCD. Next, the SuperCD DNA sequence was inserted into basic retroviral vector pLXSN[16], resulting in generation of pLXSN-SuperCD (Figure 1B, upper construct), in which transgene expression is driven by the retroviral 5´LTR. For comparison of cytotoxic effectiveness, we likewise generated retroviral vectors pLXSN-YCD (Figure 1B, middle construct; solely encoding the YCD cDNA) and pLXSN-BCD (Figure 1B, lower construct; solely encoding the BCD cDNA)[25]. Employing all three constructs, PE501 ecotropic packaging cells were transiently transfected. Subsequently, respective

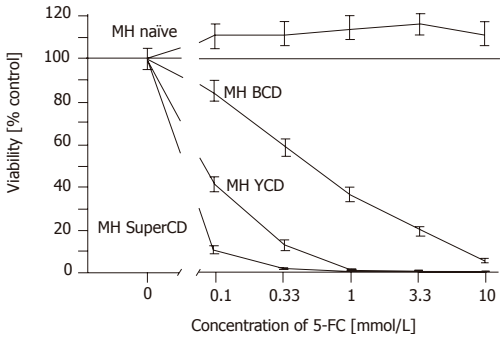

Figure 2 SRB cytotoxicity assay with stable BCD, YCD, SuperCD expressing Morris hepatoma (MH) cell lines generated by retroviral transduction. Untransduced MH3924A cells (MH naïve) and stably transduced Morris hepatoma cell lines (MH BCD, MH YCD, MH SuperCD) were seeded on 24-well plates. After 4 d of 5-FC treatment, the growth inhibition was determined by SRB staining and measured at 550 nm. All values were referred to that of the untransduced control cells without the addition of 5-FC and are given as percentage of surviving cells (control: 100%). All experiments were carried out at least in quadruplicate. Viability values plotted represent fitted medians and 95%CI.

supernatants containing recombinant retroviruses were used for transduction of MH 3924A cells. G418 selection gave rise to neo^r resistant clones (MH SuperCD, MH YCD, and MH BCD), which stably expressed suicide genes SuperCD, YCD, or BCD at comparable levels as detected by Western blotting (Figure 1C). Next, a SRB cytotoxicity assay was performed to compare the suicidal efficiencies of the different transgenes in the context of stable cell lines. As shown in Figure 2, a clear order of efficacy of the different suicide transgenes was found: in the SuperCD expressing cell line (MH SuperCD) even at a 5-FC concentration as low as 0.1 mmol/L, a very low cell survival of only 8% was observed. In contrast, sole expression of YCD (MH YCD) was much less efficient, resulting in a nearly 5-fold higher cell survival (38% at 0.1 mmol/L 5-FC). Finally, sole expression of BCD had only a minor cytotoxic effect (>80% cell survival at 0.1 mmol/L 5-FC). Thereby, convincing *in vitro* evidence was provided that the YUPRT component implemented within the SuperCD fusion gene is highly functional in the context of hepatoma cells. This corresponds to observations made by others with cell lines derived from non-liver tumor tissues (e.g. human colon cancer cells, human pancreas tumor cells, human breast cancer cells, human glioblastoma cells)[22,26]. The efficacy of much lower 5-FC doses has to be regarded as an important finding when transferring the 5-FC/SuperCD system to the preclinical/clinical situation: in the mammalian organism, 5-FC is also metabolized by the bacteria of the gut flora. An increased intestinal production of 5-FU can lead to dramatic unwanted side effects which are feared greatly in the context of 5-FU chemotherapeutic regimes[27].

Subcutaneously implanted MH SuperCD tumors demonstrate a complete tumor regression under systemic 5-FC application

A first *in vivo* testing of the SuperCD-enhanced suicide

gene effect was performed in six animals who received two sc tumor cell injections each: (1) MH SuperCD cells into the right dorsum; and (2) as a control in the same animals MH naïve cells into the left dorsum. On d 11, when tumors had reached a measurable size, rats were randomized into two groups and treated for one week with twice daily ip injections of 5-FC or saline (control group). 5-FC serum levels of treated animals as determined by HPLC ranged from 1 to 2.6 μg/mL, whereas control animals receiving saline displayed background levels only (data not shown). During the treatment period, tumor volume increased constantly in the saline-treated negative control group, irrespectively of the tumor type implanted. In contrast, in all the three 5-FC treated animals, the MH SuperCD tumors disappeared completely, whereas the MH naïve tumors grown on the opposite dorsum further increased in volume until d 18, when the animals were killed (Table1). At post mortem examination of 5-FC-treated animals, no residual tumor tissue was found on the right dorsum in which the MH SuperCD tumors originally had grown, whereas large MH SuperCD tumors, weighing between 1.8 and 2.7 g, were found in the saline-treated animals. As expected, all animals displayed large MH naïve tumors on the opposite site, independent of 5-FC or saline treatment.

Molecular and functional analysis of subcutaneously grown control tumors explanted on d 18

In vivo selective pressure for transgene-negative tumor cells and silencing of transgenes by methylation events are well-known phenomena[28]. We, therefore, extracted DNA from subcutaneously grown xenograft tumors for PCR analysis. In all three SuperCD tumor samples obtained from saline-treated animals, a 1 143-bp SuperCD-specific PCR amplification product was detected (Figure 3A, lanes #1-#3). Thus, *in vivo* passage of SuperCD-expressing tumor cells does not cause a relevant selective pressure against the presence of the SuperCD transgene. From the same subcutaneously grown tumors explanted at d 18, we further performed a functional analysis on recultured tumor cells (saline-treated MH SuperCD/MH naïve tumors) by applying the SRB cytotoxicity assay (Figure 3B). A 4-d treatment with 5-FC had no toxic effect on *in vivo* passaged MH naïve cells (control). However, all three MH SuperCD cell cultures (#1-#3) obtained after *in vivo* passage demonstrated a profound 5-FC-induced cytotoxic effect (Figure 3B, lower curves). The cytotoxic effect following *in vivo* passage was found to be comparable with MH tumor cells that had not undergone an *in vivo* passage (compared with Figure 2). These results demonstrated that, irrespective of an 18-d *in vivo* passage, MH SuperCD tumor cells continuously exerted a strong suicide gene effect at low 5-FC prodrug levels, which is of importance for further preclinical and clinical suicide gene therapy approaches.

Orthotopically implanted MH SuperCD tumors demonstrate a profound tumor regression under systemic 5-FC application

Based on the overwhelming efficacy of 5-FC treatment

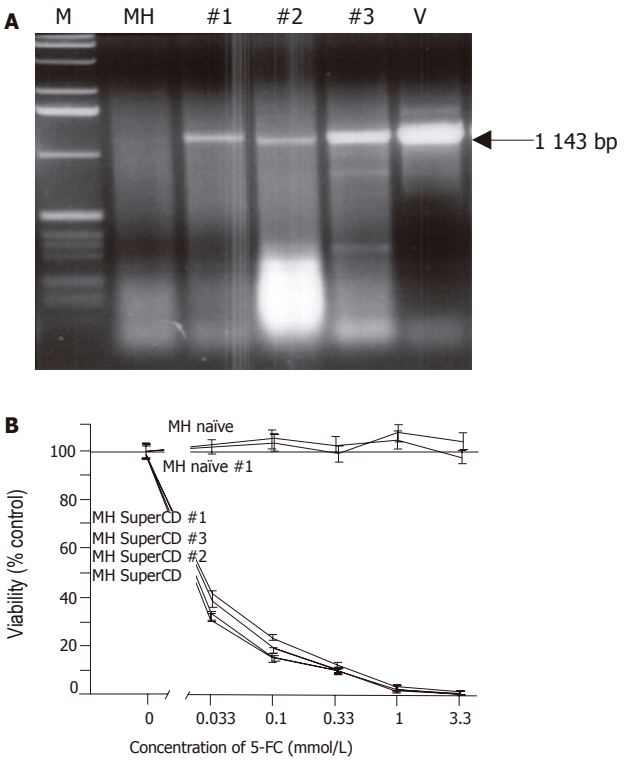

Figure 3 Molecular and functional analysis of subcutaneously grown control tumors explanted on d 18 (saline-treated MH SuperCD/MH naïve tumors).
A: Agarose gel electrophoresis of SuperCD DNA-specific PCR products. Lane M: marker DNA ladder; lane MH: MH parental cell line (no transgene; negative control; PCR performed with 1 μg of DNA); lanes 1-3: PCR amplifications performed on MH SuperCD tumor tissues of animals 1, 2, 3 (PCR performed with 1–3 μg of DNA); lane V: vector control lane (PCR performed with 1 pg of pLXSN-SuperCD). Arrow: indicates 1 143-bp SuperCD-specific amplification product. **B:** SRB cytotoxicity assay with recultured tumor cells explanted after 18 d of subcutaneous growth. As in Figure 2, cytotoxicity was measured after 5-FC treatment for 4 d *in vitro*. MH naïve: negative control with MH parental cell line (no transgene; no animal passage); MH naïve, #1: MH naïve tumor explanted from a saline-treated animal (control); MH SuperCD, cell line: MH SuperCD parental cell line (control; no animal passage); MH SuperCD 1, 2, 3, tumor passage: MH SuperCD tumors explanted from saline-treated animals 1, 2, 3. All values were referred to that of the untransduced control cells and are given as percentage of surviving cells (control: 100%). All experiments were carried out in quadruplicate. Viability values plotted represent fitted medians and 95%CI.

observed in subcutaneously grown MH SuperCD tumors, we next treated orthotopic liver tumors in the same rat hepatoma model in a larger number of animals, thereby investigating the statistical relevance of SuperCD suicide protein expression. As caliper measurement of small intrahepatic tumors is impossible, this study was based on non-invasive MRI imaging. Twenty-one days after the implantation of solitary MH SuperCD tumors into the livers of recipient animals, a first MRI was performed. Maximum tumor areas were analyzed. Rats with tumor areas ranging from 20 to 156 mm^2 (representative day 21 MRI images shown in Figures 4B and C, respectively, column 1 "untreated") were then randomized into two groups with six rats in each, and treated twice daily with ip injections of 5-FC or saline for 10 d.

MRI-based measurement of tumor sizes at the end of

Table 1 Effect of 5-FC treatment on subcutaneous MH tumor growth

		Suicide gene	
		None (control)	SuperCD
Treatment	5-FC	1.4 g	n.d.
		3.2 g	n.d.
		1.8 g	n.d.
	Saline (control)	2.5 g	1.8 g
		2.9 g	1.9 g
		3.7 g	2.7 g

Six animals received two sc tumor cell injections (1×10^7 cells in 70 μL PBS/animal). On d 11, tumor-bearing rats were randomized into two groups and treatment started with twice daily ip injections of 5-FC (283 mg/kg body weight) or saline (control). At the end of 5-FC treatment (d 18), animals were killed, tumors were harvested and weighed. Complete regression of tumors was observed only in the 5-FC-treated SuperCD tumors (n.d.: no detectable tumors).

the treatment (d 31) revealed a persistent orthotopic tumor growth for saline-treated control animals (Figure 4A, solid lines). In contrast, all six animals treated systemically for 10 d with 5-FC exhibited a clear decline of tumor sizes, either complete regressions or dramatic reductions (Figure 4A, broken lines). Ranking area differences revealed a significant difference between the untreated and the treated groups (*U*-test, $P = 0.0051$). Thus, bifunctional SuperCD suicide gene expression was found to be highly effective against a rat hepatoma model under both subcutaneous and orthotopic implantation conditions.

Low dose 5-FC application found to be sufficient to achieve complete tumor regressions of orthotopically implanted MH SuperCD cells

Anticipating an enhanced SuperCD suicide gene effect, we already had started to administer twice daily with 5-FC dosage of 283 mg/kg body weight, which is only half of the dosage of about 500 mg/kg body weight used by others[6,29-33]. Since this prodrug dosing regimen was found to be highly efficient for the eradication of both subcutaneous (Table 1) and orthotopic (Figure 4) MH SuperCD hepatomas, we aimed next at further decreasing the 5-FC dose by reducing the application frequency. Thereby, side effects due to 5-FU metabolites resulting from unwanted routes of "collateral" gut toxification could be even further reduced.

We tested this hypothesis on three animals with small MH SuperCD liver tumors (#7, #8, #9) having received saline only as control animals during the first treatment period. The other animals had to be euthanized due to their tumor burden. In these animals, low dose treatment was started on d 31 with only twice weekly ip injections of 5-FC (283 mg/kg body weight) for 28 d. When MRI was again performed at d 59, all MH SuperCD tumors had completely disappeared (Figure 5, right column). In none of these three animals, any solid tumor tissue was found at autopsy. Instead, only small yellowish fatty "scars" were visible. Thereby, bifunctional SuperCD suicide gene expression was found to be highly effective in a rat hepatoma model under both subcutaneous and orthotopic growth conditions, even when a strongly reduced 5-FC dosing regime was applied.

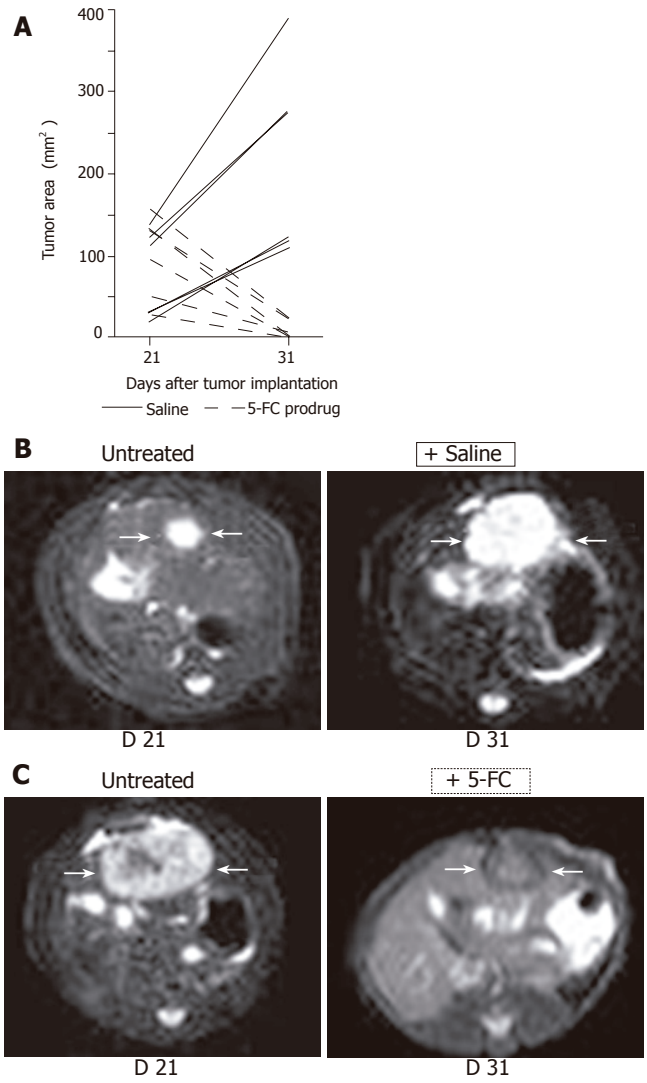

Figure 4 Non-invasive MRI detection of tumor growth of orthotopically implanted MH SuperCD hepatomas (saline *vs* 5-FC prodrug treatment). Animals with MRI detectable liver tumors in T2 weighed images were randomized into two groups (6 rats/group) and treated twice daily with ip injections of saline or 5-FC (283 mg/kg body weight) over a 10-d period. Panel A: Maximum tumor areas (mm^2) at d 21 and d 31; solid lines: tumor growth of control animals (saline-treated); broken lines: tumor regression of serum animals (5-FC-treated). Panel B: Representative MRI tumor images of the saline-treated control animal exhibiting the smallest tumor area at d 21 (left); and a dramatic tumor growth was observed at d 31 (right). Panel C: Representative MRI tumor images of the serum animal (treated with 5-FC) exhibiting the largest tumor area at d 21 (left); and a dramatic tumor regression was measured at d 31 (right).

Determination of in vivo suicide gene effectiveness by direct in vivo comparison of suicide genes SuperCD vs YCD vs BCD

Until now, no study encompassing a direct *in vivo* comparison of different suicide genes (SuperCD *vs* YCD *vs* BCD) has been performed. Therefore, 1×10^7 cells of the four cell-lines (1) MH naïve (negative control), (2) MH BCD, (3) MH YCD, and (iv) MH SuperCD were injected subcutaneously into ACI rats. In this course, each animal

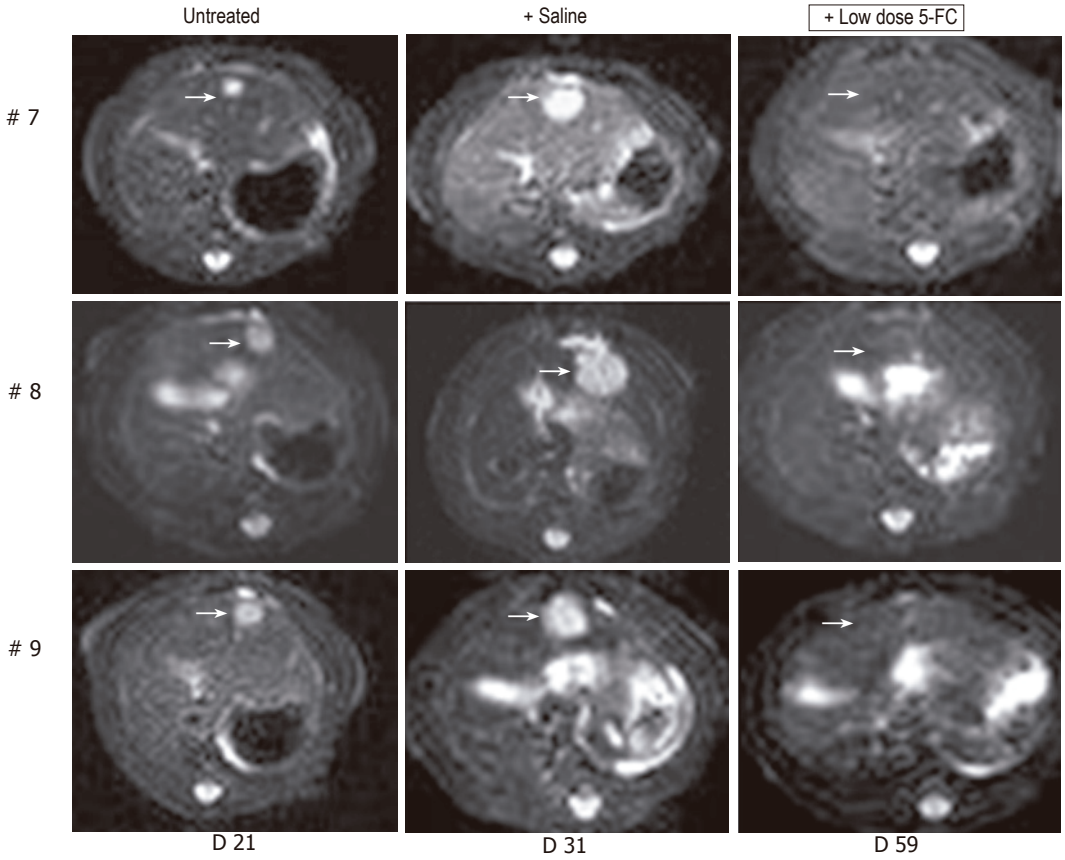

Figure 5 MRI detection of tumor growth of orthotopically implanted MH SuperCD hepatomas treated under a low-dose 5-FC regimen. Animals #7, #8, #9 (column 1: tumor size at d 21), which first had been treated with saline only for over a 7-d period and thereafter, uniformly exhibiting a substantial tumor growth (column 2: tumor size at d 31), were then treated by a low-dose 5-FC regimen [twice weekly ip injections of 5-FC (283 mg/kg body weight)] over a 28-d period until d 59. Analysis of subsequent MRI sections did not reveal any MH SuperCD tumors (column 3, d 59: +low dose 5-FC); T2 weighed images are depicted; arrows in column 3 point out to places of former tumor localizations before the onset of 5-FC treatment.

received two injections with two different cell-lines, one inoculated at the left dorsum, and the other one at the right dorsum. Based on a balanced incomplete block plan, the six possible pairs of cell lines were implanted into six groups, each comprising eight animals. Tumor volumes were determined by caliper measurement. At d 15 after hepatoma cell inoculation, prodrug therapy with twice weekly ip injections of 283 mg 5-FC/kg body weight (low dose regime) was started. Interestingly, 8 out of 18 MH SuperCD tumors on d 28 and 11 out of 18 MH SuperCD-tumors on d 31 had shrunken to an immeasurable size (Figure 6A, right panel). A subsequent analysis of covariance of log tumor volumes revealed a significant reduction in median tumor volumes under our low dose 5-FC application scheme only for the MH SuperCD tumors. The reduction in median tumor volume was almost complete (95%CI for the reduction between d 14 and 31 from 98.7% to 99.6%) (Figure 6B). The maximum likelihood ratio χ^2 test of the global hypothesis was significant $\chi^2 = 264$; 3 df; $P = 6\times10^{-57}$). Thus, for the first time *in vivo* evidence was provided demonstrating that the SuperCD *in vivo* suicide gene effect might be superior to the one of YCD ($P < 10^{-10}$), which itself was superior to BCD (Figures 6A and B).

DISCUSSION

Although the study described here demonstrated that the expression of YCD and YUPRT as a fusion protein with 5-FC administration exerted a striking antitumor effect on solid tumors like hepatomas, further improvements are needed for clinical applications. Current limitations of *in vivo* liver tumor transduction efficiencies could be further compensated with the help of intercellular cargo proteins (e.g. VP22, our own work[18,34], and Refs. [35,36]). At the moment, we are evaluating the properties of VP22-SuperCD/SuperCD-VP22 fusion proteins to further potentiate suicide gene therapy efficiencies in our rat hepatoma model, thereby improving the intratumoral distribution of enzymatically enhanced suicide genes. Other promising approaches rely on the employment of strong hepatoma-specific promoters which are suitable to achieve high levels of hepatoma-specific SuperCD expression *in vivo* (e.g. the cell growth-related midkine promoter)[37]. Most importantly, gene transfer systems have to be identified, which are suitable to provide a significant increase of the accessibility of liver tumor cells to systemically applied gene transfer vectors. In a recent study, herpes thymidine kinase suicide gene transducing liposomes, based on the hemagglutinating

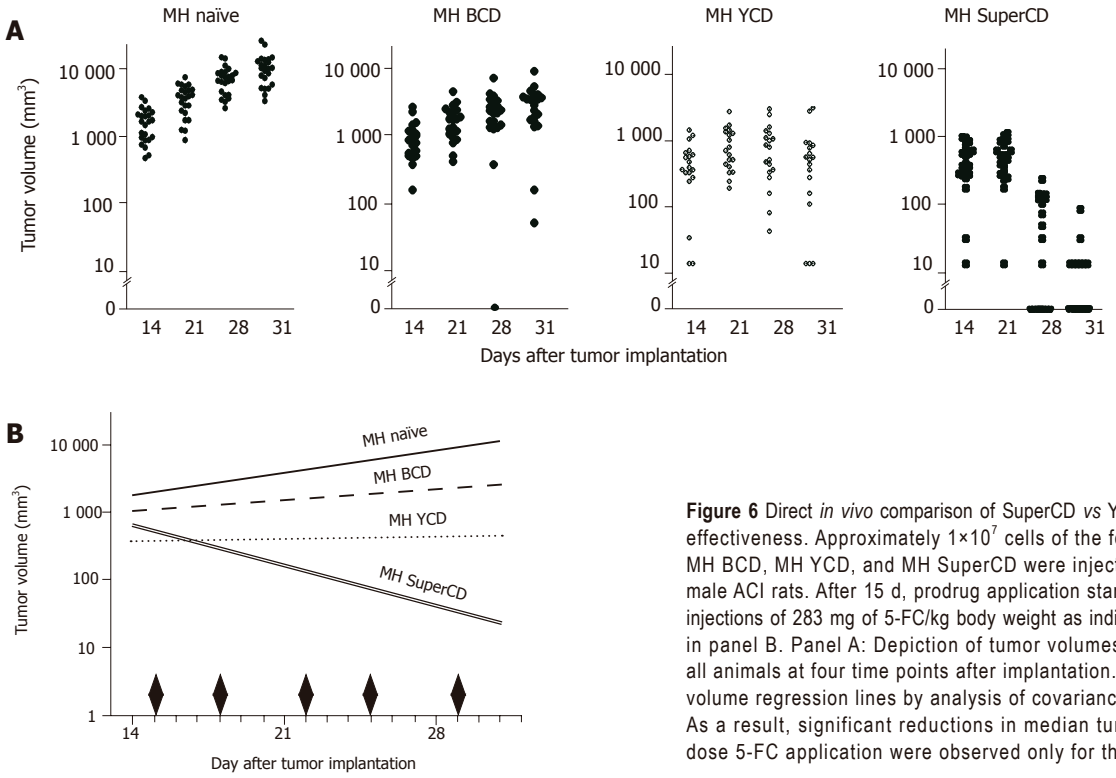

Figure 6 Direct *in vivo* comparison of SuperCD *vs* YCD *vs* BCD suicide gene effectiveness. Approximately 1×10^7 cells of the four cell-lines MH naïve, MH BCD, MH YCD, and MH SuperCD were injected subcutaneously into male ACI rats. After 15 d, prodrug application started with twice weekly ip injections of 283 mg of 5-FC/kg body weight as indicated by black diamonds in panel B. Panel A: Depiction of tumor volumes of all four cell lines in all animals at four time points after implantation. Panel B: Median tumor volume regression lines by analysis of covariance of log tumor volumes. As a result, significant reductions in median tumor volumes under low dose 5-FC application were observed only for the MH SuperCD tumors.

virus of Japan, were injected directly into the portal vein of severe combined immunodeficiency mice, and reported to be as an efficient tool for the transduction of multilocalized HUH7 human hepatocellular carcinomas in this animal model[38]. Thus, transduction properties of hemagglutinating virus of Japan (also defined as Sendai virus) seem to favor transduction of liver tumors. Concluding from this, also recombinant Sendai virus vectors[39,40] encoding optimized suicide genes might be suitable to overcome the liver tumor transduction barrier[41,42]. HIV-derived lentiviral vectors have also been successfully used for suicide gene therapy in hepatocellular carcinoma[43]. In addition, newly developed replication-competent vectors/oncolytic vectors[42,44-47] could be used to cope with the liver tumor transduction barrier.

Concerning our current knowledge on severe gene therapeutic side effects employing state-of-the-art retroviral[48], adenoviral[49], or adeno-associated virus vectors[50], a reduction of vector dosages might become possible with the SuperCD suicide gene. This would constitute an important additional safety factor for further clinical gene therapy applications. Subsequent *in vivo* studies will compare application of the therapeutic SuperCD suicide gene by virtue of direct (injection), systemic (iv) or regional (ia) gene transfer and treatment with 5-FC.

In summary, a combination of synergistic strategies as described above may allow a further enhancement of the suicide gene effect in the near future. Thus, further refinements may help to make suicide gene therapy a feasible treatment modality for solid malignant tumors in human beings.

Abstract

AIM: To explore the potential prognostic role of preoperative tumor grade and blood AFP mRNA in a cohort of patients with hepatocellular carcinoma (HCC) eligible for radical therapies according to a well-defined treatment algorithm not including nodule size and number as absolute selection criteria.

METHODS: Fifty patients with a diagnosis of HCC were prospectively enrolled in the study. Inclusion criteria were: (1) histological assessment of tumor grade by means of percutaneous biopsies; (2) determination of AFP mRNA status in the blood; (3) patient's eligibility for radical therapies.

RESULTS: At preoperative evaluation, 54% of the study group had a well-differentiated HCC, 42% had AFP mRNA in the blood, 40% had a tumor larger than 5 cm and 56% had more than one nodule. Surgery (resection or liver transplantation) was performed in 29 patients, while 21 had percutaneous ablation procedures. After a median follow-up of 28 mo, 12-, 24-, and 36-mo survival rates were 78%, 58%, and 51%, respectively. Surgical therapy, performance status and three tumor-related variables (AFP mRNA, HCC grade and gross vascular invasion) resulted as significant survival predictors at univariate analysis. Nodule size and number did not perform as significant prognosticators. Multivariate study selected only surgical therapy and a biologically early HCC profile (AFP mRNA negative and well-differentiated tumor without gross vascular invasion) as independent survival variables.

CONCLUSION: The preoperative determination of tumor grade and blood AFP mRNA status may potentially refine the prognostic evaluation of HCC patients and improve the selection process for radical therapies.

Key words: Hepatocellular carcinoma; Prognosis; Treatment policy; Biomarker; Tumor biology

INTRODUCTION

Liver transplantation (LT), hepatic resection and percutaneous treatments[1-3] are commonly considered as potential radical therapies for patients with hepatocellular carcinoma (HCC). Macroscopic tumor characteristics detected by imaging studies (nodule size and number) undoubtedly identify a subgroup of HCC patients at an early stage of hepatic disease (single nodule <5 cm, <3 nodules, and <3 cm) able to achieve long-term survival figures when radically treated[4,5]. Large pathologic retrospective studies[6-9], however, have shown that these macro-morphological features are indirect markers of specific tumor histological characteristics such as grade of differentiation and microscopic vascular invasion which have therefore the potential to refine the HCC prognostic assessment[10-12]. On the other hand, many molecular biological factors have been studied and related to the HCC biological aggressiveness[13]. However, preoperatively detectable biomarkers (histological and/or hematic) have not yet been introduced in the

routine HCC prognostic evaluation. In our experience, the preoperative determination of the HCC grade by means of percutaneous biopsy performed as a valid tool in the selection of unresectable HCC patients for transplantation[14]. Moreover, we retrospectively showed that some patients with morphologically advanced but well-differentiated HCC may benefit of potentially radical therapies[15]. Among the proposed HCC molecular markers, alpha-fetoprotein messenger RNA (AFP mRNA), detected in the blood by reverse-transcription polymerase chain reaction (RT-PCR), has been the most diffusely studied in last years[16-19]. Our preliminary experience with this marker showed its significance and promising correlation with HCC invasiveness parameters[16]. However, the prognostic utility of AFP mRNA when detected before the treatment remains controversial[20-22]. In this prospective study, a group of HCC patients were selected for radical therapies according to a precise treatment schedule. In addition to conventional HCC parameters, their preoperative study also included the determination of tumor grade and AFP mRNA status in the blood. The enrolled patients were prospectively followed in order to identify the main preoperative predictors of survival.

MATERIALS AND METHODS

Patient enrolment

Between April 2001 and October 2002, 50 patients with a diagnosis of HCC were prospectively enrolled in the study. Patients were eligible for inclusion if they met the following criteria: (1) HCC diagnosis histologically confirmed by the examination of liver specimens obtained by percutaneous biopsies. Pathological grading was contextually assessed in all the patients according to Edmonson's classification; (2) patient's informed consent to provide blood samples for AFP mRNA determination; (3) patient's eligibility for radical therapies according to a published schedule[14,23].

Hepatic resection was considered for HCC patients with preserved liver function (Child-Pugh A-B) and a technically resectable liver tumor without extra hepatic metastasis. If resection was not feasible, patients were considered for LT. The following exclusion criteria for LT were established as previously reported[14]: general contraindications to transplant (age, severe extrahepatic diseases, recent malignancies, and compliance), extra hepatic spread or gross vascular invasion (preoperatively evident or suspected), poorly-differentiated HCC (G3) at pre-OLT percutaneous biopsy. Size and number of nodules were not considered as absolute selection criteria. Patients not fulfilling the criteria for any surgical procedure were assessed for other loco-regional treatments such as percutaneous radiofrequency (RF) or ethanol injection (PEI), and transarterial chemoembolization (TACE).

After discharge, the patients were followed up regularly according to the main treatment received. To detect tumor recurrence after surgery, patients received clinical and laboratory assessment every month, and US and CT every 3rd and 6th mo, respectively. When HCC recurrence was noted, patients were further treated with the most appropriate procedure according to our treatment schedule. After PEI, RF or TACE, dynamic CT examinations were performed to determine therapy efficacy and, when residual staining was noted, these procedures were repeated and the outcome was examined. None of the enrolled patients were lost during follow-up or died within 30 d after first observation or treatment. Therefore, all the 50 patients initially entering the study were available for the survival analysis.

Detection of AFP mRNA in nucleated cells

The AFP mRNA status in the blood was determined in each enrolled patient within 3 mo from treatment application. In brief, total RNA was extracted from 7 mL of peripheral blood and converted to complementary DNA. A nested polymerase chain reaction (PCR) protocol was performed as previously reported[16]. Positive results were evidenced as a 282-bp band in agarose gel stained with ethidium-bromide. As a positive control, cDNA obtained from human hepatocyte was used in each run. Negative controls for each step were also always included.

Statistical analysis

All variables were described by statistical characteristics: categorical data were described by frequency and percentage, whereas continuous data by median (range). Comparison between groups was done by using the χ^2 test or the Fisher's exact test for qualitative variables and the logistic regression for quantitative variables. Follow-up length and survival are expressed as median (range). Recruitment of follow-up data was closed on December 31, 2004. Twenty-four preoperative variables were assessed in the univariate survival analysis: age, sex, performance status, presence of cirrhosis, etiology of cirrhosis, clinical evidence of portal hypertension (presence of esophageal varices, splenomegaly with a platelet count <100 000/mm^3, or ascites), Child-Pugh's classification[24], bilirubin, albumin, prothrombin activity, alkaline phosphatase, gamma-glutamyl transpeptidase, creatinin, aspartate, and alanine aminotransferase, AFP, AFP mRNA blood-status, tumor morphology at preoperative imaging study (TNM, bilobarity, number and size of nodules, gross vascular invasion), differentiation degree at preoperative liver biopsy, and type of treatment. For continuous variables, the cut-off level was their median value. Univariate survival analysis was performed including each variable in a Cox regression model and calculating its related likelihood-ratio of χ^2 and *P* value. Survival curves were calculated using the Kaplan-Meier method and compared by means of the log-rank test. All variables significantly influencing survival in the univariate analysis were analyzed together in a Cox's proportional hazard regression model (multivariate analysis) with the aim of studying the independent contribution of each variable in explaining survivorship. The results of the Cox regression were expressed using both the risk ratios with its related confidence interval and the likelihood ratio of χ^2 with its related *P* value. Analyses were performed using the SAS Institute statistical package

(JMP). Differences were considered significant at $P<0.05$.

RESULTS

The main characteristics of the study group are shown in Table 1. At presentation, only 20% of patients had a compromised general condition due to cancer-related symptoms (PST ⩾1), 63% had a Child B-C cirrhosis and 62% had a clinically relevant portal hypertension. As for tumor characteristics, 52% of patients had a T3-T4 HCC; the tumor was larger than 5 cm in 20 patients (40%), while 28 (56%) had more than one nodule; macroscopic vascular invasion was detected in 12 patients (24%) and 27 patients (54%) had a well-differentiated HCC. AFP mRNA was found in the blood of 21 HCC patients (42%). As previously reported[16], the presence of AFP mRNA in blood was significantly related to cholestatic indices, gross vascular invasion, nodule size, and G2-G3 tumors (Table 1). Surgery was performed in 29 patients (58%), including 22 liver resections and 7 OLT, while 21 patients (42%) had percutaneous ablation procedures eventually associated with TACE.

Survival analysis

As at December 31st 2004, the median follow-up for the whole HCC group (50 patients) was 28 months (range 1-45 mo). Overall mortality was 48% (24 cases) and 12-, 24-, and 36-mo survival rates were 78%, 58%, and 51%, respectively (Figure 1A). Five out of the twenty-four variables had predictive prognostic value for survival in the univariate analysis (Table 1): PST, AFP mRNA, gross vascular invasion, histological grade, and surgical therapy.

A first multivariate study including these five variables selected only surgical treatment as independent survival predictor (Table 2, Figure 1B). Taking into account the strict correlation between AFP mRNA, vascular invasion and HCC grade in the study group[16], in a further analysis we combined these three tumor-related variables in a single parameter defined early HCC (AFP mRNA negative and well-differentiated tumor without gross vascular invasion). This second multivariate study selected tumor early biological status as the most important prognostic factor (Table 2 and Figure 1C).

DISCUSSION

Prognostic prediction and therapeutic decision for HCC patients are currently based in most centers on macroscopic tumor characteristics detected by imaging studies (nodule size and number). In the last decade, an empirical rule

of single nodule smaller than 5 cm in diameter and of multiple nodules (2 or 3) smaller than 3 cm has been used to define early HCC, reflecting the excellent outcomes achieved after LT[25,26]. Although the use of these strict selection criteria for the treatment has undoubtedly improved survival rates of a subgroup of HCC patients in the previous years[4,5], such a diffuse therapeutic policy has dramatically reduced the use of potentially radical therapies for those HCC patients not meeting the same criteria. In virtue of such a tight selection philosophy, on one hand it has obtained an important reallocation of resources but on the other it has faced the concrete risk that a considerable proportion of HCC patients have been unfairly excluded from radical treatment[6-8]. In this context, the identification of new reliable prognostic factors may play a crucial role in improving the treatment criteria process of HCC patients[27].

This study was designed to identify prospectively the main preoperative HCC predictors of survival with particular reference to the prognostic utility of preoperative AFP mRNA and tumor grade. In order to avoid the bias associated to predefined selection criteria, less restrictive enrollment criteria for radical treatment in terms of both tumor status and liver function were deliberately used. If on one hand such a selection policy may account for the relatively unsatisfactory outcome of the 50 enrolled patients (Figure 1A), on the other it allowed us to develop an effective analysis of predictive factors for survival. Moreover, in spite of the relatively low number of enrolled patients, our study has the advantage of a monocentric, prospective analysis in which a well-defined treatment algorithm was used[14,23].

According to other studies[28,29], tumor biological parameters appeared as the most relevant prognostic factors selecting those patients achieving the best survival outcome when radically treated (Tables 1 and 2). In the present study, macro-morphological parameters failed in defining early HCC, since they showed a marginal impact on survival in our group of patients (Table 1). On the contrary, other tumor characteristics such as AFP mRNA in the blood, histological grade and vascular involvement served as more adequate markers of HCC biological

aggressiveness.

In this context, the independent prognostic power of surgical treatment (Table 2 and Figure 1B) may not be misinterpreted as a therapeutic disadvantage in using other loco-regional options. It is not the aim of the present study, in fact, to make a comparison between treatment options since such an analysis may be correctly performed only in the experimental setting of a randomized clinical trial.

This study, in fact, showed that some HCC biological features such as grading, AFP mRNA status in the blood and gross vascular invasion influence patient prognosis independently from the type of adopted therapy (Table 2). A prognostic stratification of the study group in two main tumor stages according to significantly predictive variables was obtained (Figure 1C). A favorable biological picture of HCC (AFP mRNA negative, well-differentiated and without gross vascular invasion) appeared hierarchically as the most relevant factor in determining patient prognosis. Conversely, liver function parameters, such as Child-Pugh classification, bilirubin and portal pressure, did not reach a significant impact on survival in our small study group suggesting a secondary prognostic role when compared to tumor features. In this view, our study does not claim to provide a new definition of early HCC but it wants to simply and strongly underline the urgent need to readdress the focus of the HCC patients selection process for radical treatment more on tumor biological aggressiveness rather than on size and number of tumor nodules.

Concerning the single HCC parameters selected from survival analysis, tumor grade is a well recognized prognostic factor for HCC patients as showed by many large retrospective pathological analyses[1,6,11]. There are, however, no studies evaluating the prognostic role of preoperative determined HCC grading in a prospective setting.

Previous experiences exploring the prognostic role of preoperative AFP mRNA showed controversial results[30-32]. It is likely that this biologic HCC parameter alone does not reach an adequate prognostic power in highly selected populations undergoing radical therapies. In this view, the present study suggests that in the context of a larger population basis, AFP mRNA may be probably useful in identifying morphologically advanced HCC suitable for radical therapies. The introduction of appropriate molecular methods to quantify AFP mRNA in the blood in perspective will further improve the prognostic power of this promising biomarker.

In conclusion, this study showed that the preoperative determination of tumor grade and blood AFP mRNA may potentially refine the prognostic evaluation of HCC patients. On a purely preliminary basis, these two parameters may probably help the treatment decision process for that group of HCC patients suitable for radical therapies consequently improving the currently used restrictive selection criteria.

Abstract

AIM: To assess the functional status and etiology of liver cirrhosis by quantitative ^{31}P magnetic resonance spectroscopy (MRS).

METHODS: A total of 80 patients with liver cirrhosis of different etiology and functional status described by Child-Pugh score were examined and compared to 11 healthy volunteers. MR examination was performed on a 1.5 T imager using a ^{1}H/^{31}P surface coil by the 2D chemical shift imaging technique. Absolute concentrations of phosphomonoesters (PME), phosphodiesters (PDE), inorganic phosphate (Pi) and adenosine triphosphate (ATP) were measured.

RESULTS: MRS changes reflected the degree of liver dysfunction in all the patients as well as in individual etiological groups. The most important change was a decrease of PDE. It was possible to distinguish alcoholic, viral and cholestatic etiologies based on MR spectra. Alcoholic and viral etiology differed in PDE (alcoholic, viral, controls: 6.5±2.3, 6.5±3.1, 10.8±2.7 mmol/L, P<0.001) and ATP (alcoholic, viral, controls: 2.9±0.8, 2.8 ±0.9, 3.7±1.0 mmol/L, P<0.01) from the control group. Unlike viral etiology, patients with alcoholic etiology also differed in Pi (alcoholic, controls: 1.2±0.4, 1.6±0.6 mmol/L, P<0.05) from controls. No significant changes were found in patients with cholestatic disease and controls; nevertheless, this group differed from both alcoholic and viral groups (cholestatic, alcoholic, viral: 9.4 ±2.7, 6.5±2.3, 6.5±3.1 mmol/L, P<0.005) in PDE.

CONCLUSION: ^{31}P MRS can significantly help in non-invasive separation of different etiological groups leading to liver cirrhosis. In addition, MRS changes reflect functional liver injury.

INTRODUCTION

Cirrhosis is the final stage of various liver diseases. Regardless of etiology (i.e., viral, alcoholic, autoimmune, metabolic and others), the liver injury leads to the excessive accumulation of extracellular matrix and to nodular regeneration of parenchyma. Information about the etiology and degree of liver derangement is indispensable and usually needs to be verified by means of liver biopsy. This procedure is invasive, uncomfortable for the patient and sometimes not without serious complications. Therefore, efforts have been made to non-invasively obtain information concerning liver injury.

Additional important information is the degree of functional limitation of the liver. In clinical settings, this is usually described by a Child-Pugh score (CPS), which is calculated from clinical and laboratory tests[1-3]. As clinicians need to determine the specific etiological diagnosis of liver cirrhosis, all possible additional information is valuable in clinical practice to find an appropriate treatment[4]. Imaging examinations, which are capable of improving the diagnostic process, are very helpful.

One of the promising techniques is the application of magnetic resonance (MR) spectroscopy[5]. Phosphorus (^{31}P) MR spectroscopy has been used to study liver metabolism *in vivo* for several years[6-9]. It enables the observation of energy metabolism and intracellular compartmentation through the signals of phosphomonoesters (PME), phosphodiesters (PDE), inorganic phosphate (Pi) and nucleotide triphosphates, mainly adenosine triphosphate (ATP). The PME and PDE signals are multicomponent with phosphorylcholine and phosphorylethanolamine which are the main contributors to PME as well as

glycerophosphorylcholine and glycerophosphorylethanola mine which are the main contributors to PDE [10]. The final typical signal of ^{31}P MR spectra *in vivo* is phosphocreatine (PCr). Although it is a dominant signal in muscles, it is not readily observable in spectra of the liver because of its low contribution to hepatic metabolic processes. Its presence indicates some contribution of signals from abdominal wall muscle as a partial volume effect.

In this study we investigated whether quantitative ^{31}P MR spectroscopy can distinguish different etiologies of liver cirrhosis and assess the functional severity of liver injury. The main goal of the study was to describe the relationship between the concentration of phosphorylated metabolites in the liver and the different etiological groups of liver cirrhosis.

METHODS

Subjects

A group of 80 patients (49.7 ± 11.5 years) with confirmed liver cirrhosis of different etiology (alcoholic cirrhosis in 33 cases, viral hepatitis in 22 cases (B virus in three cases, C virus in 17 cases, combined B+C in two cases), cholestatic liver disease in 16 cases (primary biliary cirrhosis in six cases, one case of secondary biliary cirrhosis, primary sclerosing cholangitis in eight cases and one case of biliary atresia), and other etiologies in nine cases (one Budd-Chiari, two congenital fibrosis, two autoimmune, and four cryptogenic cases) were examined. The last nine patients were excluded from etiological evaluations because of their etiological diversity and small number. Patients with combined etiologies (especially viral and alcoholic) were strictly excluded from the study as well as another 19 patients with insufficient resolution or low signal to noise ratio due to technical problems. Results were compared to those of a group of 11 healthy volunteers (40.5 ± 10.9 years). Liver biopsy was performed in all cirrhotic patients except for those whose clinical, laboratory, endoscopic and imaging studies (abdominal ultrasound and CT) were typical and without any doubt for severe liver cirrhosis. Etiological diagnosis was made using standard diagnostic rules. All alcoholic patients admitted had a previous regular drinking of alcohol more than 80 g/d, patients with viral hepatitis B and C were confirmed by specific antibodies and/or PCR DNA/RNA positivity. Patients with primary biliary cirrhosis were AMA positive, patients with primary sclerosing cholangitis had typical cholangiography, all cholestatic patients were confirmed by liver biopsy. Similarly strict criteria were used for other etiologies. All patients were originally examined for the liver transplantation program and six-month alcohol abstinence in alcoholic patients was proved by independent observers, i.e. family members, primary care physicians and psychiatrists trained in substance abuse treatment. All subjects, including the healthy volunteers, abstained from alcohol during 48 h before MR examination and underwent standard clinical biochemical testing just before the MR examination which was performed in early morning after an overnight fast (at least 8 h of fasting). A Child-Pugh score [1-3] was obtained in all patients (mean CPS = 9.3) and patients were distributed into groups A, B, and/or C for statistical evaluation. MELD score was not used because of its main application in donor allocations. The subjects were fully informed and signed the protocol of the examination in accordance with rules approved by the ethical committee, which conform to the ethical guidelines of the 1975 Declaration of Helsinki.

MR examination

MR examination was performed on a Siemens Vision (Erlangen, Germany) whole-body MR imager operating at 1.5 Tesla equipped with a commercial dual ^{1}H/^{31}P surface coil. The subjects were examined in a prone position with the liver centered on the surface coil. Neither ECG nor breathing monitoring due to this position was found to be necessary. No tremor because of encephalopathy which might also influence the quality of MR examination was observed. Basic MR images in all orientations were obtained for the localization of voxels (Figure 1). ^{31}P MR spectra were measured using a standard two-dimensional chemical shift imaging (CSI) technique[5] in the transversal plane with the following parameters: TR = 323 ms, TE = 2.3 ms, matrix 16 × 16, field of view (FOV) = 480 mm, flip angle = 90º, slice thickness = 4 cm, voxel volumes were 3 cm × 3 cm × 4 cm, 12 acquisitions, acquisition time = 16 min.

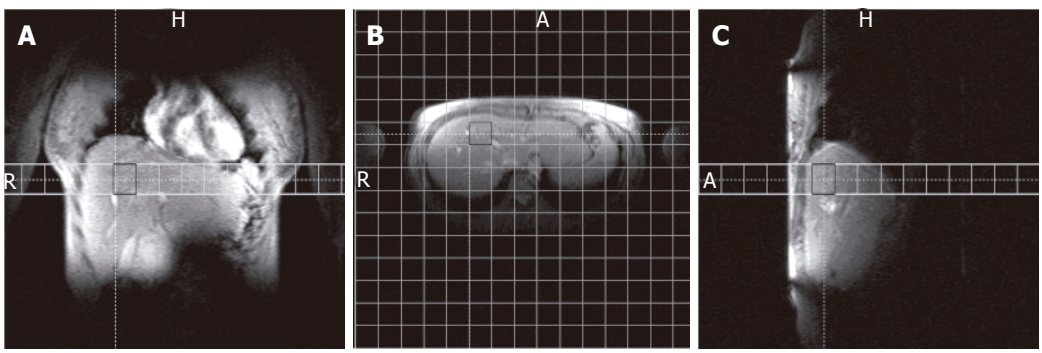

Figure 1 MR images of a healthy volunteer in all orientations with selected matrix for spectroscopic measurement and indicated volume of interest for spectra evaluation.

Spectra evaluation

Approximately 12 voxels (in the normal size of the liver) were selected from a whole CSI matrix (256 voxels). The most appropriate voxel for the quantitative evaluation[11] had to fulfill two conditions: (1) no visible PCr signal characterizing the presence of abdominal muscles; (2) no visible large intrahepatic blood vessels (portal vein truncus and its left and right lobar branches, inferior vena cava and large branches of hepatic veins). Such voxel was chosen using a standard postprocessing method (the movement of the whole CSI matrix) and considered as volume of interest (VOI) for quantitative evaluation. However, the contribution of small hepatic veins to measured signal intensities could not be excluded.

Spectra were evaluated using standard Siemens Numaris software (Gauss apodization with halfwidth = 30 ms, manual phase and spline baseline correction, Fourier transformation and curve fitting with the assumption of Gaussian line shapes). We used Pi chemical shift = 5 ppm as a standard frequency for the assignment of observed signals. Signal intensities of PME, Pi, PDE and β ATP (αATP and γATP signals were not used for the evaluation because of overlap with signals of other compounds) were used for the measurement of absolute molar concentrations. The methodology of the absolute quantification using the CSI sequence was published previously[11,12]. The signal intensity ratios were not used because of the signal intensity dependence on the distance of the VOI from the center of the surface coil.

Statistical analysis

The comparison of several neighboring voxels from different places in the liver was performed and a VOI of 36 mL was found to be large enough to disregard structural heterogeneities. All data represented three independent evaluations and were expressed as mean ± SD unless otherwise indicated.

Statistical analysis was performed using paired *t* tests and the technique of "contrast analysis" in the ANOVA module of STATISTICA 6[13] for multiple comparisons. Pattern recognition analysis of data was performed by principal component analysis (PCA) using the Multivariate Explanatory Techniques module of the STATISTICA software and by linear and nonlinear discriminant analyses (LDA and NDA, respectively)[14] using MaZda B11[15].

A Levene's test of homogeneity of variances in groups confirmed that there was no effect at $P<0.05$. This means data had the same variance and could be compared by standard t test. The null hypothesis H_0 (group means are not different from the control group) was rejected if $P<0.05$ (5 % error level).

RESULTS

Figure 2 shows typical examples of phosphorus spectra from healthy and cirrhotic liver tissue. The altered hepatic phosphorus metabolism in cirrhosis could be described by calculated molar concentrations of selected compounds in the liver tissue. The spectroscopic data of patients and controls together with Child-Pugh score are summarized in Table 1. Compared to controls, molar concentrations of PDE and ATP were significantly lower in all patients with liver cirrhosis. We divided patients into three groups according to CPS, independent of etiology. In this case, no significant differences were found between controls and patients with mild cirrhosis status (CPS-A) whereas groups CPS-B and CPS-C showed statistical differences to the control group in PDE ($P<0.001$) and ATP ($P<0.02$). If groups of patients were compared to each other, differences in patients within the CPS-A grouping increased for PDE as CPS worsened, no statistical differences were found in ATP. The relationship between calculated molar concentrations and the known etiology of liver cirrhosis is summarized in Table 2.

Spectroscopic data (PME, Pi, PDE and ATP concentrations) were also evaluated by various pattern recognition methods. We found similar levels of misclassification of subjects by using PCA, LDA and NDA procedures[15]. For demonstration and graphical output we used PCA plots from STATISTICA software[13], LDA and NDA results were not shown. To distinguish the different etiology and functional status of the liver cirrhosis from the controls, we highlighted individual subgroups of patients in PCA plots. If individual etiological groups were projected together with a control group, trends demonstrating the functional status of the liver were highlighted, i.e. the distance from the control area directly depended on CPS. The alcoholic group differed from

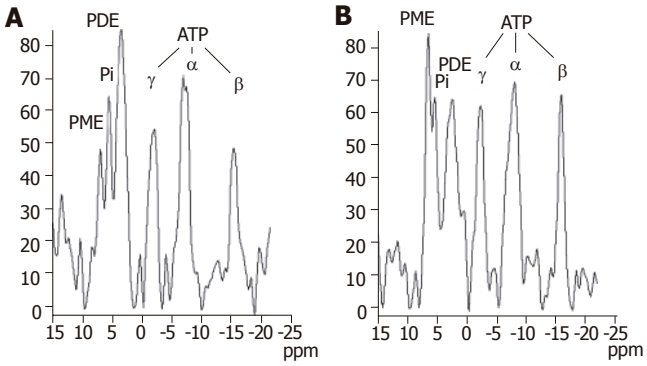

Figure 2 ^{31}P MR spectra of the liver in a healthy volunteer (**A**) and in a patient with liver cirrhosis (**B**). PME - phosphomonoesters; Pi - inorganic phosphate; PDE - phosphodiesters; γATP, αATP, βATP - γ, α and β phosphates of adenosine triphosphate.

Table 1 Concentrations of ^{31}P visible metabolites (mmol/L) in the liver according to the degree of liver injury

	n	PME	Pi	PDE	ATP
Controls	11	3.09±1.45	1.63±0.55	10.83±2.68	3.72±0.99
All patients	80	3.53±1.45	1.33±0.61	7.16±2.88[d]	2.95±0.84[b]
CPS-A	18	3.64±1.68	1.37±0.56	9.16±2.32	3.24±0.85
CPS-B	25	3.60±1.31	1.31±0.57	7.31±2.62[d]	2.93±0.78[a]

[a]P<0.05, [b]P<0.01, [d]P<0.001 *vs* the control group; [c]P<0.05 between alcohol and viral etiological groups; [f]P<0.001 *vs* the cholestatic group.
[1]The cholestatic group was not divided into subgroups reflecting CPS because of the insufficient number in groups CPS-A and CPS-C.

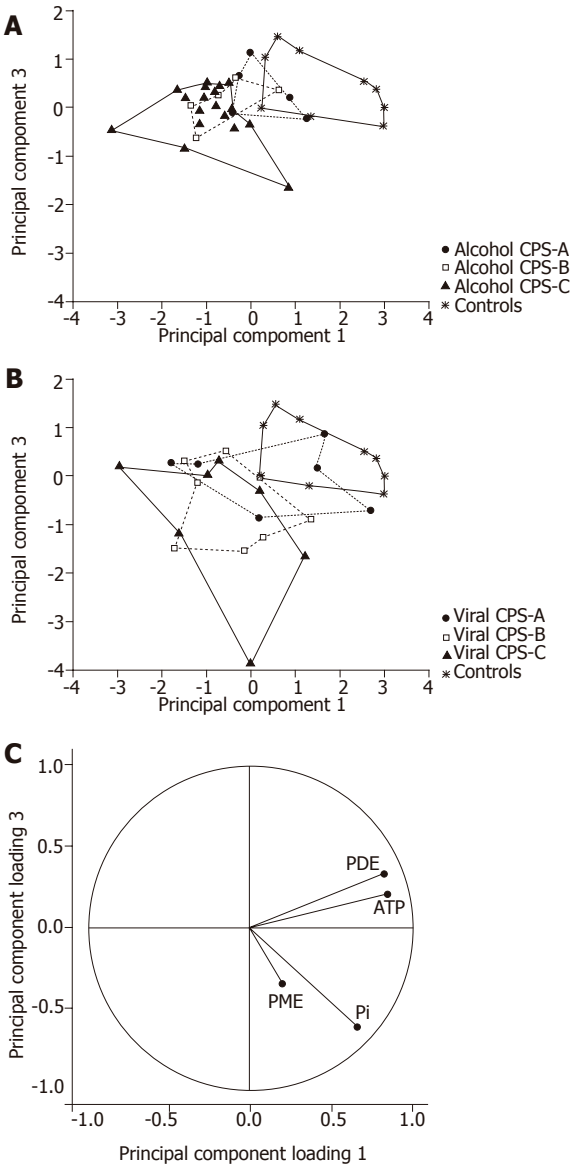

Figure 3 Results of principal component analysis (CPS). Individual positions of spectra displayed on the PCA scatterplots. Principal components are standardized (centered and scaled to unit variance). Principal component 1 explains 47 % of total variance, principal component explains 3 16% of total variance. (**A**) Patients with only alcoholic etiology and controls; (**B**) patients with only viral etiology and controls. Child-Pugh score subgroups (**A, B,** and **C**) and controls are bounded. (**C**) Projection of the principal component loadings on the planes 1 and 3.

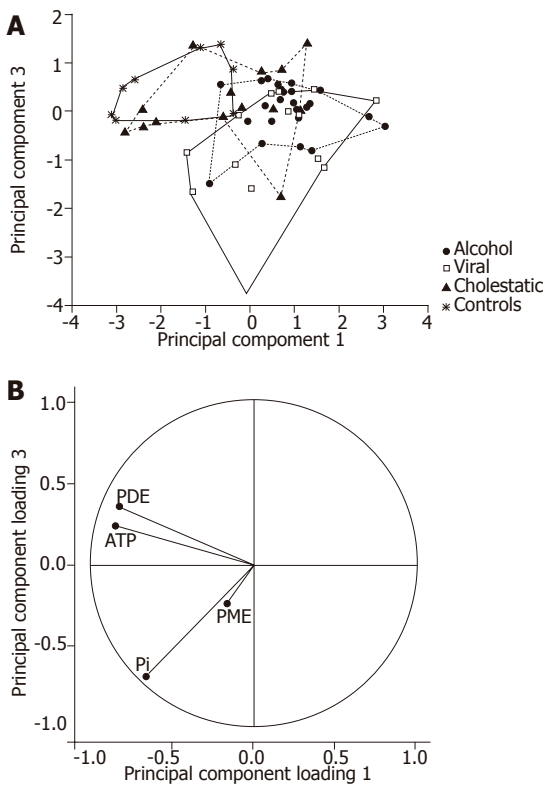

Figure 4 Results of principal component analysis (etiology). (**A**) Individual positions of spectra of patients with CPS-B and C together with a control group are displayed on the PCA plot. Etiological groups (alcoholic, viral and cholestatic) and controls are bounded. Principal component 1 explains 46 % of total variance, principal component 3 explains 17% of total variance; (**B**) Projection of the principal component loadings on the planes 1 and 3.

controls in the CPS-C area, whereas the viral group differed in the CPS-B area (Figure 3). Because of the insufficient number of cholestatic patients in the CPS-A and CPS-C groups, that plot was not presented.

As data from the CPS-A groups overlapped with controls, we used patients with CPS-B or CPS-C liver status for another statistical analysis (Figure 4). In this case, principal component analysis confirmed clear separation of viral patients from controls. Partial overlap was seen between alcoholic patients and controls. Finally, the group

of cholestatic patients overlapped all groups.

By comparing differences in ^{31}P MR spectra of patients to controls we could distinguish alcoholic, viral and cholestatic etiologies of liver cirrhosis. Patients with alcoholic and viral etiology differed in PDE and ATP from the control group. Unlike viral etiology, patients with alcoholic etiology also differed from the control group in Pi (P<0.05). No significant changes were found in patients with cholestatic disease and the control group; however, this group differed from both alcoholic and viral groups in PDE.

DISCUSSION

Diagnosis of liver cirrhosis is mainly based on invasive methods such as liver biopsy, laparoscopy, various radiological examinations and other clinical tests. The functional severity of liver cirrhosis is usually described by CPS which is partially based on subjective parameters. Thus, this description is not fully sufficient and can impair accuracy. On the other hand, signals from ^{31}P MR spectroscopy reflect intracellular and membrane metabolism *in vivo* non-invasively and they are objective parameters[6,7,8,10].

From our data above, we are able to conclude: (1) three basic etiologies can be distinguished by using correlation with metabolite concentrations; (2) there exists a correlation between the Child-Pugh score and the concentration of PDE and ATP, which is also observable in single etiologies.

The majority of published ^{31}P MR spectroscopic studies have dealt with quantification of relative signal intensities characterized by ratios such as PCr/Pi, Pi/ATP etc. Unlike previous studies, where only relative signal ratios were used, we measured absolute concentration of the metabolites[11]. Absolute quantification of metabolites in mmol/L is not often used because of technical problems[12,16]. However, we believe that only relative quantification using signal intensity ratios cannot fully describe metabolic changes and absolute quantification should be taken into account even if a number of correction factors must be calculated. For example, if two or more compounds increase or decrease together, only the absolute quantification of independent metabolites accurately describes the event as signal ratios may remain unchanged.

PCA analysis of PME, Pi, PDE and ATP concentrations showed different localization of the etiological groups and trends in accordance with the CPS (Figures 3 and 4). Projection of the variables confirmed the similarities of ATP and PDE spectroscopic parameters. The best separation was obtained in the projection on the principal component-planes 1 and 3 despite losing some information available in the projections 1 and 2. The principal component 2 correlated specifically with PME. Nevertheless, in our study PME had high variation so that we did not use the projection on the component-plane 1 and 2.

Standard statistic tests confirmed the trends observable in PCA graphs. Data show a mean decrease of about 23% in ATP in patients with alcohol etiology versus the control group. A similar decrease of ATP concentration was also observed in the group of patients with viral etiology. In both groups we found that the decrease strongly depend on the CPS. Nevertheless, the higher difference was foud between CPS group A and CPS groups B and C. A very small difference was observed between CPS groups B and C which could be explained by the overall severity of hepatocyte dysfunction. Contrary to the alcoholic and viral groups, no statistically significant changes were found in ATP concentration in the cholestatic group.

Our findings in the group of alcoholic patients correspond to the results of animal studies. A number of reports show decreased levels of ATP in the liver of animals chronically fed ethanol. ATP levels could be measured using the intragastric feeding model[17,18]. In rats feeding a high-fat, low protein diet plus alcohol (similar to the diet of malnourished human alcoholics) levels of ATP decreased and remained constant at 35 % lower than levels of ATP in control animals. Hypoxia resulted in a decrease in hepatic levels of ATP in both ethanol-fed and control rats, but the magnitude of the decrease was significantly greater in the ethanol-fed group. Levels of adenosine monophosphate (AMP) and adenosine diphosphate (ADP) were not changed.

The most important change was a decreased concentration of PDE which is considered to be an indicator of membrane phospholipids and catabolic processes. The rate of PDE change was different in various etiologies. When etiological groups were compared to the control group regardless of CPS status (Table 2), mean PDE values were found to be about 60% in alcoholic and viral patients (P<0.001 to controls, and P<0.005 compared to the cholestatic group) and about 86% in the cholestatic group (without statistical significance). Moreover, in CPS-C groups, PDE concentration decreased to 39% of the control value in viral patients (58% in CPS-B) whereas in alcoholic patients PDE did not further decrease (57% of control PDE value in CPS-B and CPS-C). The fact that the changes are already significant in milder stages of cirrhosis (CPS-B) can improve the diagnostic effectiveness of this method. Unlike a previous study[9], our results were more pronounced in more severely affected patients.

We also studied PME concentration, which mainly represents intermediates on the phospholipid biosynthesis pathway. Although some other studies describe an increased PME signal[7,9,19-21], our data only show a statistically non-significant trend.

The last measured concentration - inorganic phosphate Pi - has been found to change only in alcoholic patients (P<0.05). Thus, inorganic phosphate concentration could be used to separate patients with alcoholic and viral etiology.

Observed signals in ^{31}P MR spectra describe many metabolites in intra and extracellular liver tissue. It is known that many types of cells (hepatocytes, cholangiocytes, vascular wall cells, hepatic stellate cells macrophages and others) contribute to liver metabolism depending on their status. Changes in extracellular matrix also influence the concentration of energetic metabolites. Although ^{31}P MR signals from the liver represent whole parenchymal tissue, the results of our study have confirmed previous

findings that metabolic changes in energetic phospholipid metabolism are observable by ^{31}P MRS in patients with decompensated cirrhosis in contrast to patients with compensated cirrhosis. In addition, different concentrations of metabolites in various etiologies indicate different damages of liver parenchyma.

In conclusion, according to differences in ^{31}P MR spectra of patients and controls, we can differentiate various etiologies of liver cirrhosis, i.e. alcoholic, viral and cholestatic. Patients with alcoholic etiology differed in all selected metabolites except for PME from the control group. Patients with viral etiology differed from controls only in PDE and ATP, and no significant changes were found in patients with cholestatic disease. We suppose that this reflects different pathophysiological mechanisms of various liver diseases.

The importance of a larger, multicentric study to delineate ranges, borders and significant parameters for different cirrhotic groups (etiological and/or functional) in the nearest future is advisable. That will be the only way to assess the clinical relevance and usefulness of ^{31}P MRS in liver cirrhosis. The application of this noninvasive method in liver patients will increase. The ultimate goal is the use of ^{31}P MRS as a standard tool in the armamentarium of clinical hepatologists.

Abstract

AIM: To evaluate the usefulness of three-dimensional computed tomography (3DCT) in laparoscopic surgery for colorectal carcinoma.

METHODS: Seventy-two patients with colorectal cancer who underwent curative operation at our hospital were enrolled in this study. They were classified into two groups by operative procedures. Sixteen patients underwent laparoscopic surgery, laparoscopic group (LG), while 56 patients underwent conventional open surgery, open group (OG). At our institution, contrast-enhanced CT is routinely performed as part of intra-abdominal screening and the 3D images of the major regional vessels are described. We have previously described about the preoperative visualization of the inferior mesenteric artery (IMA) by 3DCT. This time we newly acquired 3D images of the superior mesenteric artery (SMA)/superior mesenteric vein (SMV), ileocecal artery (ICA), middle colic artery (MCA), and inferior mesenteric vein (IMV). We have compared our two study groups with regard to five items, including clinical anastomotic leakage. We have discussed here the role of 3DCT in laparoscopic surgery for colorectal carcinoma.

RESULTS: The mean length of the incision in LG was 4.625±0.89 cm, which was significantly shorter than that in OG (P<0.001). The association between ICA and SMV and SMA was described in the right-sided colectomy. The preoperative imaging of IMA and IMV was created in the rectosigmoidectomy. There was no significant difference in anastomotic leakage between the two groups, but no patients in LG experienced anastomotic leakage.

CONCLUSION: Most of the patients are satisfied with the shorter incisional length following laparoscopic surgery. Preoperative visualization of the major regional vessels may be helpful for the secure treatment of the anastomosis in laparoscopic surgery for colorectal carcinoma.

Key words: Three-dimensional computed tomography; Laparoscopic colorectal surgery; Colorectal cancer

INTRODUCTION

Laparoscopic colectomy has been generally accepted, and the instruments and techniques have been developed considerably. The advantages of laparoscopic approaches include shorter hospital stay, quicker return of gastrointestinal function, less pain, fewer wound complications, and quicker recovery[1-6]. However, laparoscopic colorectal surgery for malignancies requires the use of advanced surgical techniques that entail a long learning curve[7,8]. In right-sided colon cancer, the regional anatomy is relatively complicated[9]. In the lymph node dissection around the surgical trunk, it is important to recognize two patterns in the relationship between the ileocecal artery (ICA) and the superior mesenteric vein (SMV). One pattern is that the ICA is in front of SMV (Type A), and the other is that ICA is in back of SMV (Type B)[10]. A previous study have described about the risk of more anastomotic leakage in the converted laparoscopic colorectal surgery compared to the conventional open surgery[11]. In laparoscopic colorectal surgery, understanding of the anatomical orientation, including the regional vessels, is important. We have previously reported that preoperative visualization of the inferior mesenteric artery (IMA) by three-dimensional computed tomography (3DCT) is useful in colorectal surgery[12]. In this study, we have described about the three-dimensional (3D) images of the other major visceral vessels, such as the superior mesenteric artery (SMA), SMV, ICA, middle colic artery (MCA), and inferior mesenteric vein (IMV). Here, we have

evaluated the efficacy of 3DCT in performing laparoscopic colorectal surgery for carcinoma.

MATERIALS AND METHODS

Patients

Between April 2002 and March 2005, 72 patients with colorectal cancer underwent curative surgery at our hospital. Operative procedures were laparoscopic colorectal surgery [laparoscopic group (LG); 16 patients: 5 men and 11 women] and open colorectal surgery [open group (OG); 56 patients: 32 men and 14 women]. The mean age was 66.6±7.4 years (range, 52-83 years) in LG and 68.2±11.3 years (range, 36-91 years) in OG. The following data were examined and compared between LG and OG: (1) patient's age and gender; (2) Duke's staging; (3) presence of the postoperative ileus; (4) length of incision for exteriorization and resection of the specimen; (5) wound infection; and (6) clinical anastomotic leakage.

Methods

Contrast-enhanced CT is routinely performed to screen for intra-abdominal malignancies before the surgery at our hospital. Dual-phase helical CT was performed with a high-speed scanner [multi-detector CT (MDCT); Aquilion M8, Toshiba Medical Systems Co., Ltd, Tokyo, Japan] on the patients. During each phase, scanning was performed in a single breath-hold. Dual-phase helical CT data were then transferred to a Zio M900 workstation (Ziosoft, Inc., Morgan Hill, CA, USA), and 3DCT images of the major visceral vessels, such as SMA, SMV, ICA, IMA, and IMV, were reconstructed. The detailed imaging techniques have been described in the previous literatures[12,13]. In right-sided colectomy, the association between ICA and SMV, the variation of the right colic artery (RCA) and the image of the middle colic artery were confirmed by 3DCT before the surgery. In the resectioning of advanced sigmoid colon and rectal cancer, we routinely dissect the lymph nodes around the root of IMA while preserving the left colic artery (LCA), because resection of the root of IMA occasionally causes ischemia of the oral side of the sigmoid colon, sometimes leading to anastomotic leakage[12].

Statistical analysis

Data were expressed as the mean±SD. Statistical analysis was performed using Mann-Whitney *U* test, χ^2 and Student's *t*-test. *P* values of less than 0.05 were considered statistically significant.

RESULTS

There was no significant difference in age, gender, Duke's staging, presence of the postoperative ileus or wound infection between the LG and the OG (Tables 1 and 2). The mean length of incision in the LG (4.625± 0.885 cm) was significantly shorter, than that in OG (15.91 ±2.51 cm, $P<0.001$). Three patients in OG experienced anastomotic leakage, while no patients in LG experienced it. However, there was no statistically significant difference in anastomotic leakage between these two groups. Two of the three patients undergoing anastomotic leakage in OG suffered from advanced rectal cancer. The root of IMA was resected because of the wide-ranging lymph node metastasis. In one of the two patients, lymph node metastasis spread around the marginal vessels of the sigmoid colon.

Table 1 Characteristics of patients in the two groups

	LG (*n* = 16)	OG (*n* = 56)	*P*
Age (yr)	66.6±7.4 (52–83)	68.2±11.3 (36–91)	NS

Duke's staging			NS
A	7	12	
B	6	24	
C	3	20	

NS: not statistically significant

Table 2 Complications of surgery

	LG (*n* = 16)	OG (*n* = 56)	*P*
Postoperative ileus	0	5	NS
Wound infection	2	13	NS
Anastomotic leakage	0	3	NS

Preoperative visualization of the ICA in front of the SMV (Type A) and that in back of the SMV (Type B) is shown in Figures 1A and 2A, respectively. The variation of the RCA and MCA was evaluated. Intraoperative findings of the association between ICA and SMV are shown in Figures 1B, 2B and C. Figure 3 shows the MCA diverging at a more peripheral portion of SMA than usual. The image of IMA and LCA to be preserved can be seen (Figure 4A). The intraoperative findings are shown in Figure 4B. Preoperative visualization of the essential vessels was described in all the patients undergoing contrast-enhanced CT.

DISCUSSION

Laparoscopic approaches have been widely applied, but laparoscopic colorectal surgery for carcinoma is not yet a proven operation[1]. There exists some controversies about the safety of the operation[14,15], the oncological results[16,17] and the long-term survival rate[18]. Recently, a number of studies have shown a favorable outcome of laparoscopic surgery for colon cancer[19-23]. There appears to be no significant differences in perioperative complications between laparoscopic and open colorectal surgery[24]. In our study, we acquired the same results in the presence of postoperative ileus and wound infection. The mean length of the wound used for the extraction of specimens in LG was significantly shorter than that in OG. Most of the patients in LG were satisfied with the shortness of the incisional length during the perioperative period and the subtlety of the incisional scar during the follow-up period, as they had said[25]. In addition, laparoscopic surgery has been found to be associated with significantly decreased intraoperative blood loss and postoperative complications[19,26]. The anastomotic leak rate reported in a larger series of laparoscopic anterior resection was considerably less than 10%, which was comparable to that of conventional open anterior resection[18,27]. To date, the laparoscopic approach for colorectal surgery is not associated with a higher risk of anastomotic leaks[28].

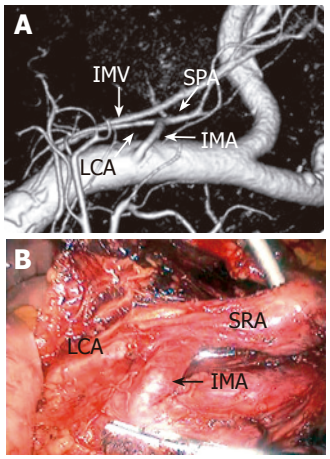

Figure 4 Three-dimensional images of the IMA, the IMV, the LCA and the superior rectal artery (SRA) were obtained (**A**) and were helpful in resecting the SRA (**B**).

In a previous report, four instances (25%) of clinical anastomotic leakage occurred in patients in whom the laparoscopic dissection had been difficult[11]. For the prevention of leakage, it is essential that there is a good supply to the colorectal anastomosis site[29]. Therefore, we preserve the LCA when dissecting lymph nodes around the root of IMA. Understanding the vascular anatomy of the regional vessels is important[12]. Preoperative visualization of SMA/SMV, ICA, MCA or IMA/IMV is crucial when performing a right-sided colectomy or a rectosigmoidectomy. Recently, a new generation of MDCT has been used in clinical practice[30]. At our hospital, MDCT has been performed not only to examine intra-abdominal malignancies, but also to provide preoperative visualization of the regional vessels. At our institution, no patients in LG had experienced anastomotic leakage, while three patients in OG experienced so. Ischemia of the oral side colon may have caused anastomotic leakage. There was no significant difference in anastomotic leakage between LG and OG, suggesting that preoperative visualization in laparoscopic surgery may be helpful in the prevention of anastomotic leakage. MDCT scanning is performed in a single breath-hold during each phase. In the past, there was a significant delay before roentgen engineers could show us the 3D images of the regional vessels, but now they are able to provide 3D images promptly after CT scanning. Having 3D images of SMA/SMV, ICA, MCA, and IMA/IMV lead to a more secure treatment of the regional vessels in laparoscopic surgery for carcinoma.

In conclusion, we suggest that preoperative visualization of the major regional vessels may have advantages in laparoscopic surgery for colorectal carcinoma.

Abstract

AIM: To evaluate the expression of fibrinogen-like protein 2 (fgl2) and its correlation with disease progression in both mice and patients with severe viral hepatitis.

METHODS: Balb/cJ or A/J mice were infected intraperitoneally (ip) with 100 PFU of murine hepatitis virus type 3 (MHV-3), liver and serum were harvested at 24, 48, and 72 h post infection for further use. Liver tissues were obtained from 23 patients with severe acute chronic (AOC) hepatitis B and 13 patients with mild chronic hepatitis B. Fourteen patients with mild chronic hepatitis B with cirrhosis and 4 liver donors served as normal controls. In addition, peripheral blood mononuclear cells (PBMC) were isolated from 30 patients (unpaired) with severe AOC hepatitis B and 10 healthy volunteers as controls. Procoagulant activity representing functional prothrombinase activity in PBMC and white blood cells was also assayed. A polyclonal antibody against fgl2 was used to detect the expression of both mouse and human fgl2 protein in liver samples as well as in PBMC by immunohistochemistry staining in a separate set of studies. Alanine aminotransferase (ALT) and total bilirubin (TBil) in serum were measured to assess the severity of liver injury.

RESULTS: Histological changes were found in liver sections 12-24 h post MHV-3 infection in Balb/cJ mice. In association with changes in liver histology, marked elevations in serum ALT and TBil were observed. Mouse fgl2 (mfgl2) protein was detected in the endothelium of intrahepatic veins and hepatic sinusoids within the liver 24 h after MHV-3 infection. Liver tissues from the patients with severe AOC hepatitis B had classical pathological features of acute necroinflammation. Human fgl2 (hfgl2) was detected in 21 of 23 patients (91.30%) with severe AOC hepatitis B, while only 1 of 13 patients (7.69%) with mild chronic hepatitis B and cirrhosis had hfgl2 mRNA or protein expression. Twenty-eight of thirty patients (93.33%) with severe AOC hepatitis B and 1 of 10 with mild chronic hepatitis B had detectable hfgl2 expression in PBMC. No hfgl2 expression was found either in the liver tissue or in the PBMC from normal donors. There was a positive correlation between hfgl2 expression and the severity of the liver disease as indicated by the levels of TBil. PCA significantly increased in PBMC in patients with severe AOC hepatitis B.

CONCLUSION: The molecular and cellular results reported here in both mice and patients with severe viral hepatitis suggest that virus-induced hfgl2 prothrombinase/fibroleukin expression and the coagulation activity associated with the encoded fgl2 protein play a pivotal role in initiating severe hepatitis. The measurement of hfgl2/fibroleukin expression in PBMC may serve as a useful marker to monitor the severity of AOC hepatitis B and a target for therapeutic intervention.

INTRODUCTION

Viral hepatitis remains a major public health problem and the most common type of liver disease worldwide[1,2]. There are an increasing number of patients with chronic hepatitis B who develop acute hepatitis on chronic condition (AOC) and die of acute hepatic failure both as a result of our lack of understanding of the pathogenesis of the disease and lack of effective treatment[3]. The hallmark of AOC is the extreme rapidity of the necro-microinflammatory process resulting in widespread or total hepatocellular necrosis in weeks or even in days[3]. Our previous studies have shown that macrophage activation and expression of fgl2, encoding a serine protease capable of directly cleaving prothrombin to thrombin, result in widespread fibrin deposition within the liver and hepatocyte necrosis[3-6]. The present study was designed to assess the expression of fgl2 and its correlation with disease progression in both mice and patients with severe viral hepatitis.

MATERIALS AND METHODS

Virus

MHV-3 was purchased from the American Type Culture Collection (ATCC), plaque was purified on monolayers of DBT cells and grown to a titer of 1×10^6 PFU/mL in 17 CL cells. Viral titers were determined on monolayers of L2 cells by a standard plaque assay as described elsewhere[5].

Animals

Female Balb/cJ mice, 8-10 wk of age and weighing 20-22 g, were purchased from Hubei Provincial Institute of Science and Technology. Female A/J mice, 8-10 wk of age and weighing 20-22 g, were purchased from Jackson Laboratory (Bar Harbor, ME, USA).

Main reagents

The affinity-purified polyclonal antibody to both murine and human fgl2 prothrombinases was produced by 21 repeated injections into rabbits with a 14-amino-acid hydrophilic peptide (CKLQADDHRDPGGN) from exon 1 of the fgl2 prothrombinase coupled to keyhole limpet hemocyanin. Rabbit brain thromboplastin was purchased from Sigma Chemical Company (St. Louis, MO, USA).

Murine hepatitis model

All animal experiments were carried out according to the guidelines of the Chinese Council on Animal Care and approved by the Tongji Hospital of Tongji Medical College Committees on Animal Experimentation. The research protocol was reviewed and approved by the Hospital Institutional Review Board of Tongji Hospital, Huazhong University of Science and Technology, Wuhan, China. All mice were housed in the animal facility in Tongji Hospital. Mice received 100 PFU of MHV-3 by intraperitoneal injection. The liver and serum were collected from both Balb/cJ and A/J mice 0, 24, 48, and 72 h after intraperitoneal injection of MHV-3.

Patients

Biochemical, histological, and clinical features were used to define patients with severe AOC hepatitis B or mild chronic viral hepatitis B and compensated cirrhosis. The patients with chronic viral hepatitis B were evaluated on the basis of a thorough history and physical examination with special emphasis on risk factors for co-infection (with hepatitis C, D, or HIV), alcohol use, family history of viral hepatitis B and liver cancer. Liver tissues were obtained by biopsies from patients in 1995-2001, including 23 severe AOC hepatitis B patients (20 males and 3 females, 36.0±7.8 years on average with a mortality of 82% ALT 586.0±570.2 IU/L, TBil 452.9±227.2 μmol/L, and PT 35±10 s), 13 mild chronic hepatitis B patients (11 males and 2 females, 43.8±5.6 years on average, ALT 300.5±325.2 IU/L, TBil 78.3±175.4 μmol/L, and PT 12±1 s), 14 compensated cirrhosis hepatitis B patients (all males, 45.0±8.6 years on average, ALT 265.3±215.8 IU/L and TBil 46.6±27.6 μmol/L, PT 14±2 s). All mild chronic hepatitis B and compensated cirrhotic hepatitis B patients recovered from the disease. There were no significant differences in HBV DNA levels among different groups of patients. Liver biopsies were performed within 30 min after the patients died of acute hepatic failure. Liver samples were also obtained from four liver donors as normal controls. PBMCs were freshly isolated from 30 patients (all males, 37.7±9.1 years on average) with severe AOC hepatitis B, elevated ALT (108.9±75.2 IU/L) and TBil (389.3±116.9 μmol/L), elevated PT (40±31 s). Ten mild chronic hepatitis B patients (8 males and 2 females, 34.0±10.5 years on average) had normal ALT and TBil. The isolated PBMCs were smeared on slides and kept at -80 ℃ for further study. Liver tissue histological sections were stained with hemotoxylin and eosin.

Immunohistochemical staining

Immunohistochemical staining was performed with a rabbit polyclonal antibody against the fgl2 prothrombinase as described previously[3,6].

Procoagulant activity (PCA)

PBMC and white blood cells (WBC) were evaluated for functional PCA in a one-stage clotting assay. Freshly isolated PBMC and WBC were washed twice with PBS (pH 7.0) and resuspended at a concentration of 10^6/mL. Samples were assayed for the ability to shorten the spontaneous clotting time of normal citrated human platelet-poor plasma. Milliunits of PCA were assigned by reference to a standard curve generated with serial log dilutions of a standard rabbit brain thromboplastin as described previously[2].

Statistical analysis

Quantitative data were expressed as mean±SD. Statistical analysis was carried out by one-way analysis of variance. $P<0.05$ was considered statistically significant.

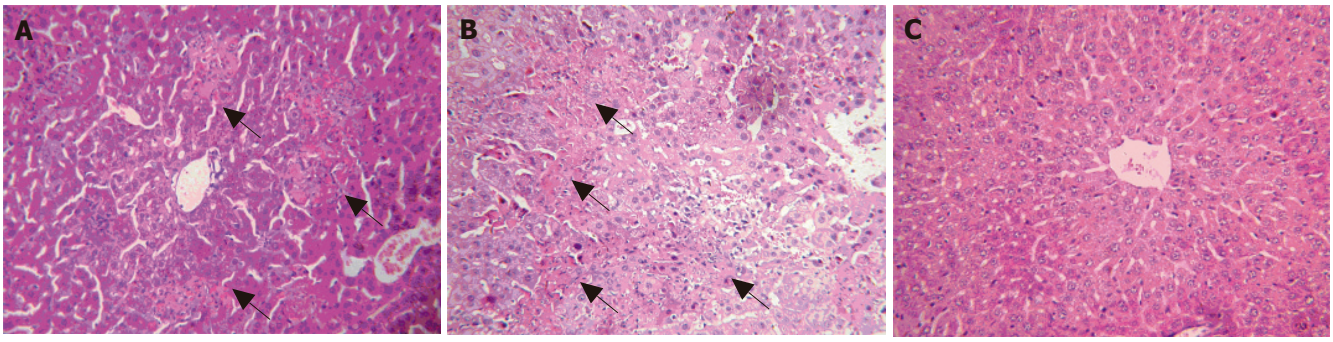

Figure 1 HE staining of liver tissue 48 h (**A**) and 72 h (**B**) after MHV-3 infection in Balb/cJ mice and 72 h (**C**) after MHV-3 infection in A/J mice. Arrows represent areas of hepatocyte necrosis.

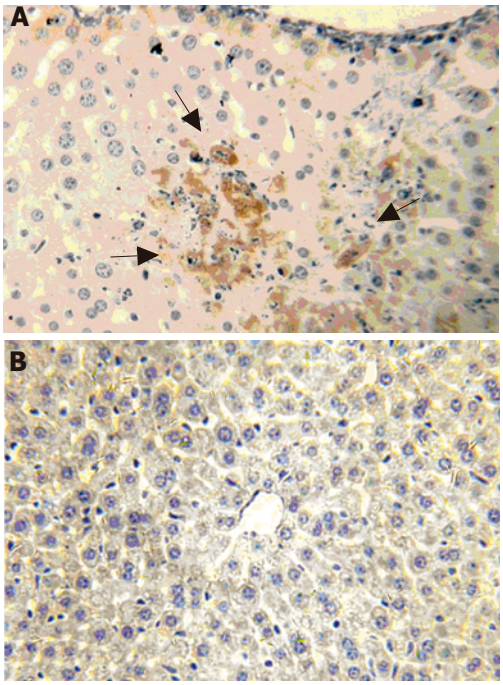

Figure 3 Mfgl2 expression in liver 24 h after MHV-3 infection Balb/cJ (**A**) and A/J (**B**) mice by immunohistochemical staining. Arrows represent mfgl2 positive cells.

RESULTS

Peritoneal administration of MHV-3-induced fulminant viral hepatitis in Balb/cJ mice

Small and discrete foci of necrosis with sparse polymorphonuclear leukocyte infiltrates were seen 12-24 h after MHV-3 infection. After 48 h, the area of these lesions enlarged and became confluent necroses (Figures 1A and 1B). There was no evidence of necrosis in the livers of MHV-3 infected A/J mice (Figure 1C). In Balb/cJ mice, serum ALT and TBil levels increased after 16-24 h, peaked at 72 h and remained elevated thereafter, while there were no significant ALT and TBil changes in MHV-3-infected A/J mice (Figures 2A and 2B).

Elevated expression of mfgl2 prothrombinase in MHV-3-infected Balb/cJ mice

mfgl2 prothrombinase expression increased in MHV-3-infected Balb/cJ mice starting from 12 to 24 h (Figure 3A) and was sustained until the animals died days after infection (data not shown). There was no evidence of mfgl2 staining in normal Balb/cJ mice (data not shown) or MHV-3-infected A/J mice (Figure 3B).

Increased hfgl2 prothrombinase and PCA in patients with severe AOC hepatitis B

Hfgl2 was detected in 21 of 23 patients (91.30%) with severe AOC hepatitis B (Figure 4A), while only 1 of 13 patients (7.69%) with mild chronic hepatitis B and cirrhosis (no evidence of active disease) had hfgl2 mRNA or protein expression. Twenty-eight of thirty patients with severe AOC hepatitis B (93.33%) and 1 of 10 with mild chronic hepatitis B had detectable hfgl2 expression in PBMC (Figure 4C). There was no hfgl2 expression either in the liver tissue or in the PBMC from the normal donors.

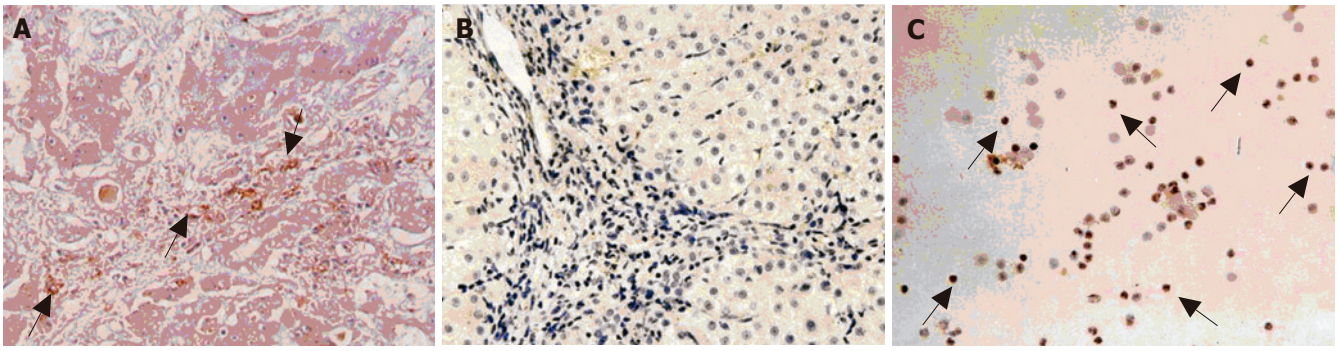

Figure 4 Immunohistochemical staining of hfgl2 in liver of patients with server AOC hepatitis B (**A**) and mild chronic hepatitis B (**B**) or in PBMC of patients with severe AOC hepatitis B (**C**). Arrows represent hfgl2 positive cells.

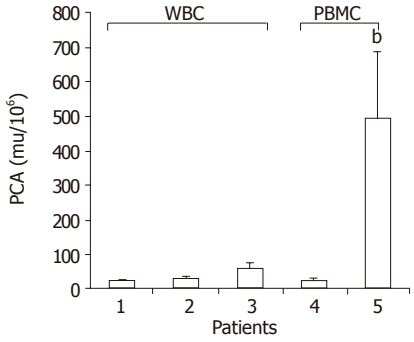

Figure 5 PCA levels in PBMC and WBC of patients.1. Healthy control; 2. patients with mild chronic hepatitis B; 3. patients with severe AOC hepatitis B; 4. healthy control; 5. patients with severe AOC hepatitis B. $^{b}P<0.01$ *vs* group 4

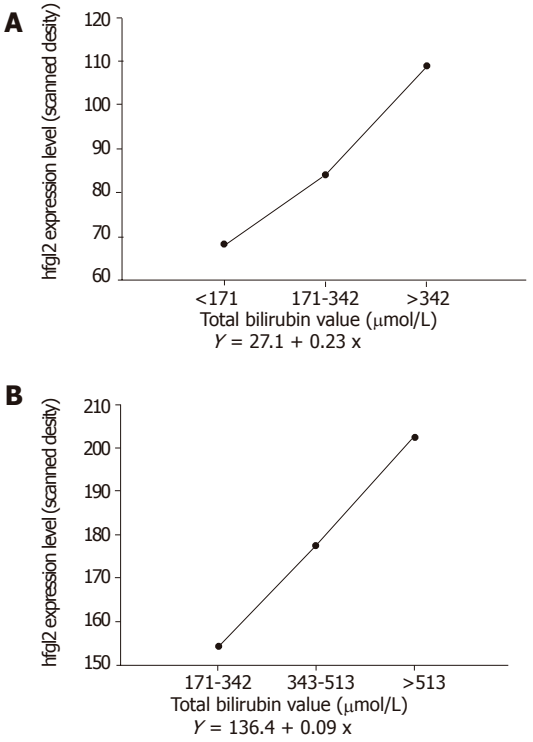

Figure 6 Correlation of hfgl2 expression in liver (**A**) and PBMC (**B**) with serum TBil level.

There was a significant increase in PCA activity in patients with serve AOC hepatitis B compared to patients with mild chronic hepatitis B, while there was no significant difference in PCA in various groups of patients (Figure 5).

Expression of hfgl2 prothrombinase correlates with the severity of hepatitis B

Hfgl2 expression both in liver and in PBMC was semi-quantified by a MPIAS-500 scanning analysis system. The data indicated that there was a close correlation between hfgl2 expression and the severity of the disease as shown in Figures 6A and 6B.

DISCUSSION

The inability to propagate human hepatitis viruses in culture and the lack of suitable animal models have impeded the determination of the pathological mechanisms of fulminant hepatic failure (FHF). However, animal models of FHF induced by murine hepatitis virus strain 3[4,7], transgenic models of hepatitis B virus infection[8,9] and clinical cases of FHF have provided insights into the pathogenesis of viral FHF[3,6]. MHV-3 produces a broad spectrum of diseases, including pneumonitis, encephalitis, enterocolitis, nephritis, and hepatitis[10,11]. This report demonstrated that Balb/cJ mice after MHV-3 infection developed fulminant viral hepatitis. HE staining showed infiltration of lymphocytes and massive hepatic necrosis in association with mfgl2 expression in the endothelial cells of hepatic sinusoids and in areas of focal necrosis. The serum ALT and bilirubin levels reflected the damage of liver tissue in MHV-3-induced FHF in Balb/cJ mice. In contrast, there was no or only minor hepatocyte injury with no mfgl2 in MHV-3-infected A/J mice. Therefore, these results further demonstrate that though MHV-3 replicates in tissues of both resistant and susceptible animals, suggesting that host factors may be more critical than viral replication in the pathogenesis of MHV-induced hepatitis. Our previous study have demonstrated that MHV-3 infection of macrophages results in transcription of host inflammatory cytokines, including TNF-α, IL-1, and superoxides[4]. Cytokines can play an important role in the course of inflammatory injury *in vivo*, and interference

with their action can alter the course of inflammatory diseases[12-15]. The importance of mfgl2 prothrombinase in the pathogenesis of MHV-3 infection is supported by the observation that a neutralizing antibody to this protein prevents fibrin deposition and protects mice from the lethality of MHV-3 infection. Furthermore, mfgl2 knockout mice lack fibrin deposition and liver necrosis and survival increased from 0% to 33%[3,16].

To address the relevance of hfgl2 in human chronic viral hepatitis, we studied patients with both minimal and severe AOC hepatitis B. We detected robust expression of hfgl2 near or within the areas of hepatic necrosis and elevated levels of hfgl2 were seen in PBMC isolated from patients with severe AOC hepatitis B. These findings are in contrast to the lack of expression of hfgl2 in the livers and PBMC of patients with minimal chronic hepatitis B. Functional assay of hfgl2 prothrombinase in PBMC showed a robust increase of PCA in patients with severe AOC hepatitis B compared to patients with minimal chronic hepatitis B. Semiquantitative analysis of hfgl2 expression both in liver tissue and PBMC showed a close correlation with the severity of the disease as indicated by elevations in serum bilirubin levels. There was no significant difference in terms of HBeAg level and HBV DNA level between different groups of patients, further supporting that host factors may be critical in the pathogenesis of severe hepatitis.

In conclusion, MHV-3-induced hfgl2 prothrombinase/fibroleukin expression and the potent function of the protein it encodes play a pivotal role in initiating both acute and fulminant hepatitis on chronic liver injury. The measurement of hfgl2 expression in PBMC may serve as a useful marker to monitor the severity of AOC hepatitis B and a target for therapeutic intervention.

Abstract

AIM: To observe the interaction between the expression of telomerase activity (TA) and its associate genes in regulation of the terminal restriction fragment length (TRFL) in esophageal squamous cell carcinoma (SCC).

METHODS: Seventy-four specimens of esophageal SCC were examined. The TA was measured by telomeric repeat amplification protocol (TRAP) assay, and the associated genes [human telomerase-specific reverse transcriptase (hTERT), hTERC, TP1, c-Myc, TRF1, and TRF2] were detected using RT-PCR method. The TRFL was measured by Telomere Length Assay Kit and Southern blotting. The correlations between the expression of telomerase and its associated genes with the TRFL and survivals were examined.

RESULTS: Expressions of the TA, hTERT, hTERC, TP1, c-Myc, TRF1, and TRF2 genes were observed in 85.1%, 64.9%, 79.7%, 100.0%, 94.6%, 82.4%, and 91.9% of the tumor tissues, respectively. The TRFL of the tumor and normal esophageal tissues were 2.70±1.42 and 4.93 ±1.74 kb, respectively (P<0.0001). The TRFL of the telomerase positive and telomerase negative tumor tissues were 2.72±1.44 and 2.58±1.32 kb, respectively (P = 0.767). The TRFL ratios (TRFLR) of the telomerase positive and telomerase negative tumor tissues were 0.55±0.22 and 0.59±0.41, respectively (P = 0.742). The expression rates of h-TERT (P = 0.0002), hTERC (P<0.0001), and TRF1 (P = 0.002) in the tumor tissues are higher than those of the normal paired tissues. Though TA is markedly activated in tumor tissues (P<0.0001), its expression is not related to clinicopathological parameters including gender, tumor differentiation, and TNM stages. The cumulative 4-year survival rates of telomerase positive and telomerase negative cases were 35.86% and 31.2%, respectively (P = 0.8442). The cumulative 4-year survival rates of patients with their TRFLR ≤85% and >85% were 38.7% and 15.7%, respectively (P = 0.1307).

CONCLUSION: Though telomerase expression is not related to tumor stages and prognosis, our data support that the TA increased as the TRFL decreased, probably under the control of hTERT, hTERC, and TRF1. When telomerase expression was activated, only TRF2 overexpression persisted to stabilize T-loop formation. Furthermore, as the TRFLR decreased to 85%, a trend of better prognosis was observed. Cox model analysis indicates a higher t/n TRFLR and distant metastasis are independent poorer prognostic factors (P = 0.035 and P = 0.042, respectively).

INTRODUCTION

Telomerase is a ribonucleoprotein, which is responsible for the synthesis and maintenance of the telomeric repeats at the distal ends of human chromosomes. These end structures, named telomeres, serve as protective caps and consist of specific tandem repeats (5'-TTAGGG-3') with an average length of 5-20 kb[1-3]. Upon each cell division, the chromosomal ends shorten at a rate of 50-200 bp[4] This molecular erosion sets a physical limit to the potential number of cell divisions and serves as a "mitotic clock" defining the lifespan of somatic cells. Unlike somatic cells, new telomeric repeats are added to the chromosomal end of the germline cells to maintain their stability and also preserve their full genomic information for the next

generation[5]. Similarly, immortalized cell lines and more than 85% of the cancer cells can prevent the telomere from progressive shortening by telomerase activation. This phenomenon is regulated by a length-sensing feedback mechanism when the critical point is reached[6]. Telomerase contains a catalytic human telomerase-specific reverse transcriptase (hTERT) and a RNA template (hTERC) for the telomere, provides the cancer cells unlimited replicative capacity and prevents lethal chromosomal instability. Other telomerase-independent mechanism called as alternative lengthening of telomeres (ALT) may ensure the same chromosome ends replication functions.

Normally, the 3' DNA terminal protein-DNA complexes of the telomeres form capping structures to stabilize chromosomal ends and prevent them from being recognized as DNA double-strand breaks by the cells. The current model for chromosome capping is that telomeres form a higher-order chromatin structure that physically hides the 3'-chromosome end from cellular activities. This protective structure could be provided by the ability of the 3'-overhang to fold back and invade the double-strand region of the telomere forming the so-called T-loop and D-loop with the help of TRF1 and TRF2[7,8]. If these checkpoints fail, chromosomal instability may ensue leading to oncogenic mutations.

Since 1994, the telomeric repeat amplification protocol (TRAP) assay was extensively used for the detection of TA. Our previous report has demonstrated good correlations between the expressions of hTERT (not telomerase) and its associated genes such as c-Myc, TRF1 and TRF2[9]. We also found that the expression of the TA may indicate poorer prognosis[10]. A tumor-to-normal telomere restriction fragment length ratio (t/n TRFLR) $\leq$ 75% indicates a better prognosis[11]. In addition, we found a negative linear correlation between the t/n TRFLR and expression of TA, suggesting a negative feedback mechanism in the maintenance of TRFL[11]. In this study, we investigated for correlations between the changes of t/n TRFLR and expression of the telomerase associated genes including c-Myc, TRF1 and TRF2 in squamous cell carcinoma of the esophagus.

MATERIALS AND METHODS

Patients and follow-up

Between June 1999 and December 2003, we included 74 cases of squamous cell carcinoma of the esophagus who underwent surgical resection in this prospective study. Patients who received pre-operative chemotherapy or radiotherapy were excluded. Whole body bone scan and liver sonography were performed for all of the patients to rule out systemic metastasis. The tumor differentiation included well-differentiated carcinoma in none, moderately differentiated carcinoma in 49, and poorly differentiated carcinoma in 25. Tumor staging was performed according to the AJCC (6th edition) criteria[12]. The p-TNM stages included stage I in 2, stage II in 25, stage III in 33, and stage IV in 14. The clinicopathological characteristics of the patients are summarized in Table 1.

Preparation of cell extracts

Twenty milligrams of frozen tissue samples were lysed with 200 μL lysis buffer and homogenized by polytron. Samples were then incubated in ice for 30 min and the lysate was centrifuged at 16 000 g at 4 °C for 20 min. The supernatant was transferred to a fresh tube and the protein concentration was determined by the Bradford assay (Bio-Rad Protein Assay Kit, Bio-Rad Lab., Hercules, CA, USA).

DNA isolation from tissues

Twenty-five milligrams of fresh frozen tissue was lysed with 800 μL lysis buffer containing 0.5% sodium dodecyl sulfate (SDS), 2 mmol/L EDTA, 0.5 mol/L NaCl, 10 mmol/L $MgCl_2$, 10 mmol KCl and 10 mmol Tris-HCl (pH 76), and digested with proteinase K at 50 μg/mL at 50 °C for at least 2 h. High molecular weight DNA was extracted with phenol/chloroform.

Assay for telomerase activity

TA was measured twice in independent experiments using 1-3 μg of total protein. Assays were performed using Telomerase PCR ELISA Kit (Boehringer Mannheim GmbH, Mannheim, Germany) including TRAP assay and detection by ELISA in two steps. In the first step, using TRAP, cell extracts were incubated with biotinylated telomerase substrate oligonucleotide (P1-TS) at 25 °C for 30 min, followed by 94 °C for 10 min to inactivate the telomerase. The extended products were amplified by PCR using Taq polymerase, the P1-TS, P2 primers and nucleotides. The PCR conditions were 33 cycles of 94 °C for 30 s on a DNA thermocycler (GeneAmp PCR System 9700, Perkin Elmer, Norwalk, CT, USA). In the second step, using the ELISA method, the amplified products

were immobilized onto streptavidin-coated microtiter plates via biotin-streptavidin interaction, and then detected by anti-digoxigenin (DIG) antibody conjugated to peroxidase. After the addition of the peroxidase substrate (3,3',5,5'-tetramethyl benzidine), the amount of TRAP products were determined by measurement of their absorbance at 450 nm (with a reference wavelength of 690 nm). Negative control reactions were performed by incubating cell extracts with 1 μg/μL RNase for 20 min at 37 °C. The results were interpreted as negative, 1+, 2+, and 3+ when the optic density (OD) values were <0.2, 0.2-1, 1-2, and >2, respectively.

Moreover, to confirm the ELISA results, amplified products were systemically run on 15% non-denaturing polyacrylamide gel. After transferring the PCR products onto a positively charged nylon membrane, Southern blotting was performed by the semi-dry electrophoretic blotting instrument (Multiphore II NovaBlot Unit, Amersham Pharmacia Biotech, Buckinghamshire, UK). The membrane was then incubated with a streptavidin alkaline phosphatase conjugate (1:5 000 dilute in blocking solution), and after rinsing, blotted products were visualized by Biotin Luminescence Detection Kit (Boehringer Mannheim). In addition, all telomerase-negative tumor specimens were re-checked by additional TRAP assay using a 150 bp internal telomerase assay standard to exclude the possibility of Taq DNA polymerase inhibition in the tumor extracts[13].

Reverse transcription-polymerase chain reaction (RT-PCR) for telomerase-associated genes

Total RNA was isolated from tissue by SV Total RNA Isolation System (Promega Corporation, USA). First strand complementary DNA (cDNA) was synthesized using 5 mg of total cellular RNA with reverse transcriptase (Invitrogen Tech-Line SM, USA) and random primers (Protech Technology Enterprise Co. Ltd). PCR was performed using RT-MPCR* Kits for Human Telomerase Genes (Maxim Biotech, Inc., USA). RTMPCR* Kits included PCR primers for human 18S (hTELS-18S, 554 bp), PCR primers for human TRF-1 (hTELS-TRF1, 433 bp), PCR primers for human c-Myc (hTELS-MYC, 381 bp), PCR primers for human TRF-2 (hTELS-TRF2, 337 bp), PCR primers for human TP-1 (hTELS-TP1, 292 bp), PCR primers for hTERT (hTELS-TERT, 255 bp), and PCR primers for human TER (hTELS-TER, 191 bp). PCR reaction mixture contained RT-MPCR buffer, 200 mM each of dATP, dCTP, dTTP, and dGTP, 5U Taq DNA polymerase and 1 mL primers. The thermal cycles of PCR were performed as follows: 3 cycles at 95 °C for 1 min and 56 °C for 4 min followed by 30 cycles at 94 °C for 1 min and 55 °C for 2.5 min and then an extension of 1 cycle at 70 °C for 10 min. PCR products were subjected to electrophoresis through 3% agarose gel stained with ethidium bromide.

Terminal restriction fragment (TRF) length measurement and tumor-to-normal TRFL ratio (t/n TRFLR)

TRFL measurement was performed using TeloTAGGG Telomere Length Assay Kit (Roche, Mannheim, Germany). Eight micrograms of genomic DNA was digested with each 30U Hinf 1/Rsa l at 37 °C for 16 h. The resulting fragments were fractionated by electrophoresis on 0.8% agarose gel and transferred to nylon membrane using Southern blotting. After transfer, the transferred DNA was fixed on the membrane by UV-crosslinking (120 mJ). The membrane was first pre-hybridized at 42 °C for 30 min and then hybridized with telomere-specific DIG-labeled probe at 42 °C for 3 h. After washing the membrane in 2× SSC, the membrane was incubated with anti-DIG-alkaline phosphatase (1:5 000 dilute in blocking solution). Finally, the immobilized telomere probe was visualized by alkaline phosphatase metabolizing CDP-Star, a highly sensitive chemiluminescent substrate. The membrane was then exposed to X-ray film, and the average TRFL was determined by comparing the signals relative to a molecular weight standard (using BIO-PROFIL Bio-1D Software, Version 99, Vilber Lourmat, France), and the mean of three measured TRFLs deducted by 2.5 kb was used as the presented telomere length[14,15]. Furthermore, the TRFLR was defined as the ratio between the length of tumor tissue TRF (t-TRF) and their paired normal tissue TRF (n-TRF) from the same patient.

Statistical analysis

All probabilities were two-tailed, with a *P*-value less than 0.05 regarded as statistically significant. The statistical calculations were conducted with SPSS software (v10.5, SPSS Inc., Chicago, IL, USA).

RESULTS

Expression of telomerase activity and its associated genes

Positive TAs were observed in 63 of 74 (85.1%) tumor tissue samples, and 24 of 74 (32.4%) normal tissue samples, respectively. Expressions of hTERT, hTERC, TP1, c-Myc, TRF1 and TRF2 genes were observed in 64.9%, 79.7%, 100.0%, 94.6%, 82.4%, and 91.9% of the tumor tissues, respectively. Representative samples showing the expression of the TA by TRAP assay, and the associated genes in paired tumor (T) and normal (N) tissues are shown in Figure 1. Expression of TA according to the patient's clinicopathological characteristics are listed in Table 2. Expression of the telomerase associate genes in normal and tumor tissues are listed in Table 3. Expression of the telomerase associate genes in tumor tissues according to the TA are listed in Table 4.

Terminal restriction fragment (TRF) length and tumor-to-normal TRFL ratio (t/n TRFLR)

The mean TRFL of the tumor and normal esophageal tissues were 2.70±1.42 and 4.93±1.74 kb, respectively (P<0.0001). The mean TRFL of the telomerase positive and telomerase negative tumor tissues were 2.72±1.44 and 2.58±1.32 kb, respectively (P = 0.767). The TRFLR of the telomerase positive and telomerase negative tumor tissues were 0.55±0.22 and 0.59±0.41, respectively (P = 0.742). The mean TRFL were 3.04±0.42 kb in stage I tumor, 2.65±1.44 kb in stage II tumor, 2.83±1.44 kb in stage III

tumor, and 2.41±1.49 kb in stage IV tumor, respectively (stage I+II *vs* stage III+IV, $P = 0.936$). The t/n TRFLR were 0.818±0.019 in stage I tumor, 0.686±0.184 in stage II tumor, 0.729±0.265 in stage III tumor, and 0.649±0.185 in stage IV tumor, respectively (stage I+II vs stage III+IV, $P = 0.867$). Table 5 lists the TRFL and t/n TRFLR data of our patients. The representative samples showing TRFL in paired T and N tissues are shown in Figure 2.

Survival analysis

The influence of TA expression was evaluated by cumulative survival period. The 5-year cumulative survival

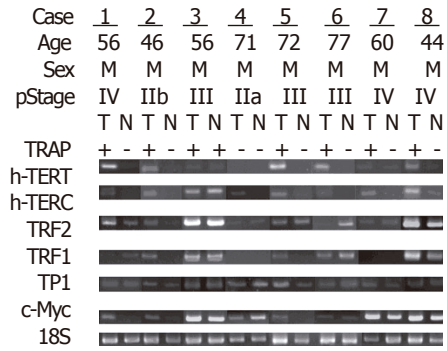

Figure 1 Representative samples showing expression of the telomerase activity by TRAP assay, and the associated genes in paired tumor (T) and normal (N) tissues.

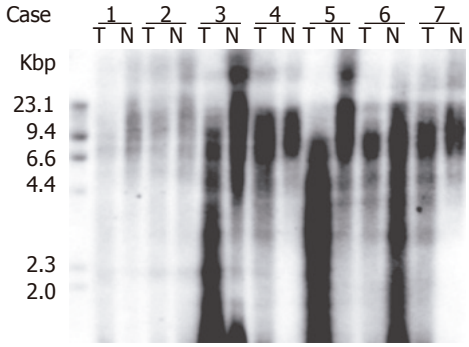

Figure 2 Representative samples showing TRFL by telomere length assay kit in paired tumor (T) and normal (N) tissues are shown.

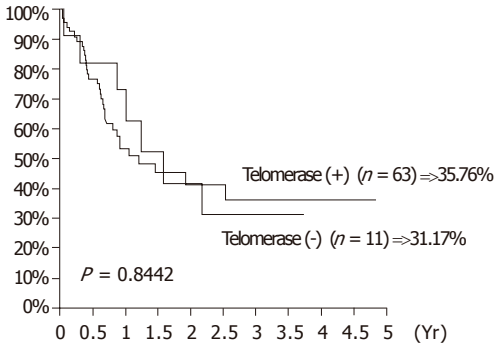

Figure 3 Cumulative survival rates according to the expression of telomerase activity in 74 SCC of esophagus.

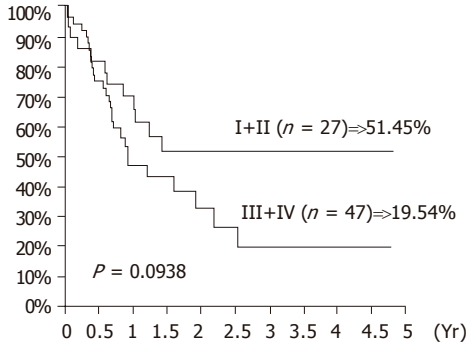

Figure 4 Cumulative survival rates according to the TNM stages in 74 SCC of esophagus.

rates of the patients by tumor stages and presence of distant metastasis are shown in Figures 3 and 4. As shown in Figure 5, the 4-year cumulative survival rates of telomerase-positive and telomerase-negative patients were 35.8, and 31.2%, respectively (P = 0.8442). When survival analyses were performed based on the change of TRFL in the tumor tissues, a cut-off value of 50% demonstrated a trend in survival difference. As shown in Figure 6, the 4-year cumulative survival rates of lower t/n TRFLR (≤85%) and higher t/n TRFLR (>85%) patients were 38.7, and 15.7%, respectively (P = 0.1307). Multivariate survival analysis using Cox proportional hazards model revealed

independent prognostic factors that includes t/n TRFLR (P = 0.035), and M-status (P = 0.042) of the tumor (Table 6).

DISCUSSION

Cell numbers are vigorously controlled within the body and, in human adults, only a few cell types are capable of continued division. Cultured cells *in vitro* can undergo only a limited number of cell divisions, known as the Hayflick limit, before entering a state of senescence where they remain metabolically active but have lost their capacity to replicate (M1 crisis). Reduction in telomere length could provide the signal to cause growth arrest. Cultured cells can be induced to continue to divide beyond the Hayflick limit by inactivation of p53 or p16INK4a genes. During this process of oncogenesis, their telomeres continue to shorten with each division and at a certain point cells enter a crisis where the majority will die (M2 crisis). Rare immortalized clones that emerge from crisis express the enzyme telomerase[16]. The regulation of TA is a complex issue, involving the transcriptional activity of the hTERC (telomerase RNA component gene), and the hTERT, as well as the interaction of telomerase with other telomerase-associated proteins, such as TP1/c-Myc/TRF1/TRF2/ Tankyrase. TP1, which is expressed ubiquitously, may play a role in coordinating telomerase holoenzyme tertiary or/and quaternary structures and/or serve as a docking/ scaffold protein in recruiting telomerase regulatory factors. The ability of c-Myc to function as a transcription factor has been shown to depend upon its dimerization with the protein Max[17]. In addition to the formation of stable complexes with c-Myc, Max also heterodimerizes with proteins of the Mad(Mxi1) family[18]. These Mad/Max complexes act in an antagonistic manner to c-Myc/Max-induced transactivation and result in potent repression of gene expression. Two proteins that bind to the double-stranded region of mammalian telomeres have been identified: TTAGGG repeat binding factor 1 (TRF1) and factor 2 (TRF2). These proteins are related and have a similar domain organization. Both proteins are associated with telomeres throughout the cell cycle and bind to the cognate telomeric sequence as homodimers using a carboxy-terminal myb-type DNA binding domain. TRF1 regulates telomere length and TRF2 protects chromosome ends. These two paralogs bind to double stranded telomeric DNA with high affinity, but no interaction between TRF1 and TRF2 has been observed so far[19,20]. However, TRF1 and TRF2 interact with other proteins in regulating telomeric repair. Together with tankyrase, TRF1 is involved in telomere length regulation via negative feedback mechanism; overexpression results in shortened telomeres, and mutation of telobox causes elongated telomeres[20,21]. Removal of TRF2 from the telomere results in the loss of the 3'-overhang, covalent fusion of telomeres, and the induction of ATM and p53 dependent apoptosis. Overexpression of TRF2 in telomerase negative cells prevents critically short telomeres from fusion and delays the onset of senescence[19] .

The expression rates of telomerase and hTERT were 85.1% and 64.9%, which were consistent with other reports. We also found telomerase expression in 32.4% of the paired normal esophageal mucosa. This had been attributed to actively dividing basal layer cells[22,23] or submucosal tumor infiltration[24]. A higher telomerase and hTERT expression rate in the normal esophageal mucosa makes it a distinct finding as compared with other digestive tract mucosa[25]. The telomerase expression of the tumor is not related to the clinicopathological parameters including gender, tumor differentiation, and TNM stages of the patients (see Table 2). Controversy in interpretation of the clinical significance of telomerase expression may be related to the presence of the alternative telomere lengthening (ATL) mechanism. ALT cells have long heterogeneous telomeres thought to be generated by a recombination-based mechanism[26]. Interestingly, tumor cells may simultaneously obtain both telomerase and ATL mechanisms in maintaining telomere length[27]. This will cause more complexity in analyzing the relation between the telomerase expression, telomere maintenance, and their impact on prognosis.

In a previous study in non-small cell lung cancers, we found that c-Myc, TRF1, and TRF2 expression was closely related to hTERT expression, although there was no association with telomerase expression[9]. We also found that when the TRFL decreased to a critical level, the TA could be elicited[11]. This hypothesis was further confirmed by the establishment of a negative linear association between the t/n TRFLR and the expression of TA in NSCLC tumor tissues[11] In the current study, we found a higher expression rate of the hTERT, hTERC, and TRF1 in the tumor tissues (Table 3). This suggests that hTERT, hTERC, and TRF1 are incorporated in the regulation of telomerase expression in the tumor tissues as the TRFL becomes progressively shortened. However, once the telomerase expression was activated, TRF1 expression becomes suppressed to prevent interference with telomerase binding. Instead, TRF2 overexpression persisted (see Table 4), which increases the number of TRF2 molecules binding on the telomeric DNA, and subsequently leads to more efficient and stable T-loop formation as described in the *in vitro* study[28]. Therefore, it is not only the telomere length, but also the TRF2 that determines whether senescence ensues or not.

Though a decreased TRFL was observed in the tumor tissues, there were no significant changes in TRFL between different tumor stages or different telomerase expression. Also, the t/n TRFLR did not change accordingly in different tumor stages. But when the t/n TRFLR decreased to a critical level ($\leqslant 85\%$), a better survival was observed (Figure 6). This may be due to the failure of the tumor cells to regain an adequate telomere length, which subsequently triggers the apoptosis pathway. Cox model analysis also confirmed t/n TRFLR as an independent prognostic factor in addition to distant metastasis.

In summary, our data suggest that telomerase expression in esophageal cancers is not related to tumor stages and patient's prognosis. This may be due to a high telomerase expression in the normal esophageal mucosa which makes telomerase not a reliable biomarker in esophageal tumors. However, TA can be elicited as the TRFL decreased in the tumor tissues, probably under the control of hTERT, hTERC, and TRF1 (but not TRF2).

Once the telomerase expression was elicited, TRF1 expression becomes suppressed to prevent interference with telomerase binding. Instead, TRF2 overexpression persisted, which increases the number of TRF2 molecules binding on the telomeric DNA, and subsequently leads to more efficient and stable T-loop formation. Moreover, as the t/n TRFLR decreased to 85%, a trend of poorer prognosis was observed. These findings further confirm our previous proposal using the t/n TRFLR as an indicator of chromosome ends replication ability[11]. The complex interweaving of the regulatory pathway for telomere maintenance and the mechanism involved in the detection of telomere loss by tumor cells, which subsequently activates telomerase expression require further study.

Abstract

AIM: To further evaluate the relationship between BSA and the effects of lamivudine in a greater number of cases and over a longer period of observation than in our previous evaluation.

METHODS: We evaluated 249 patients with chronic hepatitis B. The effects of treatment for one year (n = 249), two years (n = 147), and three years (n = 72) were evaluated from the levels of serum ALT and HBV-DNA, as biological and virological effects (undetectable levels by PCR), respectively. Moreover, several variables that could influence the response to treatment, including ALT, albumin, bilirubin, platelet counts, BSA, HBV-DNA, and HBeAg were analyzed.

RESULTS: For 1-year treatment, multivariate analysis revealed that BSA (P = 0.0002) was the only factor for the biological effect, and that ALT (P = 0.0017), HBV-DNA (P = 0.0004), and HBeAg (P = 0.0021) were independent factors for the virological effect. For 2-year treatment, multivariate analysis again showed that BSA (P = 0.0147) was the only factor for the biological effect, and that ALT (P = 0.0192) and HBeAg (P = 0.0428) were independent factors for the virological effect. For 3-year treatment, multivariate analysis, however, could not reveal BSA (P = 0.0730) as a factor for the normalization of ALT levels.

CONCLUSION: BSA is a significant predictor for the normalizing the effect of lamivudine therapy on ALT for an initial 2-year period, suggesting that lamivudine dosage should be based on the individual BSA.

INTRODUCTION

Chronic hepatitis B is an important cause of morbidity and mortality resulting from cirrhosis-related liver failure and hepatocellular carcinoma (HCC)[1-3]. Lamivudine is an oral nucleoside analog approved for the treatment of chronic hepatitis B. It inhibits viral DNA replication by means of chain termination, and competitively inhibits viral polymerase. A daily dosage of lamivudine of 100 mg has been accepted worldwide for the treatment for chronic hepatitis B, since early studies showed that there was no

significant difference in the effect of lamivudine at doses of 100 and 300 mg[4,5]. However, to establish ideal dosages in those studies, efficacy was mainly evaluated by measuring hepatitis B virus (HBV)-DNA, and the assay used was much less sensitive than the polymerase chain reaction (PCR) assay. Studies in which HBV-DNA was measured by PCR assay reported an additional viral suppressive activity with high doses (300 mg) of lamivudine for 24 wk[6]. In addition to the limits imposed by the assay methods that were used, the observation periods in the studies on lamivudine doses of 100-300 mg were limited to a period of 12[4] or 24 wk[5]. Although the effect of doses greater than 100 mg on the emergence of YMDD mutants has not been evaluated, baseline body mass index has been reported to be significantly related to the emergence of HBV mutants during lamivudine treatment in patients co-infected with HBV and human immunodeficiency virus-1 (HIV-1)[7]. In a previous study of 134 patients treated for 23.1 mo(mean observation period), body surface area (BSA) was shown to be an independent factor contributing to the effects of lamivudine treatment[8]. In the present study, to further confirm these results, we evaluated the relationship between BSA and the effects of lamivudine effects in a greater number of patients and for longer observation periods than those in the previous report.

MATERIALS AND METHODS

Patients

Criteria for entry into this study were as follows: (a) the patients had not been treated with lamivudine previously; (b) they had chronic hepatitis caused by HBV, and persistent abnormal levels of alanine aminotransferase (ALT); and (c) patients with HCC were excluded. A total of 249 patients with chronic hepatitis B were evaluated. They had been treated with 100 mg of lamivudine for more than 1 year at Kyushu University Hospital and its affiliated hospitals (Table 1). For all the patients, the existence of serum HBV-DNA was confirmed by transcription-mediated nucleic acid amplification (TMA) assay ($10^{3.7}$-$10^{8.7}$ genome equivalents/mL; 3.7-8.7 log genome equivalents [LGE]/mL) (Chugai Diagnostic Science, Tokyo, Japan) or by a Roche Monitor kit ($10^{2.6}$-$10^{7.6}$ copies/mL; 2.6-7.6 log copies/mL) (Roche Diagnostics, Tokyo, Japan) before the treatment. None of the patients dropped out and all were treated with 100 mg/d lamivudine until the end of the observation period. After the start of medication, basic hepatic function and serum levels of HBV-DNA were measured at least every 3 mo for all the patients. The efficacy of lamivudine was evaluated from the serum levels of ALT and HBV-DNA, as biological and virological effects, respectively. The categories for the biological evaluation based on serum ALT were as follows: (1) sustained responder (SR) ALT: the serum levels of ALT decreased and remained at less than 30 U/L continuously during the observation period; and (2) non-responder (NR) ALT: the serum ALT was more than 30 U/L at the end of the observation. Similarly, the categories for the virological evaluation based on HBV-DNA were: (1) SR-HBV: serum HBV-DNA decreased to levels undetectable by PCR (<2.6 log copies/mL) and remained negative continuously during the observation period; and (2) NR-HBV: serum HBV-DNA was detectable at the end of the observation period (>2.6 log copies/mL). BSA was calculated using the method of DuBois.

Statistical analysis

The baseline characteristics of the patients prior to the beginning of the lamivudine therapy are expressed as mean±SD for the quantitative variables. In order to determine the contribution of these variables to the effect of the treatment, univariate and multivariate logistic analyses were performed. For multivariate logistic analysis, we analyzed BSA as an independent factor contributing to the effects of lamivudine treatment variables that showed χ^2 values of more than 1.0 in the univariate logistic

RESULTS

The effects of lamivudine for 1 year were analyzed in a total of 249 patients (Table 1), of which 150 (60.2%) were identified as SR-ALT and 99 (39.8%) as NR-ALT, and 183 (73.5%) were identified as SR-DNA and 66 (26.5%) as NR-ALT (Table 1). To evaluate the contribution of the variables to the effect of treatment, univariate and multivariate logistic analyses were performed. In the univariate logistic analysis, BSA and ALT in the biological evaluation, and ALT, albumin, bilirubin, platelet count, BSA, HBV-DNA, and HBeAg in the virological evaluation, had χ^2 values of more than 1.0 (Table 2). Therefore, we used these factors as variables for multivariate logistic analysis. The results of multivariate analysis revealed that BSA was the only significant factor for the improvement of ALT levels (χ^2 = 14.3, P = 0.0002), and ALT, albumin, HBV-DNA and HBeAg were independent factors for the disappearance of serum HBV-DNA (ALT: χ^2 = 9.8, P = 0.0017; albumin: χ^2 = 5.1, P = 0.0238; HBV-DNA: χ^2 = 12.6, P = 0.0004; and HBeAg: χ^2 = 9.5, P = 0.0021) (Table3).

The effects of 2-year therapy were evaluated in 147 patients (Table 4). Of these patients, 75 (51.0%) were identified as SR-ALT and 72 (49.0%) as NR-ALT, while 85 (57.8%) were identified as SR-DNA and 62 (42.2%) as NR-ALT (Table 5). In the univariate logistic analysis, bilirubin, platelet count and BSA in the biological evaluation, and ALT, bilirubin, platelet, BSA and HBeAg in the virological evaluation, were selected (χ^2>1.0) (Table 5). Multivariate analysis revealed that BSA was the only significant factor in the biological effects (χ^2 = 5.6, P = 0.0147), and ALT and HBeAg were independent factors in the virological effects (ALT: χ^2 = 5.5, P = 0.0192; and HBeAg: χ^2 = 4.1, P = 0.0428) (Table 6).

Finally, the effects of 3-year therapy were evaluated in 72 patients (Table 7). Of these patients, 33 (45.8%) were identified as SR-ALT and 39 (54.2%) as NR-ALT, while

38 (52.8%) were identified as SR-DNA and 34 (47.2%) as NR-DNA (Table 8). In the univariate logistic analysis, albumin, platelet count, BSA, and HBeAg in the biological evaluation, and no variables in the virological evaluation, were selected (χ^2>1.0) (Table 8). Multivariate analysis did not reveal BSA as a factor for predicting the biological efficacy of lamivudine therapy $\chi^2 = 3.2$, $P = 0.0730$) (Table 9).

DISCUSSION

In this present study, we found that BSA was a significant factor that could contribute to the normalization of serum ALT (biological response) after the treatment with lamivudine for an initial 2-year period. Body weight was also a significant factor contributing to the effects of lamivudine treatment (data not shown). Because χ^2 values of BSA were higher than those of body weight and BSA is determined with body weight and height, we used BSA as a variable for statistical analysis. We initially reported that BSA was an independent factor contributing to both the biological and virological responses[8]. The difference in the contribution to the virological response between the present and the previous study might be attributed to the differences in the criteria used to evaluate treatment effects. In our previous study, we used a third category in addition to SR and NR transient responder (TR) which included patients with serum ALT levels that initially decreased to less than 30 U/L but increased to more than 30 U/L during the subsequent observation period (TR-ALT), and the patients in whom serum HBV-DNA initially decreased to undetectable levels (<2.6 log copies/mL) but became positive again during the subsequent observation period (TR-DNA). Regardless of the differences in evaluation criteria, both studies clearly demonstrated that BSA independently contributed to the normalization of ALT in the patients treated with lamivudine for an initial 2-year period. Because the pharmacokinetics of lamivudine correlate with body weight, as is the case with many other drugs[9], it is reasonable to conclude that patients with lower BSA would have achieved higher blood concentrations

of lamivudine, although we did not actually monitor the concentration of lamivudine. Recent reports suggest that the baseline body mass index is significantly related to the emergence of HBV mutation during lamivudine treatment (300 mg/d, >6 mo) in patients co-infected with HBV and HIV-1[7]. Therefore, the results of our studies again question whether a lamivudine dosage of 100 mg/d is adequate, particularly for long-term treatment.

The standard lamivudine dose of 100 mg daily was based on early studies in which doses of 25, 100, and 300 mg were compared for 12[4] or 24 wk[5]. Because there were no significant differences reported in the rates of non-detection of HBV-DNA and normalization of ALT levels between the 100 and 300 mg doses, the dose of 100 mg has become a well-accepted therapeutic standard[4,5]. However, several factors should be considered when evaluating the results of these studies, including the number of patients, duration of treatment, emergence of lamivudine-resistant mutants over long-term treatment, and detection limits for HBV-DNA.

In the present study, we found that there was a significant difference in the contribution of BSA to the biological effect, although the differences in the mean values of BSA between SR-ALT and NR-ALT were relatively small. Therefore, it is possible that previous studies failed to detect a significant contribution of BSA to the effects of lamivudine because of the smaller number of patients examined. The major drawback of lamivudine monotherapy is the emergence of resistant HBV with mutations of the tyrosine-methionine-aspartate-aspartate (YMDD) motif. The incidence of these mutants rises from 15-20% in the first year of therapy to 40% by the second year, and to 67% by the fourth year[10]. In some cases, fatal liver failure subsequent to the emergence of the mutant was reported[11]. Therefore, observation periods of 24 wk may not be adequate for detecting the emergence of lamivudine-resistant mutants. In our evaluation of HBV-DNA, the rates of NR-DNA were found to be 26.5%, 42.2%, and 57.2% in patients who were positive for HBV-DNA (>2.6 log copies/mL) by the first, second, and third year, respectively. Although we did not confirm YMDD mutation in all cases of NR-DNA, the increase in NR-DNA ratio might be attributable to the emergence of mutants. Concomitant with the increases in HBV-DNA seen over the 3-year period, the NR-ALT ratio rose from 39.8% in the first year to 49.0% by the second year and to 54.8% by the third year in the present study, suggesting that the emergence of mutants could abolish the contribution of BSA to biological effects in the third year. Further studies will be needed to confirm whether BSA affects the incidence of YMDD mutants.

In previous studies that showed no difference in the effects of 100 and 300 mg lamivudine on HBV-DNA levels (as aforementioned)[4,5], HBV-DNA was measured quantitatively by liquid hybridization assay (Abbott Laboratories), which has a detection limit of 10^7 geq/mL[12]. Honkoop *et al*.[6] studied the efficacy of 100 and 300 mg lamivudine in viral suppression for 24 wk using a semi-quantitative PCR method with a detection limit of 10^2-10^3 geq/mL. In the present study, we used a Roche Monitor kit, which has detection limit of 2.6 log copies/mL, and could not find a significant relationship between BSA and the virological effect of lamivudine. Chun *et al*.[13], reported that there was no significant correlation between viral replication and liver damage in chronic hepatitis B. Hence, it seems reasonable that we did not find a contribution of BSA to the virological effects of treatment. Further study will be needed to evaluate dose-dependent lamivudine effects on viral suppression including the emergence of mutants which could directly affect the viral load.

In conclusion, we have shown that BSA is a statistically significant and potentially important factor for predicting the efficacy of lamivudine therapy for chronic hepatitis B. A noteworthy finding in our study was that small differences in BSA might significantly influence the effect of lamivudine treatment, suggesting that a small increase in lamivudine dose might markedly increase its therapeutic efficacy. We believe that a long-term clinical trial with higher-dose lamivudine treatment in a large number of cases is warranted, since lamivudine will continue to be a first-line treatment for HBV.

Abstract

AIM: To evaluate the effects of a portocaval shunt on the decrease of excessive portal flow for the prevention of sinusoidal microcirculatory injury in extremely small-for-size liver transplantation in pigs.

METHODS: The right lateral lobe of pigs, i.e. the 25% of the liver, was transplanted orthotopically. The pigs were divided into two groups: graft without portocaval shunt (n = 11) and graft with portocaval shunt (n = 11). Survival rate, portal flow, hepatic arterial flow, and histological findings were investigated.

RESULTS: In the group without portocaval shunt, all pigs except one died of liver dysfunction within 24 h after transplantation. In the group with portocaval shunt, eight pigs survived for more than 4 d. The portal flow volumes before and after transplantation in the group without portocaval shunt were 118.2±26.9 mL/min/100 g liver tissue and 270.5±72.9 mL/min/100 g liver tissue, respectively. On the other hand, in the group with portocaval shunt, those volumes were 124.2±27.8 mL/min/100 g liver tissue and 42.7±32.3 mL/min/100 g liver tissue, respectively (P<0.01). As for histological findings in the group without portocaval shunt, destruction of the sinusoidal lining and bleeding in the peri-portal areas were observed after reperfusion, but these findings were not recognized in the group with portocaval shunt.

CONCLUSION: These results suggest that excessive portal flow is attributed to post transplant liver dysfunction after extreme small-for-size liver transplantation caused by sinusoidal microcirculatory injury.

INTRODUCTION

Since the first successful living donor liver transplantation (LDLT) in a child[1] patient and an adult[2] patient, LDLT has become the established method to reduce the number of patients on the waiting list and is considered as an alternative to standard liver transplantation[3-7]. The survival rate of adults is significantly lower than that in children[8] and the key to a successful LDLT, especially in adult recipients, is the adequacy of the size of the graft that can be safely harvested from the donor[9-11]. In some cases, graft weight ratio of the recipient native liver weight (GWRLW) of 30% or less has been transplanted successfully, but in general, graft weight per recipient's body weight (GWBW) less than 0.8% or GWRLW less than 40% has been considered marginal or small-for-size. These small-for-size grafts are associated with an increased incidence of complications and graft failure[9-12]. A small-for-size graft cannot supply the metabolic demand of an adult recipient in the early posttransplant period. Poor early graft function is characterized by protracted

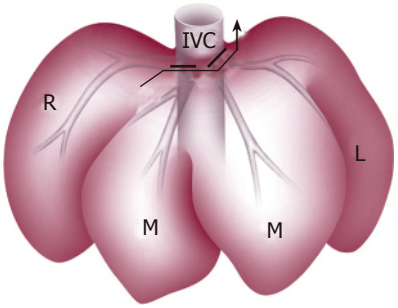

Figure 1 Anterior view of left tri-segmentectomy. Bold line indicates the left and middle hepatic veins ligated by transfixing suture; arrow indicates parenchymal transection of the left lobe and right paramedian lobe; L: left lateral lobe; M: median lobe; R: right lateral lobe; IVC: inferior vena cava.

cholestasis, coagulopathy and ascites, and these findings are proposed to be the essential symptoms of small-for-size syndrome[13]. However, the precise mechanism for this dysfunction remains unclear.

Previously, we have reported that portal hypertension after reperfusion is one of the most important factors aggravating the microcirculatory injury of the graft[14]. In the present study, we hypothesized that the increment of portal flow played a major role in graft injury and poor function of small-for-size grafts, and investigated the effects of portocaval shunt (PCS) on the excessive portal flow for the prevention of the sinusoidal microcirculatory injury after extremely small-for-size liver transplantation using pigs.

MATERIALS AND METHODS

Animals

Landrace white pigs, weighing 18-28 kg, were used as donors and recipients. All experiments were conducted according to Principles of Laboratory Animal Care (NIH publication No. 86-23, revised in 1985). Food was withheld for 24 h before the operation. Anesthesia was induced by intramuscular administration of ketamine (5 mg/kg) and atropine sulfate (1.0 mg/body) followed by endotracheal intubation and maintenance with oxygen and isoflurane by positive pressure mechanical ventilation. A catheter was placed in the internal jugular vein for fluid administration and central venous pressure (CVP) monitoring and fixed at the back of the neck for postoperative venous sampling. A carotid arterial line was also placed for intraoperative blood sampling and monitoring mean arterial pressure (MAP). In recipients, an opposite internal jugular vein was used for the venovenous bypass from the portal vein and femoral vein. Eleven transplantations were carried out in each group.

Donor operation

After laparotomy, the left hepatic artery supplying the left lateral and left median lobes was ligated and divided. Glisson's sheaths of the left lobe and the right median lobe were identified and resected. After mobilization of the liver, by dissecting all ligamentous attachments, the left and middle hepatic veins were ligated with transfixing sutures (Figure 1). Parenchymal transection of the left lobe and the right median lobe was performed and finally left tri-segmentectomy of the liver was done.

Following intravenous administration of heparin, catheters were cannulated in the lower abdominal aorta and splenic vein. The diaphragm was widely opened and the supradiaphragmatic aorta was divided and encircled. Cold University of Wisconsin (UW) solution (4℃) was flushed in from both the aorta and the splenic vein after aortic clamp. The right lateral lobe was removed and preserved in UW solution.

Back table operation

In the group with shunt, the PCS was made on the back table and placed by means of side-to-side anastomosis between the portal vein and the infra-hepatic inferior vena cava (IVC) (Figure 2). The diameter of the PCS was 6 mm. The graft was weighed after the back table preparation.

Recipient operation

Total hepatectomy was performed under ilioportaljugular venovenous bypass[15]. The reduced-size graft with or without PCS was implanted orthotopically with end to end vascular anastomosis of the suprahepatic IVC, the portal vein, the infra-hepatic IVC, and the hepatic artery. Before anastomosis of the portal vein, rinse solution was perfused into the portal vein of the graft. Hepatic arterial reconstruction was performed under a microscope. A catheter was inserted into the common bile duct for bile drainage.

After transplantation, the pigs were placed in a warmed cage with free access to water and food. FK506 (0.1 mg/kg • d) was injected for immunosuppression from postoperative day (POD) 1-7. When recipients died, autopsy was performed to exclude the possibility of technical complications and to confirm the patency of all anastomoses. Liver grafts were also weighed.

Monitoring

Systemic hemodynamic monitoring of MAP and CVP was carried out continuously during the operation, as well as portal vein pressure was monitored. Portal flow

and hepatic arterial flow (HAF) were measured before hepatectomy in donors and after arterial reperfusion in recipients using ultrasound transit time flow probes and a flow meter (Transonic Systems Inc., Ithaca, NY, USA). The diameter of the probe was 8 mm for the portal vein and 3 mm for the artery. Total liver blood flow (TLBF) was calculated as the sum of portal flow and HAF. Liver biopsies were performed before hepatectomy, after reperfusion, and on every other day up to POD 7, and tissue specimens were examined under light microscope and Ki-67 staining was performed for the determination of proliferating hepatocytes. Transmission electron microscopical findings were also investigated in the specimen after reperfusion. Arterial blood samples were obtained hourly for gas analysis during the operation and determining alanine aminotransferase (ALT), aspartate aminotransferase (AST), total bilirubin (T-Bil), and anti-thrombin III (AT-III) before the operation, at 3 and 6 h after reperfusion and on every POD up to POD 7.

The graft weight at the time of transplantation expressed as a percentage of GWRLW and GWBW was calculated.

Statistical analysis

Values of parameters were expressed as mean±SD. Statistical significance was determined by Student's *t*-test. The survival rate was calculated by the Kaplan-Meier method. Values between the two groups were statistically analyzed by generalized Wilcoxon test. *P* values less than 0.05 were regarded as statistically significant.

RESULTS

Graft volume and operation time

Body weight, graft volume, and operation time are shown in Table 1. The graft volume was approximately 25% of the recipient native liver volume, and 0.6% of the recipient body weight in both groups. The cold ischemic time in the group with PCS was slightly longer than that in the group without PCS because of the time required for the PCS at the back table, but there was no statistical difference. There was no significant difference in MAP or CVP between the two groups (data not shown).

Table 1 Graft characteristics (mean±SD)

Parameters	Group without PCS (n = 11)	Group with PCS (n = 11)
DBW (kg)	21.8±2.7	20.8±1.1
RBW (kg)	22.8±1.2	22.1±2.6
GW (g)	131.8±18.3	139.3±32.0
RLW (g)	525.4±41.4	548.3±63.8
GWRLW (%)	25.1±2.7	25.4±3.4
GWBW (%)	0.58±0.09	0.63±0.13
Anhepatic time (min)	43±2	41±4
Operation time (min)	261±28	263±44
Total ischemic time (min)	151±51	161±20

DBW: donor body weight; RBW: recipient body weight; GW: liver graft weight at implantation; RLW: recipient native liver weight; GWRLW: percentage of GW to the recipient native liver weight; GWBW: percentage of GW to the recipient body weight.

Survival rate

In the group without PCS, all pigs except one died of liver dysfunction within 24 h after reperfusion. On the other hand, in the group with PCS, eight pigs survived for more than 4 d and the remaining three died of portal vein thrombosis at the anastomotic site of PCS or perforated gastric ulcer within 3 d. The PCS significantly improved the survival rate of the animals in comparison to the animals without the shunt after transplantation (P<0.05) (Figure 3).

Portal pressure

There were no significant differences in portal vein pressures at laparotomy in both groups. However, after reperfusion, portal vein pressures significantly increased up to 2.2±0.7 KPa in the group without PCS and 1.6±0.6 KPa in the group with PCS (Figure 4).

Hepatic hemodynamics

Hepatic hemodynamic parameters including portal flow, HAF and TLBF at laparotomy and after reperfusion in both groups are shown in Table 2. The portal flow after reperfusion in the group without PCS increased significantly more than that at laparotomy, whereas it decreased in the group with PCS (P<0.01). The HAF after reperfusion decreased compared to that at laparotomy in the group without PCS, while it increased more than that at laparotomy in the group with PCS (P<0.05).

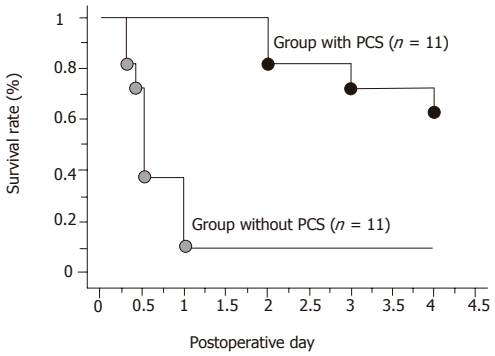

Figure 3 Survival rates. [b]P<0.01 *vs* the group without PCS.

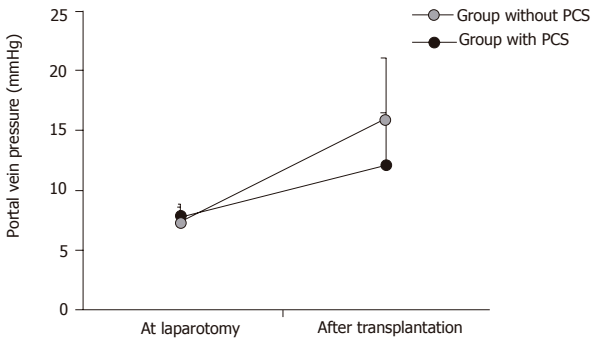

Figure 4 Changes of portal vein pressure (n = 11). [a]P<0.05 *vs* the group with PCS.

Table 2 Changes of hepatic hemodynamics (mean±SD)

Parameters	Group	At laparotomy	After transplantation
Portal flow	Group without PCS	118.2±26.9	270.5±72.9[b,a]
(mL/min/100 g liver tissue)	Group with PCS	124.2±27.8	42.7±32.3[a]
Hepatic arterial flow	Group without PCS	50.1±8.3	37.7±21.0[a]
(mL/min/100 g liver tissue)	Group with PCS	50.5±11.6	75.1±39.5
Total liver blood flow	Group without PCS	168.3±30.9	308.2±52.8[b,a]
(mL/min/100 g liver tissue)	Group with PCS	174.8±29.1	117.8±42.1[c]
Ratio of PF/TLBF (%)	Group without PCS	70.2±4.2	87.8±8.2[b,a]
	Group with PCS	71.1±4.9	36.3±19.5[a]

PF: portal flow; TLBF: total liver blood flow.

[b]P<0.01 *vs* the group with PCS; [a]P<0.01 *vs* at laparotomy; [a]P<0.05 *vs* the group with PCS; [c]P<0.05 *vs* at laparotomy.

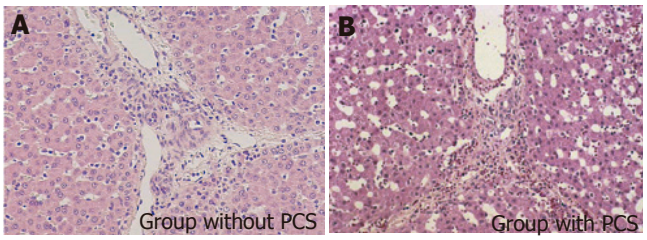

Figure 5 Histological findings of hepatic tissues after reperfusion (×100).

The TLBF after reperfusion increased significantly higher than that at laparotomy in the group without PCS, whereas the TLBF slightly decreased after reperfusion in the group with PCS. After reperfusion, the TLBF in the group without PCS was significantly greater than that in the group with PCS (P<0.01). In the group without PCS, the contribution of portal flow to TLBF increased from 70.2% to 87.8%, while in the group with PCS the contribution of the portal flow to TLBF decreased from 71.1% to 36.3%.

Histological findings

The light microscopical findings of the liver graft after reperfusion are shown in Figure 5. In the group without PCS, enlargement of the sinusoidal lumen and bleeding in the peri-portal triads were observed but these abnormal findings were not recognized in the group with PCS.

Transmission electron microscopic findings of the sinusoid after reperfusion are shown in Figure 6. In the group without PCS, the sinusoidal endothelial cells were destroyed and detached into the sinusoidal space with destruction of the Disse's spaces, while in the group with PCS the sinusoidal endothelial cells were well preserved, the Disse's spaces were intact, and the structure of endothelial lining was well preserved.

Liver regeneration in the group with PCS

The graft weight in the recipients who survived for more than 4 d (n = 8) increased to 87.3% of the recipient native liver. Ki-67 labeling index before and after transplantation is shown in Figure 7. The Ki-67 labeling index showed only 1.0% of hepatocytes at laparotomy. However, it increased abruptly after transplantation, reaching a peak value of approximately 60% at POD 2, and decreasing to 30% on POD 4.

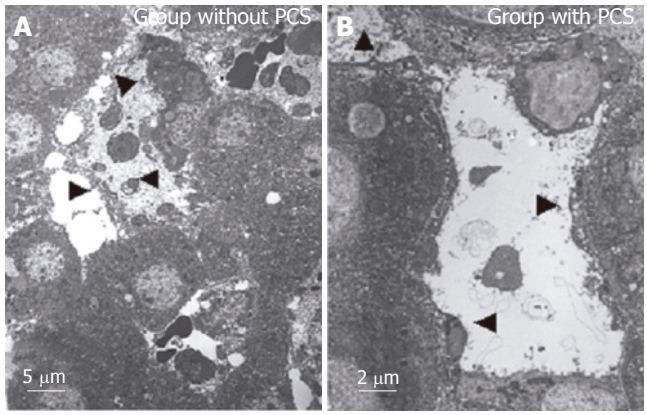

Figure 6 Transmission electron microscopical findings of the sinusoid after reperfusion. Arrowheads indicate the destroyed or preserved or detached sinusoidal endothelial cells into the sinusoidal space with destructed or intact Disse's spaces.

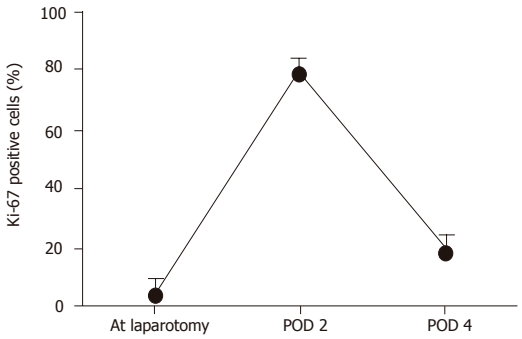

Figure 7 Ki-67 detection in the pigs that survived for more than 4 d in the group with PCS (n = 8).

Liver function

There were no significant differences in ALT, AST or T-Bil until POD 1 after reperfusion in either group (Table3). ALT and AST increased after reperfusion, taking a peak value on POD 2 and POD 1 and then decreased. However, T-Bil increased continuously until POD 4. AT-

Table 3 Changes of serum ALT, AST, T-Bil, and AT-III (mean±SD)

Parameters	Group	Preo	RP 3 h	RP 6 h	POD 1	POD 2	POD 3	POD 4
ALT (KU)	A	22±1	16±2	20±3	35±18	-	-	-

III decreased after reperfusion in both groups. At 6 h after reperfusion and on POD 1, AT-III in the group with PCS was significantly higher than that in the group without PCS ($P<0.05$).

DISCUSSION

In clinical liver surgery, an extended hepatectomy of 80% or 85% of the whole liver can be tolerable in patients with a normal liver[16]. In previous reports, 70-75% hepatectomy in animals represents a model of critical residual liver volume and is used to study the mechanism of liver regeneration[17-19]. This means that 25-30% of the liver can sustain hepatic function. However, this cannot be translated directly into a minimum graft volume in small-for-size liver transplantation, in which grafts are subjected to cold and warm ischemia and subsequent reperfusion injury. This is why the minimum graft volume for successful liver transplantation is presumably higher than the residual liver volume in extended hepatectomy. Currently, experience with living-related and split-liver transplantation has demonstrated that the size of the graft required for a successful liver transplantation is at least 40% of the recipient's native liver volume and more than 0.8% of the recipient body weight[6,20]. This is associated with lack of portosystemic collateral circulation, which lessens the influence of a high portal flow on the grafts and prevents the development of severe portal hypertension[21]. The precise mechanism of graft injury in a small-for-size liver transplantation remains still unknown. But there is a case report of hemorrhagic necrosis secondary to excessive portal flow in an adult LDLT[22]. An adult LDLT with small-for-size graft has been successfully performed using a mesocaval shunt to avoid graft failure caused by portal hyperperfusion[23]. From these reports, we hypothesized that excessive portal flow could attribute to postoperative liver dysfunction caused by sinusoidal microcirculatory injury after small-for-size liver transplantation. In our experiment, we investigated the effect of PCS on excessive portal flow for the prevention of sinusoidal microcirculatory injury in extremely small-for-size liver transplantation in pigs, focusing on the prevention of primary graft dysfunction. We chose the pig model because the anatomy, metabolism, and physiology of the liver are similar to those in human beings. As a result, we clarified that PCS could prevent portal hypertension and excessive portal inflow in small-for-size liver transplantation.

The sinusoids are the principal vessels involved in the transvascular exchange between blood and the parenchymal cells and play an important role in hepatic microcirculation. In an experimental transplantation model using a small-for-size graft weighing less than 30% of the native liver, Asakura *et al*.[14] and Man *et al*.[24] demonstrated that portal hypertension is a determinant factor for the injury of sinusoidal endothelial cells and hepatic parenchyma. The portal flow through the reduced microvascular bed of the small-for-size graft after reperfusion is likely to induce injury of sinusoidal endothelial cells and activation of Kupffer's cells, which is similar to those after extended hepatectomy in rats reported by Panis *et al*.[19].

In this study, TLBF after reperfusion increased approximately twice in comparison to the flow at laparotomy in the group without PCS. The portal flow increased predominantly and HAF reduced. Histological findings clearly indicated disruption of the sinusoidal lining and disturbance of the sinusoidal microcirculation. Furthermore, the graft became swollen after reperfusion, progressing into severe bowel congestion and then blood oozing. These phenomena were associated with a poor survival rate in the group without PCS. On the other hand, in the group with PCS, graft inflow was modified by PCS which permitted a significantly lower portal flow and a higher HAF. The pathological findings of microcirculatory disturbance after reperfusion recognized in the group without PCS were not observed in the group with PCS. The results of our study strongly suggest that an excessive portal flow after reperfusion in small-for-size liver transplantation is one of the major factors that cause sinusoidal microcirculatory injury and result in graft failure.

With regard to the graft regeneration in the group with PCS, though the TLBF was low, the weight of the graft and Ki-67 index increased remarkably in the pigs that survived for more than 4 d. The decreased HAF subsequent to the excessive portal flow observed after reperfusion in the group without PCS was also believed to contribute to the poor regeneration of residual liver and the poor outcome. Sato *et al*.[25] reported that portal hypertension is a trigger of liver regeneration following partial hepatectomy. But surplus portal hypertension

induces liver dysfunction[25]. Results of our study support the hypothesis that portal flow controls liver regeneration in small-for-size liver transplantation and maintains liver function.

In conclusion, an extreme small-for-size graft weighing less than 25% of the native liver can be successfully transplanted with a PCS in pigs. Portal hyperperfusion in small-for-size liver transplantation appears to play a major role in aggravating microcirculatory injury of the graft and attenuation of portal hyperperfusion by PCS minimizes the injury and improves the survival. This study provides helpful information for transplant surgeons regarding the novel therapeutic strategies for the rescue of small-for-size liver grafts.

Abstract

AIM: To evaluate the protective effect of NF-κB decoy oligodeoxynucleotides (ODNs) on ischemia/reperfusion (I/R) injury in rat liver graft.

METHODS: Orthotopic syngeneic rat liver transplantation was performed with 3 h of cold preservation of liver graft in University of Wisconsin solution containing phosphorothioated double-stranded NF-κB decoy ODNs or scrambled ODNs. NF-κB decoy ODNs or scrambled ODNs were injected intravenously into donor and recipient rats 6 and 1 h before operation, respectively. Recipients were killed 0 to 16 h after liver graft reperfusion. NF-κB activity in the liver graft was analyzed by electrophoretic mobility shift assay (EMSA). Hepatic mRNA expression of TNF-α, IFN-γ and intercellular adhesion molecule-1 (ICAM-1) were determined by semiquantitative RT-PCR. Serum levels of TNF-α and IFN-γ were measured by enzyme-linked immunosorbent assays (ELISA). Serum level of alanine transaminase (ALT) was measured using a diagnostic kit. Liver graft myeloperoxidase (MPO) content was assessed.

RESULTS: NF-κB activation in liver graft was induced in a time-dependent manner, and NF-κB remained activated for 16 h after graft reperfusion. NF-κB activation in liver graft was significant at 2 to 8 h and slightly decreased at 16 h after graft reperfusion. Administration of NF-κB decoy ODNs significantly suppressed NF-κB activation as well as mRNA expression of TNF-α, IFN-γ and ICAM-1 in the liver graft. The hepatic NF-κB DNA binding activity [presented as integral optical density (IOD) value] in the NF-κB decoy ODNs treatment group rat was significantly lower than that of the I/R group rat (2.16±0.78 *vs* 36.78 ±6.35 and 3.06±0.84 *vs* 47.62± 8.71 for IOD value after 4 and 8 h of reperfusion, respectively, $P<0.001$). The hepatic mRNA expression level of TNF-α, IFN-γ and ICAM-1 [presented as percent of β-actin mRNA (%)] in the NF-κB decoy ODNs treatment group rat was significantly lower than that of the I/R group rat (8.31 ±3.48 *vs* 46.37±10.65 and 7.46± 3.72 *vs* 74.82±12.25 for hepatic TNF-α mRNA, 5.58±2.16 *vs* 50.46±9.35 and 6.47±2.53 *vs* 69.72±13.41 for hepatic IFN-γ mRNA, 6.79 ±2.83 *vs* 46.23±8.74 and 5.28±2.46 *vs* 67.44±10.12 for hepatic ICAM-1 mRNA expression after 4 and 8 h of reperfusion, respectively, $P<0.001$). Administration of NF-κB decoy ODNs almost completely abolished the increase of serum level of TNF-α and IFN-γ induced by hepatic ischemia/reperfusion, the serum level (pg/mL) of TNF-α and IFN-γ in the NF-κB decoy ODNs treatment group rat was significantly lower than that of the I/R group rat (42.7±13.6 *vs* 176.7±15.8 and 48.4±15.1 *vs* 216.8±17.6 for TNF-α level, 31.5±12.1 *vs* 102.1±14.5 and 40.2±13.5 *vs* 118.6±16.7 for IFN-γ level after 4 and 8 h of reperfusion, respectively, $P<0.001$). Liver graft neutrophil recruitment indicated by MPO content and hepatocellular injury indicated by serum ALT level were significantly reduced by NF-κB decoy ODNs, the hepatic MPO content (A655) and serum ALT level (IU/L) in the NF-κB decoy ODNs treatment group rat was significantly lower than that of the I/R group rat (0.17±0.07 *vs* 1.12 ±0.25 and 0.46±0.17 *vs* 1.46±0.32 for hepatic MPO content, 71.7±33.2 *vs* 286.1±49.6 and 84.3±39.7 *vs* 467.8±62.3 for ALT level after 4 and 8 h of reperfusion, respectively, $P<0.001$).

CONCLUSION: The data suggest that NF-κB decoy ODNs protects against I/R injury in liver graft by suppressing NF-κB activation and subsequent expression of proinflammatory mediators.

INTRODUCTION

Liver transplantation is the only therapeutic strategy for many inherited and acquired disorders of the liver. The vulnerability of the transplantation liver to warm ischemia, cold preservation, and reperfusion injury is possibly associated with immediate posttransplant graft function loss, and graft damage caused by ischemia/reperfusion (I/R) is a serious problem after transplantation. Hepatic I/R injury still leads to primary graft nonfunction in about 4% of liver transplantation. Moreover, late consequences of ischemia injury include intrahepatic and extrahepatic biliary strictures, which further increase morbidity and jeopardize graft survival. Therefore, inhibition of I/R injury has become a more serious clinical interest.

Two distinct phases in the development of organ injury have been identified in experimental hepatic I/R injury animal models. During the initial phase of injury, Kupffer cells are activated and release reactive oxygen species and proinflammatory cytokines, including tumor necrosis factor (TNF)-α[1-4]. The enhanced production of TNF-α plays a more important role in the initiation of a cascade of events that causes significant liver injury mediated by neutrophils. One of the main functions of TNF-α is the up-regulation of adhesion molecules and neutrophil-attracting C-X-C chemokines[5,6]. The coordinated efforts of adhesion molecules and C-X-C chemokines mediate the recruitment of neutrophils into the liver. Sequestered neutrophils release protease and reactive oxygen intermediates (ROI), which directly damage hepatocytes and endothelial cells and also to capillary plugging causing hepatic hypoperfusion. The transcription factor nuclear factor (NF)-κB plays a key role in the regulation of genes that function in immune and inflammatory systems such as TNF-α, IFN-γ, chemokines and ICAM-1[7-15]. Previous studies suggested that NF-κB activation plays a deteriorative role during hepatic I/R injury[15-18]. In contrast to these studies, Bradham *et al.*[19] reported that NF-κB activation during orthotopic liver transplantation is protective.

In the present study, we have attempted to evaluate the exact effect of NF-κB activation on the I/R injury in liver graft after orthotopic liver transplantation in rats. For this aim, we used the recently developed technology of decoy ODNs. The original concept of using synthetic double-stranded ODN as "decoy" cis elements to block the binding of nuclear factors to promoter regions of target genes was introduced in 1990 by Sullenger *et al.* and Bielinska *et al.* In 1997, Morishita *et al.* reported the first *in vivo* application of this technology, they prevented myocardial infarction after reperfusion in rats by direct infusion of synthetic double-stranded 20-bp ODNs containing the NF-κB cis element into cannulated coronary arteries[20]. Subsequently, Kawamura *et al.* showed that the direct injection of NF-κB decoy ODNs into implanted tumors in mice inhibited cachexia, without affecting the tumor growth[21]. In 2000, Abeyama *et al.* reported that intraperitoneal and local administration of NF-κB decoy ODNs reduces the extent of UV-induced skin inflammation, and this is associated with NF-κB activation inhibition and decreased the transcription of inflammatory cytokines TNF-α and IL-1 and IL-6[22]. Here we report that the application of NF-κB decoy ODNs significantly attenuates the liver graft I/R injury in rats.

MATERIALS AND METHODS

NF-κB decoy ODNs and scrambled ODNs

Double-stranded NF-κB decoy ODNs were generated using equimolar amounts of single-stranded sense and antisense phosphorothioate-modified oligonucleotides containing two NF-κB binding sites(sense sequence 5' -AGGGACTTTCCGCTGGGGACTTTCC-3'; NF-κB binding sites bold and underlined)[23]. Scrambled ODNs (treatment control ODNs: 5'-TTGCCGTACCTGACTTAGCC-3')[22] were generated in the same way. Sense and antisense strands were mixed in the presence of 150 mmol PBS, heated to 100 ℃, and allowed to cool to room temperature to obtain double-stranded DNA .

Experimental design and liver transplantation

Male SD rats (220-250 g) were used for the liver graft I/R injury experiments. The animals were maintained with a 12-h light/dark cycle in a conventional animal facility with water and commercial chow provided *ad libitum*, with no fasting before the transplantation. The following experimental groups were compared: (1) the I/R group, in which orthotopic liver transplantation were performed with two-cuff method and liver graft reperfusion was initiated after 3 h of cold-preservation in chilled (4 ℃) University of Wisconsin (UW) solution containing NF-κB decoy ODNs or scrambled ODNs (5 μmol/L/mL); (2) the NF-κB decoy ODNs + I/R group, in which donor and recipient animals were injected intravenously through the penile vein with NF-κB decoy ODNs (1.0 mmol/L solution in PBS, 1 mL/rat) 6 and 1 h before liver harvesting or orthotopic liver transplantation; (3) the scrambled ODNs + I/R group in which donor and recipient animals were injected intravenously through the penile vein with scrambled ODNs (1.0 mmol/L solution in PBS, 1 mL/rat) 6 and 1 h before liver harvesting or orthotopic liver transplantation; (4) the sham control group in which rats only underwent a midline laparotomy. Orthotopic liver transplantation was performed according to the method described in our previous study[24]. All operations were performed under ether anesthesia in sterile conditions. The survival rate was >89% at 24 h after liver transplantation. Liver graft tissues and recipient blood samples (n = 5) were harvested at different time points (0, 0.5, 1, 2, 4, 8, and 16 h) after graft reperfusion and were immediately frozen in liquid nitrogen (only liver samples) and kept at -80 ℃ until use.

Myeloperoxidase assay

Liver myeloperoxidase (MPO) content was assessed by methods described elsewhere[15]. Briefly, liver tissue (50 mg) was homogenized in 2 mL of homogenization buffer (3.4 mmol/L KH_2HPO_4, 16 mmol/L Na_2HPO_4, pH 7.4).

After centrifugation for 20 min at 10 000 g, 10 volumes of resuspension buffer (43.2 mmol/L KH_2HPO_4, 6.5 mmol/L Na_2HPO_4, 10 mmol/L ethylenediaminetetraacetic acid, 0.5% hexadecyltrimethylammonium, pH 6.0) was added to the pellet and the samples were sonicated for 10 s. After heating for 2 h at 60 ℃, the supernatant was reacted with 3, 3', 3, 5'-tetramethylbenzidine (Sigma Chemicall Co.) and read at 655 nm.

Preparation of liver graft nuclear extract

Nuclear proteins from frozen liver graft tissue were extracted according to the method of Nanji[8]. One gram of liver tissue was homogenized in 5 mL buffer [0.32 mol/L sucrose, 50 mmol/L Tris-HCl (pH 7.5), 25 mmol/L KCl, 5 mmol/L $MgCl_2$, 0.5 mmol/L phenylmethylsulfonyl fluoride,10 μg/mL aprotinin, 10 μg/mL tosyllysylchloromethyl ketone(TLCK)] and centrifuged for 10 min at 600 r/min at 40 ℃. The pellet was resuspended in 2.5 mL of 2 mol/L sucrose-Tris HCl, KCl, and $MgCl_2$ (TKM) buffer and homogenized. The homogenate was centrifuged at 40 000 g at 4 ℃ for 2 h. The supernatant was carefully removed and the pellet containing the nuclear extract was resuspended in 40 μL of buffer A [10 mmol/L HEPES/KOH (pH 7.9), 2 mmol/L $MgCl_2$, 0.1 mmol/L ethylenediaminetetraacetic acid, 10 mmol/L KCl, 1 mmol/L dithiothreitol, 0.5 mmol/L phenylmethylsulfonyl fluoride] and left on ice for 10 min, mixed, and centrifuged at 15 000 g at 4 ℃ for 15 s. The pellet was then resuspended in 1.0 mL of buffer B [10 mmol/L HEPES/KOH (pH 7.9), 50 mmol/L KCl, 300 mmol/L NaCl, 0.1 mmol/L ethylenediaminetetraacetic acid, 10% (v/v) glycerol, 1 mmol/L dithiothreitol, 0.5 mmol/L phenylmethylsulfonyl fluoride, 10 μg/mL leupeptin, 10 μg/mL aprotinin, 10 μg/mL TPCK] and put on ice for 20 min. After centrifugation at 15 000 g at 4 ℃ for 5 min, the supernatant was stored at -80 ℃ as a nuclear extract. Before the experiments, the total protein concentration in the samples were determined according to the method of Bradford.

Electrophoretic mobility shift assay (EMSA) for hepatic NF-κB activity

NF-κB DNA binding activity was performed in a 10 μL binding reaction mixture containing 1×binding buffer [50 mg/L of double-stranded poly (dI-dC), 10 mmol/L Tris-HCl (pH 7.5), 50 mmol/L $NaCl_2$, 0.5 mmol/L EDTA, 0.5 mmol/L-1DTT, 1 mmol/L $MgCl_2$, and 100 mL/L glycerol], 5 μg of nuclear protein, and 35 fmol of double-stranded NF-κB consensus oligonucleotide (5' -AGTGAGGGGACTTTCCCAGGC -3') that was endly labeled with γ-^{32}P (111 TBq/mol/L at 370 GBq^{-1}) using T4 polynucleotide kinase. The binding reaction mixture was incubated at room temperature for 20 min and analyzed by electrophoresis on 7% nondenaturing polyacrylamide gels. After electrophoresis the gels were dried by Gel-Drier (Biol-Rad Laboratories, Hercules, CA, USA) and exposed to Kodak X-ray films at -70 ℃. NF-κB DNA binding activity was presented as integral optical density (OD) value.

Semiquantitative RT-PCR assay for hepatic expression of TNF-α, IFN-γ and ICAM-1 mRNA

Analysis of the expression of TNF-α, IFN-γ and ICAM-1 mRNA was determined by semiquantitative RT-PCR amplification in contrast with house-keeping gene β-actin. Total RNA from 10 mg liver graft tissue was extracted using Tripure™ reagent. First-strand cDNA was transcribed from 1 μg RNA using AMV and an oligo (dT15) primer. PCR was performed in a 25 μL reaction system. Specific primers used in PCR reaction were as follows: TNF-α, 5' primer 5'-AGCCCACGTAGCAAACCACCA-3' and 3' primer 5'-ACACCCATTCCCTTCACAGAGCAAT-3', to give a 446-bp product; $ICAM^{-1}$, 5' primer 5' -TGGAACTGCACGTGCTGTAT-3', 3' primer 5' -ACCATTCTGTTCAAAAGCAG-3', to give a 513-bp product; IFN-γ, 5' primer 5'-ACAATGAACGCTACACACTG-3', 3' primer 5'-TCAAACTTGGCAATACTCAT-3', to give a 362-bp product; β-actin, 5' primer 5' -ATGGATGATGATATCGCCGCG-3', 3' primer 5' -TGAAGGTAGTTTCGTGGATGC-3', to give a 813-bp product. PCR products of each sample were subjected to electrophoresis in a 15 g/L agarose gel containing 0.5 mg/L ethidium bromide. Densitometrical analysis using NIH image software was performed for semiquantification of PCR products, and mRNA expression was evaluated by the band-intensity ratio of TNF-α, IFN-γ and ICAM-1 to β-actin, and presented as percent of β-actin (%).

Blood assay for serum levels of TNF-α, IFN-γ and ALT

Blood was obtained by cardiac puncture at the time of killing. Serum samples were analyzed for TNF-α and IFN-γ by enzyme-linked immunosorbent assays (ELISA) according to the manufacturer's instructions. Serum samples were also analyzed for ALT level as indices of hepatocellular injury. Measurements of serum ALT level were made using a diagnostic kit from Sigma Chemical Co.

Statistical analysis

All data were expressed as mean±SE . Statistical analysis of data was performed using the Student's *t*-test; $P<0.05$ was considered statistically significant.

RESULTS

NF-κB activation in the liver graft

NF-κB activation in the liver graft at seven separate time points after reperfusion was determined by EMSA (as shown in Figure 1). NF-κB activation in the liver graft after reperfusion was induced in a time-dependent manner. Hepatic NF-κB activation was observed to start within 30 min after the initiation of reperfusion and continued for 16 h after liver graft reperfusion. NF-κB activation in the liver graft was significant at 2 to 8 h and slightly decreased at 16 h after graft reperfusion.

NF-κB decoy ODNs suppresses NF-κB activation in the liver graft

In the I/R + NF-κB decoy ODNs group rats, administration of NF-κB decoy ODNs group almost

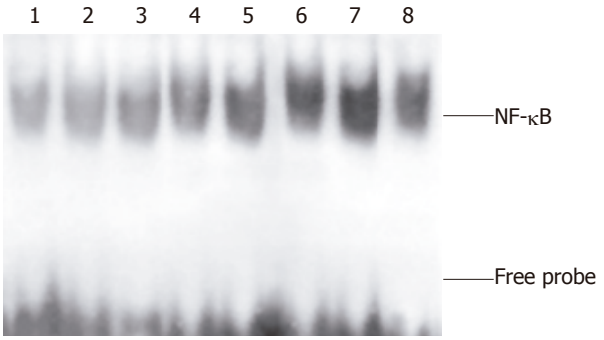

Figure 1 NF-κB activation in the liver graft. Lanes 1: Hepatic nuclear protein extracts from sham control rat; Lanes 2-8: Liver graft nuclear protein extracts on 0, 0.5, 1, 2, 4, 8 and 16 h after reperfusion.

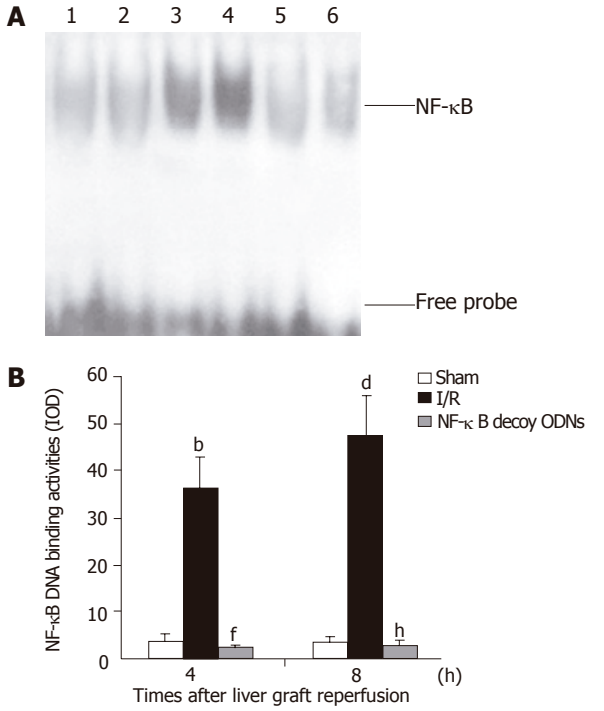

Figure 2 Hepatic NF-κB activation (**A**) and NF-κB DNA binding activities presented as IOD value (**B**). Lanes 1 and 2: Hepatic RNA extracts from sham control group. Lanes 3 and 4: Hepatic RNA extracts from I/R group. Lanes 5 and 6: Hepatic RNA extracts from I/R + NF-κB decoy ODNs group. [b, d]$P<0.001$ vs sham group, [f, h]$P<0.001$ *vs* I/R group.

completely abrogated NF-κB activation in the liver graft after 4 h and 8 h of reperfusion (as shown in Figure 2). Similar effects were observed at 0.5, 1, 2 or 16 h after hepatic reperfusion (data not shown). However, in the I/R + scrambled ODNs group rats, NF-κB activation in the liver graft were not significantly changed compared with the I/R group rats (data not shown).

NF-κB decoy ODNs suppresses hepatic mRNA expression of TNF-α, IFN-γ and ICAM-1

To investigate whether NF-κB decoy ODNs induced suppression of NF-κB was associated with reduced inflammatory mediator expression, mRNA expression of TNF-α, IFN-γ and ICAM-1 in the liver graft were assessed by RT-PCR. Hepatic ischemia/reperfusion increased hepatic mRNA expression of TNF-α, IFN-γ and ICAM-1. Administration of NF-κB decoy ODNs almost completely abrogated hepatic ischemia/reperfusion-induced increases of TNF-α, IFN-γ and ICAM-1 mRNA expression in the liver graft with reperfusion for 4 and 8 h (as shown in Figure 3). Similar effects were observed at 0.5, 1, 2 or 16 h after reperfusion (data not shown). However, administration of scrambled ODNs did not have any significant effect on the hepatic mRNA expression of these inflammatory mediators (data not shown). Thus, NF-κB decoy ODNs-mediated suppression of NF-κB activation in the liver graft is associated with the inhibited hepatic mRNA expression of these proinflammatory mediators.

NF-κB decoy ODNs reduces serum level of TNF- α and IFN-γ

To confirm the inhibitory effects of NF-κB decoy ODNs on the inflammatory mediator production, serum levels of TNF-α and IFN-γ were analyzed by ELISA. Serum levels of TNF-α and IFN-γ were significantly increased within 1 h and were maximal at 8 h after liver graft reperfusion. Administration of NF-κB decoy ODNs markedly reduced serum levels of TNF-α and IFN-γ ($P<0.001$) at every time point, respectively (Figure 4). However, administration of scrambled ODNs did not have any significant effect on the serum levels of TNF-α and IFN-γ (data not shown).

NF-κB decoy ODNs suppresses liver graft neutrophil recruitment and liver graft injury

Liver graft neutrophil recruitment was determined by liver MPO content and hepatocellular injury was assessed by serum level of ALT. Liver graft ischemia/reperfusion caused significant increases of liver MPO content and serum level of ALT compared with sham controls. In the presence of NF-κB decoy ODNs, the liver graft MPO content and the serum level of ALT were significantly reduced ($P<0.001$) (as shown in Figure 5), whereas administration of scrambled ODNs did not have any significant effect on the liver graft MPO content and serum level of ALT (data not shown).

DISCUSSION

Hepatic ischemia/reperfusion injury remains a significant problem and limitation of liver transplantation and may result in liver failure, remote organ failure, and death. Previous studies have identified many proinflammatory mediators (TNF-α, MIP-2, IFN-γ, KC, ENA-78, and ICAM-1) involved in the pathogenesis of hepatic ischemia/reperfusion injury, and production of TNF-α by activated Kupffer cells is central to this process[3,15, 6,25-27]. TNF-α enhances the inflammatory response in liver by inducing the expression of adhesion molecules on vascular endothelial cells and stimulating the production and release of neutrophil-attracting CXC chemokines[18,28]. TNF-α[29-33] and ICAM-1[15] also play significant roles in

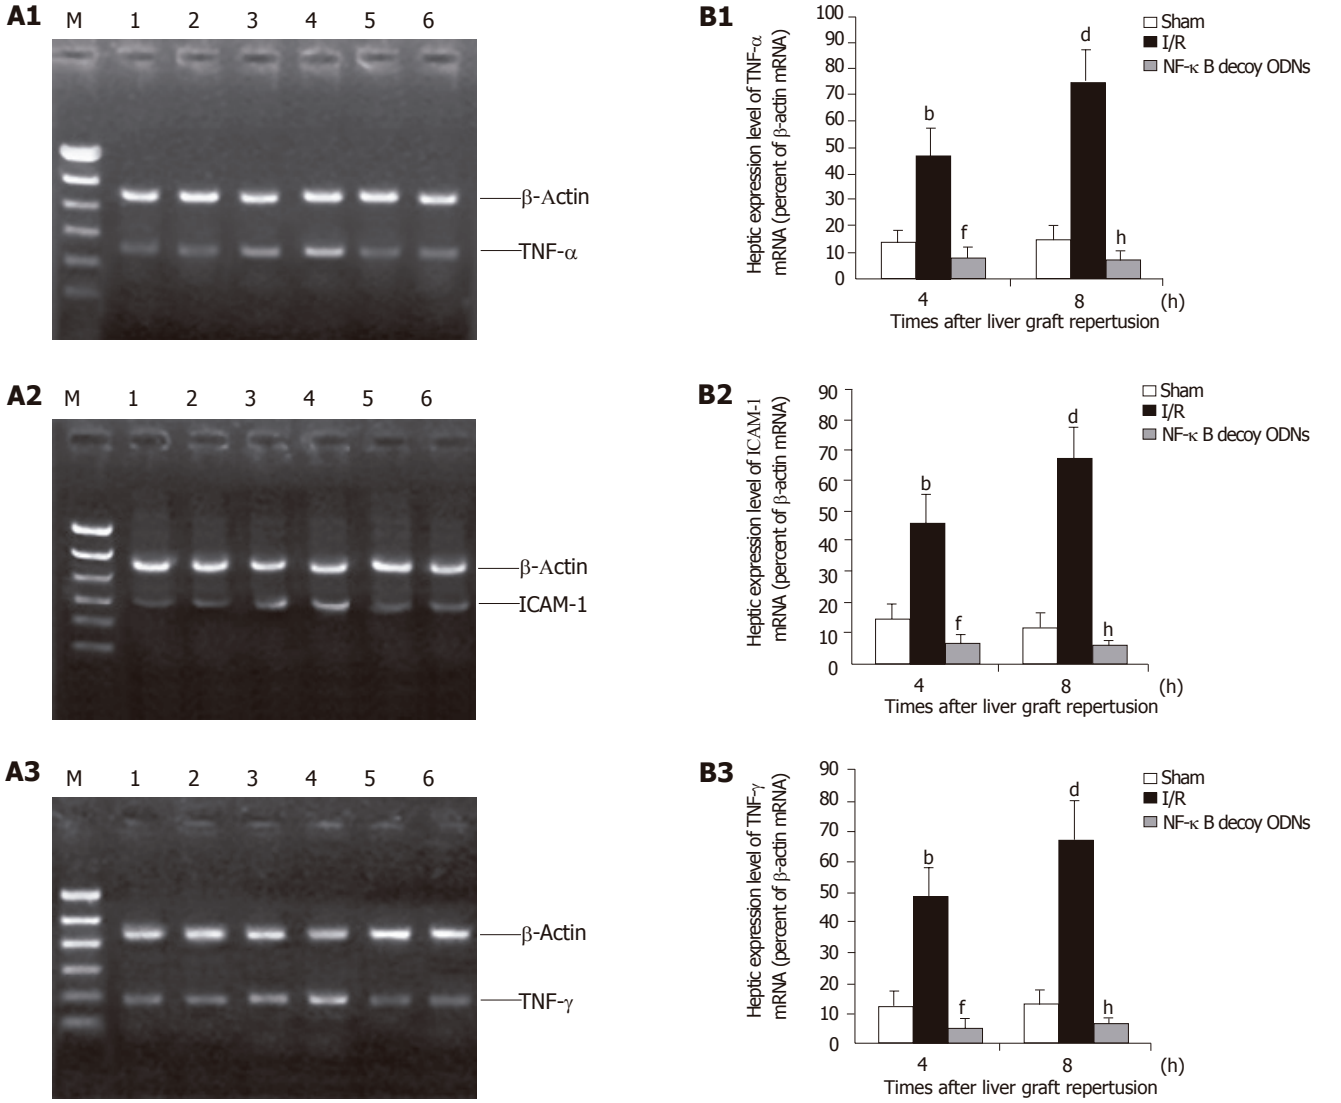

Figure 3 Hepatic expression (**A**) and the expression level (**B**) of cytokine mRNA after 4 and 8 h of reperfusion. Lanes 1 and 2: Hepatic RNA extracts from sham control group. Lanes 3 and 4: Hepatic RNA extracts from I/R group. Lanes 5 and 6: Hepatic RNA extracts from I/R + NF-κB decoy ODNs group. $^{b,d}P<0.001$ *vs* sham group; $^{f,h}P<0.001$ *vs* I/R group.

the inflammatory and immune responses that mediate allograft rejection. Thus, they are important as they are against liver graft I/R injury and rejection to suppress the production of these proinflammatory mediators. Each of these mediators is controlled, at least in part, by the transcription factor, NF-κB. Yoshidome *et al.*[15] reported interleukin (IL)-10 protected against hepatic I/R injury by suppressing NF-κB activation and subsequent expression of proinflammatory mediators. Recent studies have confirmed that hepatic ischemic preconditioning (IPC) has protective effect on hepatic cold storage-reperfusion injury, including improved graft function, reduced graft circulatory impairment, enhanced bile production, augmented responses to a bile acid challenge, elevated O_2 consumption, improved hepatic tissue blood flow and decreased hepatic vascular resistance, reduced endothelial cell damage, suppressed Kupffer cell activation, decreased apoptosis of hepatocytes, and as a result, graft survival improves after liver transplantation[34-43]. The recent study have found out that attenuation of NF-κB activation and subsequent reduction in TNF-α production after sustained ischemia play important roles in the protective mechanism of IPC against hepatic I/R injury[16,44]. These data suggest a central role of NF-κB activation in the initiation of hepatic I/R injury, and NF-κB activation inhibition could protect against hepatic I/R injury. However, there are contrary reports about the role of NF-κB activation during I/R injury and liver transplantation. Maulik *et al.*[45] showed that IPC activated NF-κB, of which p38 mitogen-associated protein kinase (MAPK) might be upstream before sustained ischemia, and also that inhibitor of p38MAPK abolished preconditioning-induced cardioprotection. Teoh *et al.*[46] recently reported that the hepatoprotective effects of ischemic preconditioning are associated with the activation of NF-κB and SAPKs that are associated with entry of hepatocytes into the cell cycle, a critical biological effect that favors survival of the liver against ischemic and I/R injury. Bradham *et al.*[19] reported that the activation of NF-κB during orthotopic liver transplantation in rats is protective, inhibition of donor hepatic NF-κB activation by adenoviral-mediated IκB alpha superrepressor gene transfer resulted in increased serum ALT levels after 3 h of transplantation. In addition, the blockade of NF-κB resulted in increased histological tissue injury and increased hepatic terminal deoxyribonucleotide transferase-mediated deoxyuridine triphosphate nick end labeling (TUNEL) staining, indicating apoptosis.

To assess the role of NF-κB activation during liver transplantation, we examined the effect of NF-κB activation inhibition by NF-κB decoy ODNs containing two NF-κB binding sites on the liver graft I/R injury. We found that cold preservation-reperfusion of liver graft rapidly activated hepatic NF-κB and concomitantly elevated hepatic mRNA expression of TNF-α, INF-γ and ICAM-1 as well as serum levels of TNF-α and IFN-γ. Administration of NF-κB decoy ODNs almost completely abrogated the increased hepatic NF-κB activation, the up-regulated hepatic mRNA expression of the proinflammatory mediators, the elevated serum levels of TNF-α and IFN-γ as well as the increased hepatic neutrophil recruitment, and as a result, attenuated liver graft I/R injury. Liver I/R injury is considered to be primarily dependent on the activation of Kupffer cells, these cells are a major source of ROIs, proinflammatory cytokines or chemokines that promote neutrophils recruitment, adhesion, and activation eventually leading to organ injury. Bradham *et al.*[19] reported that the induction of TNF-α mRNA and serum protein during liver transplantation was unaffected by Kupffer cells depletion with $GdCl_3$. These results show that Kupffer cells are not the only major source of TNF-α production after liver transplantation and that stress-signaling protein activation occurs independently of Kupffer cells. A recent study reported that hepatic I/R injury critically depends on liver activated T cells[47,48]. Indeed, both cyclosporine and FK506, which are potent T cell-deactivating agents, were reported to decrease reperfusion injury after liver transplantation or warm ischemia compared with untreated controls. Besides the role of liver reside T cells, lymphocytes recruited from the circulatory cell pool within hours or days after reperfusion are also involved in the cascade of reperfusion in the kidney and in the liver[49, 50]. Circulating monocytes/macrophages are the primary systemic sources of TNF-α[51] in response to endotoxin stimulation. Previous studies showed that endotoxin in portal vein blood was significantly increased during portal vein occlusion and after liver transplantation, and the increased endotoxin could stimulat macrophages that reside in spleen, lung, and other organs, as well as circulating monocyte/

macrophage to produce TNF-α. Tsoulfas *et al*. have shown the LPS/CD14/LBP/NF-κB signaling pathway activation in hepatic transplantation preservation injury[52]. Thus, far besides Kupffer cells, T lymphocytes and monocytes/macrophages, either residing in the organ, or being recruited from the blood, should definitely be considered effector cells in I/R injury. IFN-γ released by activated T cells is able to prime macrophages/Kupffer cells for the production of proinflammatory cytokines like TNF, and to down-regulate the synthesis of IL-10, a protective cytokine which has been identified to protect against hepatic ischemia/reperfusion injury. Conversely, monomacrophages can also activate T cells and promote the synthesis of INF-γ through the release of cytokines like IL-12 and IL-18 and the engagement of costimulatory molecules[53]. In the present study, the administration of NF-κB decoy ODNs may attenuate not only donor hepatic Kupffer cells NF-κB activation, but also recipient monocytes/macrophages and T-cells NF-κB activation, and consequently decreases the hepatic mRNA expression of TNF-α and IFN-γ as well as the protein production of TNF-α and IFN-γ. Although blockade of NF-κB can result in increased hepatocytes apoptosis induced by TNF-α, the significantly decreased production of TNF-α by NF-κB decoy ODNs may attenuates the initiation of hepatocytes apoptosis. Thus, NF-κB decoy ODNs may protect against I/R injury in the transplanted liver graft by suppressing NF-κB activation and the subsequent production of TNF-α, ICAM-1 and IFN-γ.

Abstract

AIM: To induce the pancreatic duct cells into endocrine cells with a new natural protocol for electrophysiological study.

METHODS: The pancreatic duct cells of neonatal rats were isolated, cultured and induced into endocrine cells with 15% fetal bovine serum for a period of 20 d. During this period, insulin secretion, MTT value, and morphological change of neonatal and adult pancreatic islet cells were comparatively investigated. Pancreatic β-cells were identified by morphological and electrophysiological characteristics, while ATP sensitive potassium channels (K_{ATP}), voltage-dependent potassium channels (K_V), and voltage-dependent calcium channels (K_{CA}) in β-cells were identified by patch clamp technique.

RESULTS: After incubation with fetal bovine serum, the neonatal duct cells budded out, changed from duct-like cells into islet clusters. In the first 4 d, MTT value and insulin secretion increased slowly (MTT value from 0.024 ±0.003 to 0.028±0.003, insulin secretion from 2.6±0.6 to 3.1±0.8 mIU/L). Then MTT value and insulin secretion increased quickly from d 5 to d 10 (MTT value from 0.028 ±0.003 to 0.052±0.008, insulin secretion from 3.1±0.8 to 18.3±2.6 mIU/L), then reached high plateau (MTT value >0.052±0.008, insulin secretion >18.3±2.6 mIU/L). In contrast, for the isolated adult pancreatic islet cells, both insulin release and MTT value were stable in the first 4 d (MTT value from 0.029±0.01 to 0.031±0.011, insulin secretion from 13.9±3.1 to 14.3±3.3 mIU/L), but afterwards they reduced gradually (MTT value <0.031 ±0.011, insulin secretion <8.2±1.5 mIU/L), and the pancreatic islet cells became dispersed, broken or atrophied correspondingly. The differentiated neonatal cells were identified as pancreatic islet cells by dithizone staining method, and pancreatic β-cells were further identified by both morphological features and electrophysiological characteristics, i.e. the existence of recording currents from K_{ATP}, K_V, and K_{CA}.

CONCLUSION: Islet cells differentiated from neonatal pancreatic duct cells with the new natural protocol are more advantageous in performing patch clamp study over the isolated adult pancreatic islet cells.

INTRODUCTION

The pancreatic islets (containing α, β, and δ cells that produce glucagon, insulin, and somatostatin, respectively) are intensively involved in the regulation of physiological metabolic homeostasis[1]. Patch clamp technique is considered as a very important approach for studying the endocrine activities and mechanisms of these cells. The traditional method for the isolation of rat intact pancreatic islet cells[2] has been performed for almost 40 years, and is still the most widely acceptable method in electrophysiological study of pancreatic islet cells. Nevertheless, pancreatic islet cells usually survive poorly after isolation because the cells are fragile in the *in vitro* culture condition[3]. Thus, only the freshly isolated or shortly cultured islet cells can be introduced for patch clamp experiments. Furthermore, there are some disadvantages in performing patch clamp experiments with

isolated islet cells. The endocrine pancreas is considered as a slowly and continuously renewing tissue in the kinetic balance process of apoptosis and neogenesis[4]. Thus, pancreatic β cells isolated from adult rats are heterogeneous at different ages, including neonatal, adult, and senile cells. The isolated adult and senile β cells are more susceptible than neonatal β cells to the transition from the native living surroundings to the *in vitro* culture. Because the membrane of isolated adult β cells is fragile, it is difficult to manipulate gigaseal, a key step in patch clamp experiments.

Although there are other cell sources for performing patch clamp experiments without obvious problems mentioned above, such as β cell line and islet cells differentiated from marrow mesenchymal stem cells[5] or multipotent cells, and precursor cells of fetal pancreas, they still show considerable shortcomings. According to the reports, the β cell line only retains partial characteristics of primitive pancreatic islet cells, while the islet cells differentiated from marrow mesenchymal stem cells[6] and precursor cells of fetal pancreas[7-11] exhibit poor insulin secretory response to glucose. Therefore, it is essential to seek for more optimal cell sources and approaches suitable for patch clamp experiments.

Neonatal pancreatic duct cells are composed mainly of precursor cells[12,13] and can be induced into endocrine cells if appropriate morphogen stimuli are provided[10-13], and the induced endocrine cells are stable in culture condition[12,13], and their glucose-induced insulin secretion is evident[7-10]. Thus, we suppose that the neonatal pancreatic duct cells might be more suitable for patch clamp experiments.

Here the pancreatic duct cells were differentiated into endocrine islet cells with fetal bovine serum, a physiological nutrition[14]. The cell proliferation and insulin secretion of differentiated neonatal endocrine cells were compared to isolated adult endocrine islet cells. ATP sensitive potassium channels (K_{ATP}), voltage-dependent potassium channels (K_V) and voltage-dependent calcium channels (K_{CA}) of β cells were identified with patch clamp technique to prove the usefulness of this protocol.

MATERIALS AND METHODS

Reagents

Na_2-ATP, EGTA, HEPES, repaglinide, and diazoxide were purchased from Sigma Co. The other chemicals used were of analytical reagent grade.

Isolation and culture of pancreatic islet cells

Sprague-Dawley rats aged 1-3 and 50-60 d were obtained from Laboratory Animal Center, Tongji Medical College, Huazhong University of Science and Technology. Hubei Experimental Animal Association approved the experiments. The culture medium used for both neonatal and adult cells was RPMI 1640 medium (glucose 11.1 mmol/L) supplemented with 15% fetal bovine serum, 15 mmol/L HEPES buffer, pH 7.40, without any antibiotics (to eliminate its possible influence on the differentiation of precursor cells). The cells were cultured at 37 ℃ in the atmosphere containing 950 mL/L O_2+50 mL/L CO_2. The isolation of pancreatic islet cells from adult rats was performed as previously described[2]. The isolation and induction of duct cells were performed as follows: the pancreases were moved from 10 neonatal rats and thoroughly washed in KRBH solution containing (in mmol/L) 136 NaCl, 4.8 KCl, 1 $CaCl_2$, 1.2 $MgSO_4$, 1.2 KH_2PO_4, 5 $NaHCO_3$, 25 HEPES, 1% BSA, pH 7.40. The pancreases were minced into pieces of 1-2 mm in size. The minced pancreases were hand-shaken while being digested by 0.5 mg/mL type V collagenase in PBS (pH 7.40) for about 3-8 min in a 10-mL tube bathed in 37 ℃water. Then digestion was stopped by 4 ℃ KRBH. The production was centrifuged (50 r/min) thrice to eliminate collagenase and broken cells. Thereafter, the cells were suspended in the cell culture medium and seeded in plastic dishes (18 mm in diameter) with 2 mL culture medium in each dish. After being cultured for about 24 h, the culture medium was moved, and the duct cells were washed with KRBH solution five times to remove the floated cells thoroughly. Then the left cells were mostly duct cells (Figure 1). The cells were kept in the cell culture medium for 20 d, during which the dishes were replenished with a new medium every 2 d.

Morphology observation

The incubated cells were observed under inverted microscope each day. When the marked morphologic changes were observed, photograph of the cells was taken by phase difference microscopy.

Insulin measurement

All the isolated products from neonatal duct cells or adult pancreatic islet cells were equally seeded in gelatin-coated dishes (18 mm in diameter), and each dish contained 2 mL isolated products (about 10^4 cells). The supernatant of culture media in the five dishes was harvested every 2 d and kept at -20 ℃ for insulin determination by radioimmunoassay. The dishes were washed with KRBH solution twice, then 2 mL of the cell culture medium was added again for further culture.

MTT test

MTT assay was carried out as previously described[15]. The isolated products from neonatal or adult rats (about 10^5 cells) were equally seeded in 10 dishes (96 cells in each dish, and each cell containing 150 μL isolated products), one dish of cells was used every 2 d for MTT determination, and the remaining dishes were replenished with a new medium.

Identification of pancreatic islet cells

The pancreatic islet cells were identified by dithizone staining method[16]. The viable cells were determined by trypan blue exclusive test.

Identification of pancreatic β cells

Two steps were performed to identify pancreatic β cells from α and δ cells[17]. Therefore, only large cells with a capacitance of >5 pF were selected as β cells. Then

a depolarizing protocol was applied to the large cells to identify the properties of voltage-dependent Na^+ currents[18]. Thus, cells in which a Na^+ current could be activated by a small depolarizing pulse from a prolonged holding potential of -70 mV were discarded. By contrast, cells exhibiting a Na^+ current only after a hyperpolarizing pulse to -140 mV were considered to be β cells[19].

Patch clamp experiments

Patch clamp experiments were performed on β cells of isolated islet cells only in the first 4 d after the isolation, the β cells beyond this period of time could not be introduced into patch clamp experiments. The β cells differentiated from islet cells of neonatal rats were applied for patch clamp experiments from d 10 to d 16.

Rat pancreatic islet cells plated on the plastic dishes were placed in a recording chamber mounted on an inverted microscope (Olympus). Patch clamp recordings were done for cells that were not in contact with the other cells to avoid possible cell-cell coupling artifacts. For recording K_{ATP} currents, the solutions were as follows (in mmol/L): internal solution containing 140 KCl, 2 $CaCl_2$, 4 $MgCl_2$, 10 EGTA, 0.65 Na_2-ATP, and 20 HEPES (pH 7.15 with KOH); and external solution containing 140 NaCl, 5.6 KCl, 1.2 $MgCl_2$, 2.6 $CaCl_2$, 0.5 glucose and 10 HEPES (pH 7.4 with KOH). K_{ATP} currents were measured at a holding potential of -70 to -80 mV and -60 mV at 15-s intervals, and diazoxide (100 μmol/L) and repaglinide (100 μmol/L) were added respectively to further confirm whether it was K_{ATP} currents or not. For K_V currents recording, the solutions were the same as for recording K_{ATP} currents except that 100 μmol/L repaglinide was added into external solution to block K_{ATP} currents. The cells were held at -120 mV and depolarized at 15-s intervals to 30 mV to activate K_V currents. For K_{CA} recording, the solutions were as follows (in mmol/L): internal solution containing 70 CsCl, 1 $MgCl_2$, 4 ATP, 20 HEPES, 5 EGTA, pH 7.2; external solution containing 90 NaCl, 1 $MgCl_2$, 20 TEA-Cl, 10 HEPES, 20 $BaCl_2$, 5.6 KCl, 5 CsCl, pH 7.15. All cell membrane currents were measured using whole-cell mode of patch clamp technique at 22 ℃, using an EPC-9 patch clamp amplifier (Heka Electronics, Lambrecht/Pfalz, Germany) and the software Pulsefit. Patch clamp electrodes were made from borosilicate glass capillaries (Shanghai Physiology Institute, China) using a two-stage puller (PP-830, Narishige Co., Japan) to give a resistance of 4-5 MΩ.

RESULTS

Morphological evolvement and identification

The neonatal rat pancreatic duct cells were organized in duct-like cells when incubated for 3-4 d (Figure 1A). There were precursors of pancreatic islet cells among them. When cultured for 5-10 d, some duct cells changed into round cells organized as islet clusters, being similar to pancreatic islet cells *in vivo* (Figure 1B). Then the cells grew bigger and budded out (Figures 1C and 1D). The buds grew bigger and bigger and became new ground cells in clusters (Figure 1E), which were further identified as pancreatic islet cells by dithizone (Figure 1F), a chemical considered to selectively stain pancreatic islet cells[16].

In contrast, the freshly isolated pancreatic islet cells from adult rats were round, but gradually became dispersed, broken or atrophied. After being cultured for a week, the islet cells were dispersed to be single cells, and the cell number was greatly reduced (data not shown).

Insulin release

For neonatal pancreatic islet cells, the insulin concentration in

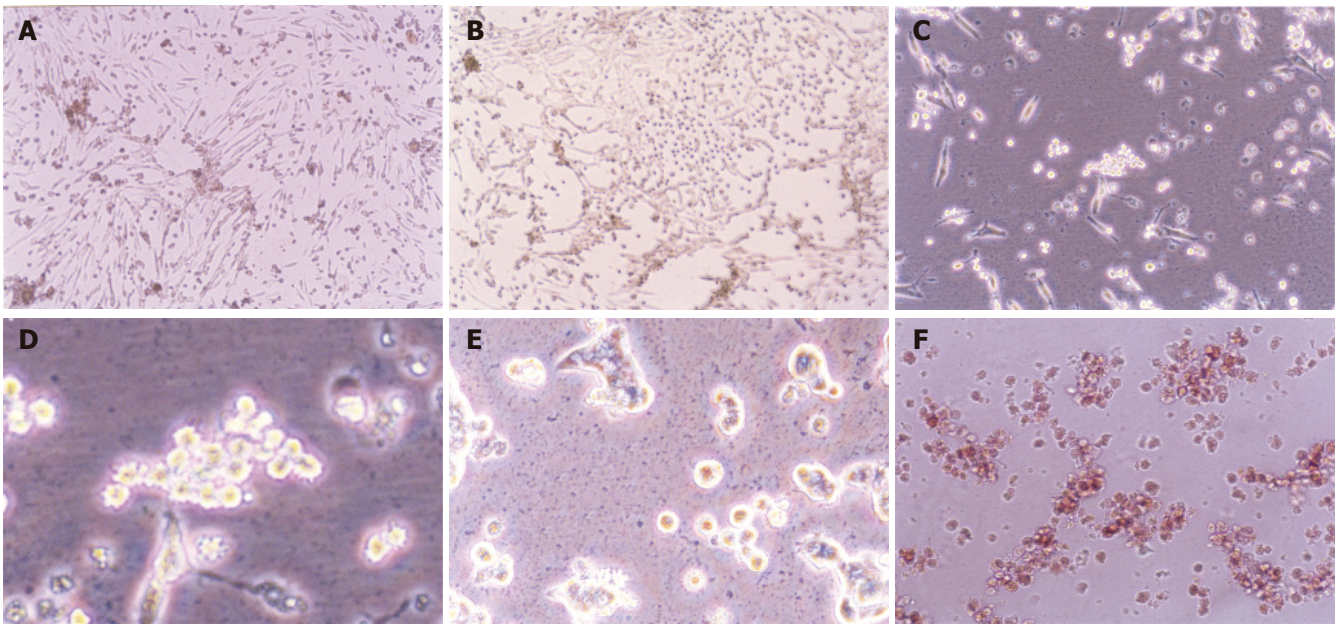

Figure 1 Morphological change of neonatal pancreatic duct cells cultured for 3-4 d (**A**), 5-7 d (**B**), 8-10 d (**C** and **D**) and more than 10 d (**E**), as well as identification of pancreatic islet cells by dithizone (**F**).

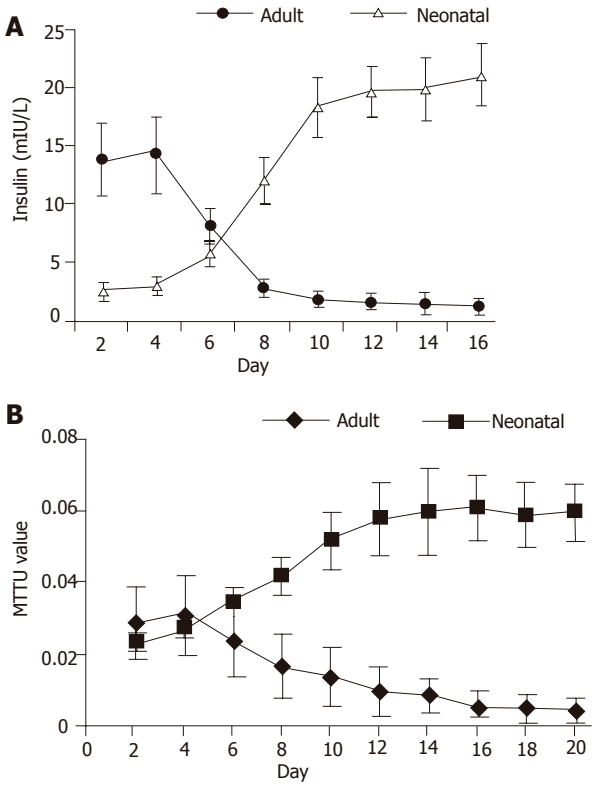

Figure 2 Insulin release curve (**A**) and MTT value curve (**B**) during the culture period of isolated adult islet cells and neonatal endocrine cells.

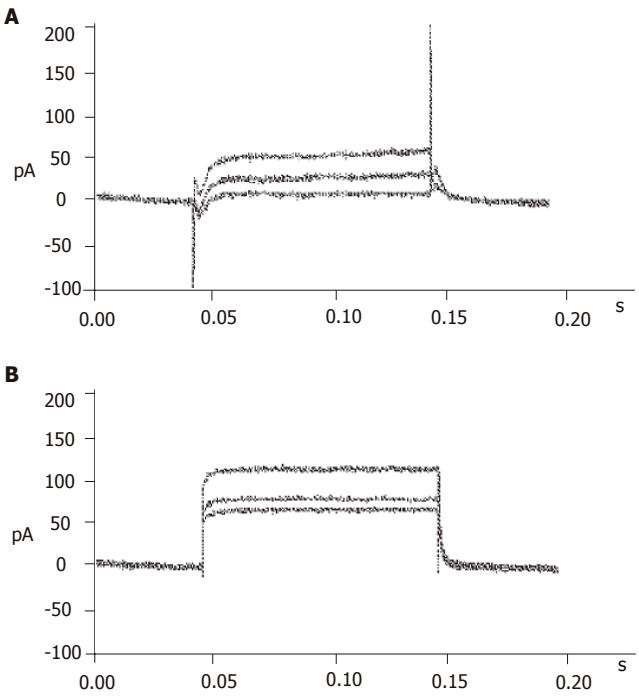

Figure 3 Identification of pancreatic β cells. **A:** Currents recorded from α or δ cells; **B:** currents recorded from β cells.

the cell culture medium was low (from 2.6±0.6 to 3.1±0.8 mIU/L) in the first 4 d, then quickly increased (from 3.1±0.8 to 12.1±2.1 mIU/L) from d 5 to d 10. Thereafter, the insulin release reached its high plateau (>18.3±2.6 mIU/L). For isolated pancreatic islet cells from adult rats, the insulin concentration was high (from 13.9±3.1 to 14.3±3.3 mIU/L) in the first 4 d, and gradually reduced (from 8.2±1.5 to 2.9 ±0.7 mIU/L) from d 5 to d 10. Then the insulin release was very low (<2.9±0.7 mIU/L) (Figure 2A).

MTT value

For neonatal pancreatic islet cells, the MTT value was low (0.024±0.003 to 0.028±0.003) in the first 4 d and gradually increased (0.028±0.003 to 0.052±0.008) from d 5 to d 10. Thereafter, the MTT value reached its high plateau (>0.052 ±0.008). For isolated pancreatic islet cells from adult rats, the MTT value was stable (from 0.029±0.01 to 0.031± 0.011) in the first 4 d and gradually reduced (0.031±0.01 to 0.014±0.008) from d 5 to d 10. Then the MTT value was very low (<0.014±0.008) (Figure 2B).

Identification of pancreatic islet cells and β cells

The big round cells (with a diameter >10 μm) were selected and their capacitance was determined (>5 pF). Then a depolarizing protocol was used to identify the properties of voltage-dependent Na^+ currents. The results showed that voltage-dependent Na^+ currents of selected cells could not be recorded at a holding potential of -70 mV (Figure 3B). On the contrary, the voltage-dependent Na^+ currents of small round cells (capacitance <5 pF) could be detected at a holding potential of -70 mV (Figure 3A). It was demonstrated that the big round cells were pancreatic β cells, while small round cells were not.

K_{ATP} current recording

With certain internal and external solutions and protocol, the currents recorded in pancreatic β cells were almost entirely K_{ATP} currents[19]. To verify this, 100 μmol/L diazoxide, a special opener of K_{ATP} channels, and 100 μmol/L repaglinide, a special antagonist of K_{ATP} channels, were added correspondingly. The results showed that diazoxide enhanced, while repaglinide reduced the currents greatly (Figure 4), suggesting that the detected currents were from K_{ATP} channels.

K_V current recording

Repaglinide was used in the external solution to block K_{ATP} currents. Then the currents recorded should be almost entirely K_V currents with the internal and external solutions and protocol. The recorded outward currents showed that the channels were inactive from -120 to -55 mV and active from -55 to 0 mV and the currents increased in proportion to voltage. When added with 100 μmol/L TEA, the currents could not be recorded, suggesting that the detected currents were from K_V channels (Figure 5).

K_{CA} current recording

To efficiently record K_{CA} currents, Cs^+ was added in the internal solution, while TEA and Ba^+ were added in the external solution to block voltage-dependent outward potassium currents. Meanwhile, Ba^+ enhanced

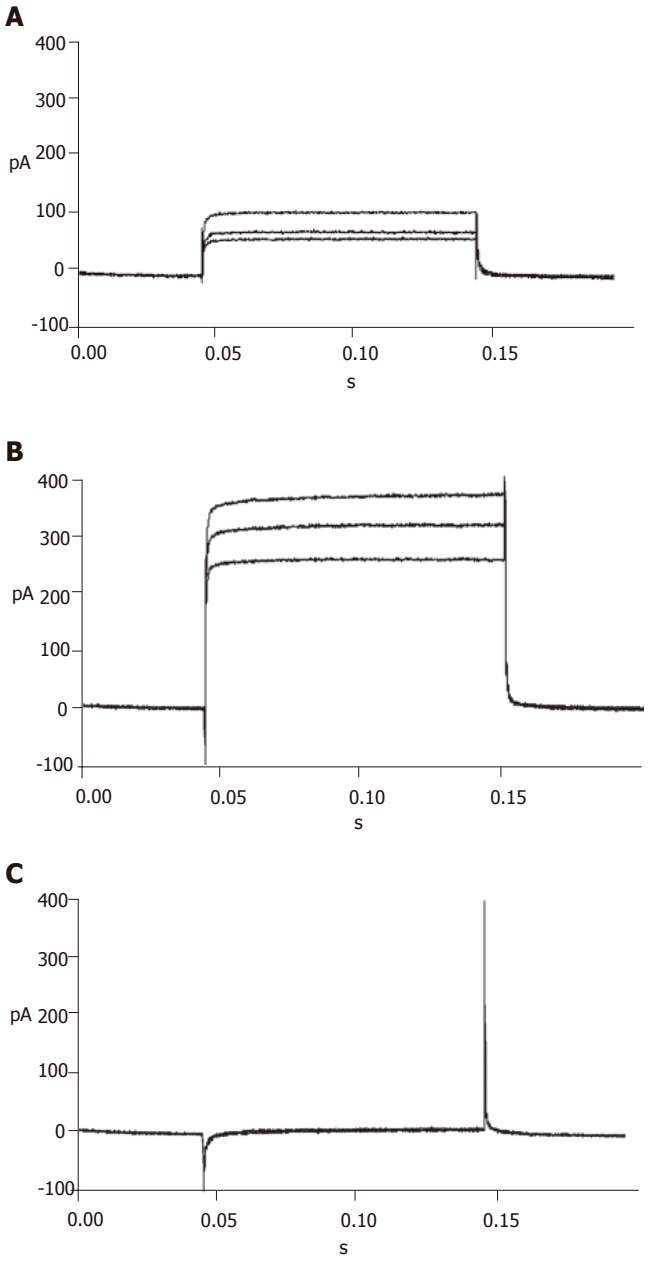

Figure 4 ATP sensitive potassium currents recorded in the absence (**A**), presence of diazoxide (**B**) and repaglinide (**C**).

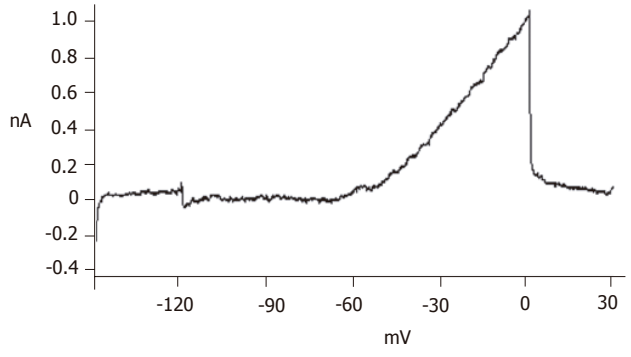

Figure 5 Voltage-dependent potassium currents recorded on neonatal pancreatic β cells.

K_{CA} currents. Inward currents were recorded at -40 mV and reached their peak at 0-10 mV, and then turned over at 50-60 mV. These dynamic electric patterns were characteristic of K_{CA} currents[20,21]. Furthermore, special opener and antagonist of K_{CA} channels were introduced to verify their existence. When added with 100 μmol/L Bay K8644, the currents enhanced greatly; while 100 μmol/L nifedipine was added, the currents reduced strikingly (Figure 6). These facts suggest that the detected currents were K_{CA} currents (mainly of L-type calcium currents).

DISCUSSION

It has been reported that pancreatic endocrine cells of neonatal rats can be used in long-term study of secretion and electrophysiology[22]. According to the experimental protocol, fibroblasts are cleared away by timerosal to enhance insulin release. However, the enhancing effect of

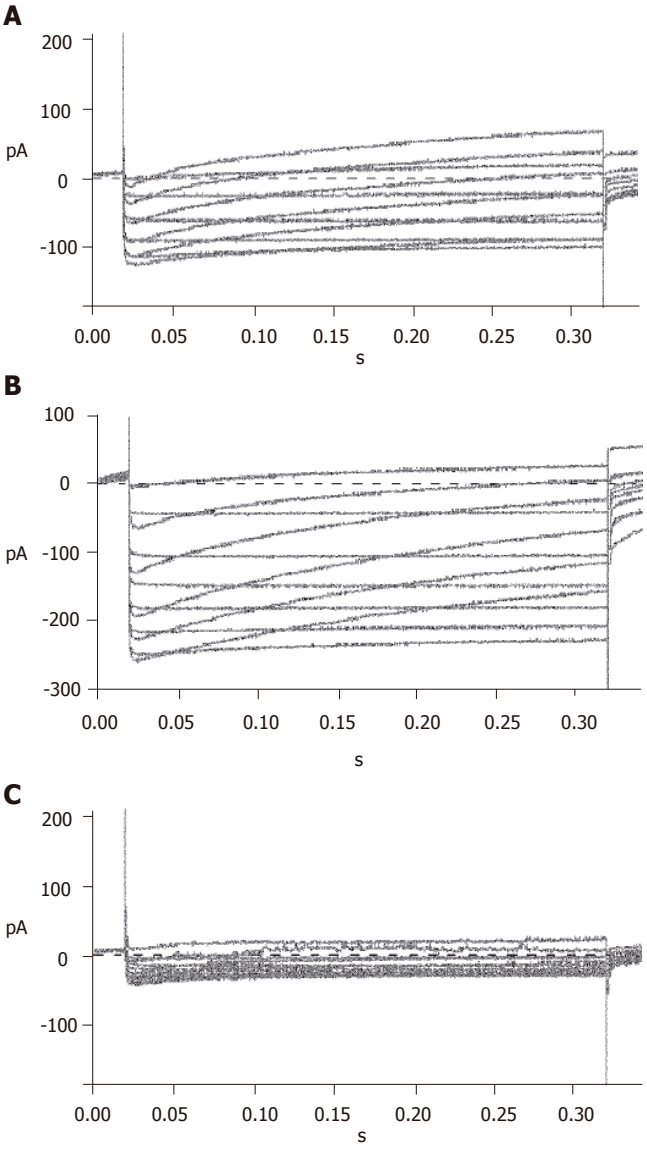

Figure 6 Voltage-dependent calcium currents recorded in the absence (**A**), presence of Bay K8644 (**B**) and nifedipine (**C**).

timerosal cannot be interpreted by the clearing away of fibroblasts, but might be produced due to the modified effects of timerosal on sulfonylurea receptor which regulates insulin release, because timerosal can modify mitochondrial sulfonylurea receptor[23]. Fibroblasts are present as the mesenchyme of islet cells, which may provide fibroblast growth factors and matrix to help the differentiation and replication of endocrine cells[24,25]. Therefore, alterations were made to optimize the experimental protocol correspondingly. Firstly, the fibroblasts in the pancreatic islet cells for the normal differentiation and replication of endocrine cells were retained. Secondly, timerosal was not introduced in our protocol to exclude its insulin regulating effect. Instead, fetal bovine serum, a physiological nutrition that does not intervene the normal neogenesis process, was administered in the cell incubation. With this natural protocol, the neonatal duct cells were successfully induced into endocrine cells.

It was reported that neonatal duct cells are composed mainly of precursor cells[12,13]. Thus, the harvested endocrine cells from neonatal rats should be mostly differentiated from precursor cells that lie in the pancreas duct tree. The harvested endocrine cells from the neonatal rats auto-organized as islet clusters (Figure 1B). Our observations that the islet cells changed from duct-like into round shape and that the round cells then budded outward *in vitro* culture, were in conformity with the report by Gershengorn *et al*.[26].

Gigaseal, the key step in patch clamp experiments, is difficult to perform on isolated islet cells because the membrane is fragile and easily gets broken by the electrode. Even when gigaseal was completed, the currents recorded may be deformed or lower than normal because there are tiny gaps between cell membrane and the electrode, through which the currents might leak out. However, we found that it was easy to manipulate gigaseal on islet cells differentiated with this natural protocol. To explain this phenomenon, we compared the morphological and functional characteristics of neonatal and adult pancreatic islet cells in culture condition. For differentiated neonatal islet cells, insulin release was low during the early phase, but increased rapidly from d 5 to d 10, and then kept in high plateau (Figure 2). Correspondingly, the cell mass grew much bigger. As for isolated islet cells from adult rats, insulin release was high in the first 4 d, but then reduced quickly (Figure 2). Correspondingly, the islet cells became dispersed, broken or atrophied. For neonatal endocrine islet cells, the MTT value increased quickly from d 5 to d 10 and then kept in high plateau. For isolated islet cells from adult rats, the MTT value was stable in the first 4 d and then reduced quickly (Figure 3). The data are in conformity with the idea that isolated islet cells survive poorly in culture condition[3] and support that neonatal pancreatic islet cells are more preferable for long-term and stable culture, thus more suitable for patch clamp experiments.

It was reported that the differentiated neonatal pancreatic islet cells have evident glucose-induced insulin secretion property[7-10]. To understand its mechanism, we investigated the electric activities of K_{ATP}, K_V, and K_{CA}, regulators of glucose-induced insulin secretion process. The role of K_{ATP} channels of β cells in glucose-induced insulinotropic process has been well demonstrated[27]; the K_{CA} and K_V channels are also suggested to couple with glucose-dependent insulinotropic effects[28-32]. Thus, the properties of these channels in differentiated islet cells were studied. The fact that K_{ATP}, K_V, and K_{CA} channels in differentiated islet β cells are sensitive to corresponding antagonist and/or opener (Figures 4-6) indicates that the differentiated islet cells have evident glucose-induced insulin secretion properties.

In conclusion, the natural protocol illustrated in this paper enables the long-term incubation of stable endocrine islet cells, which will greatly optimize and facilitate the performance of patch clamp experiments and other single cell studies.

Abstract

AIM: To construct the recombinant *Lactococcus lactis* as oral delivery vaccination against malaria.

METHODS: The C-terminal 19-ku fragments of MSP1 (MSP-1$_{19}$) of *Plasmodium yoelii* 265-BY was expressed in *L. lactis* and the recombinant *L. lactis* was administered orally to BALB/c and C57BL/6 mice. After seven interval vaccinations within 4 wk, the mice were challenged with *P. yoelii* 265-BY parasites of erythrocytic stage. The protective efficacy of recombinant *L. lactis* was evaluated.

RESULTS: The peak parasitemias in average for the experiment groups of BALB/c and C57BL/6 mice were 0.8±0.4% and 20.8±26.5%, respectively, and those of their control groups were 12.0±0.8% and 60.8±9.6%, respectively. None of the BALB/c mice in both experimental group and control group died during the experiment. However, all the C57BL/6 mice in the control group died within 23 d and all the vaccinated mice survived well.

CONCLUSION: The results imply the potential of recombinant *L. lactis* as oral delivery vaccination against malaria.

INTRODUCTION

The development of efficacious vaccines against malaria is one of the greatest challenges for the application of current life sciences in infectious diseases. The easiness of administration of a vaccine provides an attractive alternative to continue drug treatments in a population exceeding hundreds of millions of people with limited health care resources. Merozoite surface protein 1 (MSP1) is present in all species of *Plasmodium*[1,2], and has been widely studied as the major candidate for vaccine against malaria[3-5]. The high level expression of MSP1 by *Plasmodium* in the asexual stage is closely related to its invasion into erythrocytes. MSP1 can be proteolytically cleaved into five fragments by two processing steps after the maturation of merozoite, with the carboxyl-terminal 19-ku fragment (MSP-1$_{19}$) remaining on the merozoite surface[6-8]. The MSP-1$_{19}$ comprises two epidermal growth factor (EGF)-like modules. Antibodies directed to this fragment have been shown to inhibit the invasion of *Plasmodium falciparum* into erythrocyte *in vitro*[9,10] and intranasal or subcutaneous immunization may protect mice against the challenge of *Plasmodium yoelii* asexual blood-stage parasite[11]. The recombinant MSP-1$_{19}$ has been expressed in several host organisms, such as *Escherichia coli*[12], *Saccharomyces cerivisae*[11], *Bacillus Calmette-Guerin* (BCG)[13], and Baculovirus[14]. It has also been proven to be immuno-effective against the challenge of parasite. In vaccination experiments with recombinant MPS-1$_{19}$ from *P. yoelii*, immunized mice were protected against challenge with blood-stage parasites, and the protection was confirmed to be largely mediated by antibodies[15-17].

The development of efficient mucosal vaccines is one of the hotspots in modern vaccinology. One approach to deliver the protective antigens to the mucosal surfaces is to use live bacteria carrying plasmids responsible for the expression of specific antigen. Until recently most of these are derived from attenuated pathogenic microorganisms, such as *Salmonella typhi*[18] and *chlorella*[19]. As an alternative to this strategy, non-pathogenic food grade bacteria such as lactic acid bacteria are being focused for their efficacy as live antigen carriers[20]. *Lactococcus lactis* has a long history of being used in food fermentations and has been, therefore, generally regarded as a safe (GRAS) status[21]. This food-grade lactic acid bacterium is able to survive through the gastrointestinal tract of human beings and other animals, with a retention time of 2-3 d, but it does not invade or colonize the mucous and does not evoke strong host im-

mune responses[21]. The availability of various food-grade genetic engineering systems for *L. lactis*[22] makes the bacteria a potentially functional food or medicines by expressing heterogeneous peptides. Recent report using *L. lactis* preloaded with a bacterial antigen, tetanus toxin fragment C of *Clostridium tetanus*, demonstrated the feasibility of this approach: a protective systemic antibody response was elicited after nasal or oral immunization of mice[21]. Similar study was carried out by Lee *et al*.[23], in which urease subunit B (UreB) gene of *Helicobacter pylori* was expressed in *L. lactis* MG1363 and the recombinant bacterium was used as an oral vaccine against *H pylori* infection in mice. However, in this case no protective effect was observed, which implied that the adjuvant effects of *L. lactis* are likely to be insufficient to produce an effective immune response to protect against *H pylori* challenge, when used to deliver a weak immunogen like UreB.

Since the use of oral (or other mucosal) routes for immunization against malaria is also desirable due to the easiness of administration, we attempted *L. lactis* as the live vehicle for vaccine development against malaria. In this work, we showed that the oral immunization, with recombinant *L. lactis* constitutively expressing MSP-1$_{19}$ antigen, could protect BALB/c and C57BL/6 mice against malaria parasites challenge.

MATERIALS AND METHODS

Genes, plasmids, bacteria, and malarial parasites

The DNA fragment encoding for MSP-1$_{19}$ domain was amplified from the genomic DNA of *P. yoelii*. Plasmid pTRKL2 was from Prof. Todd R. Klaenhammer at Food Science Center, North California University, USA[24]. Cloning vector pBluescriptSKII(+) was from Strategene (La Jolla, CA, USA), and fusion-protein expression vector pGEX-5X-3 was from Amersham Pharmacia. *L. lactis* LM2345 was from Prof. Keith Thompson at Agriculture and Food Science Center, Newforge Lane, Northern Ireland. *Lactobacillus brevis* (ATCC8287) and *Bacillus subtilis* BR151 (ATCC33677) were purchased from the American Type Culture Collection. *P. yoelii* 265-BY was by Professor Weibin Guan at Second Military Medical University, Shanghai, China.

Construction of expression vector

The plasmid for the expression of MSP-1$_{19}$ fragment was constructed by conventional DNA recombination manipulation. The promoter region and the first five amino acids of the signal peptide-coding region of S-layer protein A (*SlpA)* gene (nucleotides 1-282, GenBank Z14250) was amplified by polymerase chain reaction (PCR) from genomic DNA of *L. brevis* with forward primer GCTGAGCTCGATTACAAAGGCTTTAAGCAGGTTAGTGAC (with *Sac*I site) and reverse primer GTCGGATCCTAAACTTGATTGCATAATCTTTCTTCCTCC (with *Bam*HI site). The DNA fragment encoding MSP-1$_{19}$ (nucleotides 5 040-5 451, GenBank AF165928) was amplified from the genomic DNA of *P. yoelii* 265BY, with forward primer ACGGGATCCAA CACATAGCCTCAATAGCT (with *Bam*HI site) and reverse primer ACGGAATTCTAGCTGG AAGAACTACAGAA (with *Eco*RI site). The terminator of *N*-acetylmuramoyl-L-alanine amidase (*cwl*B) (nucleotides 2 187-2 471, GenBank M81324) was amplified from *Bacillus subtilis* BR151 by PCR with forward primer CTCGAGCTCCACAAGCTATTCATGAC (with *Xho*I site) and reverse primer GGTACCTCTCT GCACTCACTG ACACA (with *Kpn*I site). The PCR products were cloned on T-vector (Promega, USA) first, and then joined together in a tandem way on pBluescriptSKII(+) with restriction enzyme pairs of *Sac*I/BamHI, *Bam*HI/*Eco*RI, and *Xho*I/*Kpn*I respectively to obtain plasmid pSK-PSGT. For expression of MSP-1$_{19}$ in *L. lactis*, pSK-PSGT was then digested with *Pvu*II to release the 1.6-kb blunt-end fragment, which was then inserted into the *Eco*RV site of shuttle vector pTRKL2[24]. The final construct was referred as pL2-PSGT. For expression of fusion protein GST-MSP-1$_{19}$ in *E. coli*, the DNA fragment encoding MSP-1$_{19}$ was derived by PCR and joined to fusion protein expression vector pGEX-5X-3 with *Bam*HI and *Eco*RI sites. The derived plasmid was noted as pGEX-MSP-1$_{19}$.

Transformation

Electroporation[25] was used to transform *L. lactis* LM2345 with pL2-PSGT. $CaCl_2$ method was used to transform *E. coli* BL21 with plasmid pGEX-5X-3.

Preparation of antiserum against P. yoelii 265-BY

The antiserum against *P. yoelii* 265-BY was prepared from BALB/c mice infected with 10^4 asexual blood stage parasites. The serum was collected from the eye veins 4 d after burst with 10^4 parasites one month after infection, and stored at 4 ℃.

Expression and analysis of MSP-1$_{19}$ in E. coli and L. lactis

The BL21 transformant harboring plasmid pGEX-MSP-1$_{19}$ was cultured in L-broth to A_{600} around 1.0, and was treated with supplement containing 1.0 mmol/L of isopropylthio-β-galactoside (IPTG) for 3 h. The fusion protein GST-MSP-1$_{19}$ was purified from cell lysate by affinity chromatography of Glutathione Sepharose-4B according to manual instruction provided by the manufacturer. The purified fusion protein was used as positive control of immunoblotting. To express MSP-1$_{19}$ in *L. lactis*, the transformant harboring plasmid pL2-PSGT was cultured overnight in MRS medium[26] supplemented with 10 mg/L erythromycin. The cells were collected by centrifuge, and the lysates were analyzed by using SDS-polyacrylamide gel electrophoresis analysis followed with immunoblotting by using antiserum against *P. yoelii* 265-BY (1:500 dilution). All other operations were performed following standard protocols[27].

Oral immunization of BALB/c and C57BL/6 mice with recombinant L. lactis

Oral immunization experiments were performed according

to the protocol described by Robinson *et al*.[21]. The BALB/c and C57BL/6 mice were divided into groups of 10 mice and fed for 6-8 wk. The test group was administered with recombinant *L. lactis* constitutively expressing MSP-1$_{19}$, and the control groups were administered with free *L. lactis* bacteria or phosphate-buffered saline (PBS). For BALB/c mice, every dose containing 5×10^9 bacterial cells in the suspension buffer (0.2 mol/L sodium bicarbonate, 5% Casino acids, and 0.5% glucose); and for C57BL/6 mice (two dosage groups), every dose containing 5×10^9 or 1×10^8 cells were administered. All the groups were administered with recombinant *L. lactis* on d 1, 2, 3, 29, 30, 31, and 36, respectively.

Challenge infections and evaluation of protective efficacy

Mice in each group were challenged on d 49 with 1×10^5 asexual blood stage *P. yoelii* parasites obtained from a donor mouse. Parasitemia was monitored every two days after challenge using microscopic examination of blood film with Giemsa staining.

RESULTS

Expression of fusion protein GST-MSP-1$_{19}$ in E. coli

The fusion protein GST-MSP-1$_{19}$ was expressed in *E. coli* BL21 transformed with plasmid pGEX-MSP-1$_{19}$. The transformed BL21 cells were cultured in L-broth until the A_{600} reached 1.0, and then induced with 1.0 mmol/L IPTG for 3 h. Total proteins of BL 21 *E. coli* cells were analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). As shown in lane 4 of Figure 1, the thick band of the expressed protein showed a molecular weight of 45 ku, matching well with the theoretical value of fusion protein GST-MSP-1$_{19}$. The expressed fusion protein was about 40% of the total protein of *E. coli* cells. Most of the fusion protein was found in inclusion body, but a small fraction was soluble. Glutathione Sepharose-4B affinity chromatography was carried out with the soluble fraction of *E. coli* cell lysate, and the derived fusion protein was used as the positive control of immunoblotting.

Expression of MSP-1$_{19}$ in L. lactis

For the expression of MSP-1$_{19}$ in *L. lactis*, the transformant harboring plasmid pL2-PSGT was cultured overnight at 30 ℃ in MRS medium[26] supplemented with 10 mg/L erythromycin. The cells were collected by centrifuge, and the lysates were analyzed with SDS-PAGE. However, no obvious protein bands around 19 ku were detected. Immunoblotting with antiserum against *P. yoelii* 265-BY was applied to check if there was low-level expression of MSP-1$_{19}$. As a result, the presence of MSP-1$_{19}$ was confirmed by immunoblotting as shown in lane 3 of Figure 2. The stained protein band at 19 ku was a little bit broad. This might be the result of partial degradation of MSP-1$_{19}$ in *E coli* cells. At least part of the expressed MSP-1$_{19}$ was in its native structure, since the antiserum prepared by *P. yoelii* parasites infection is considered to preferentially recognize the MSP-1$_{19}$ fragment located on erythrocyte membrane with the native conformation.

In lane 2 of the positive control, two protein bands were stained: one was at 45 ku, and the other was slightly below 45 ku, but not detectable on SDS-PAGE with Coomassie brilliant blue staining. When fusion protein is isolated from inclusion body of corresponding *E. coli* and refolded by rapid dilution method, only one protein band could be stained (data not shown). Therefore, we concluded that the low molecular weight protein was the degraded fusion protein present in the soluble fraction of *E. coli*.

Evaluation of protective immunity induced by recombinant L. lactis

Previous work of Tian *et al*.[28] indicated that mice with different genetic backgrounds may have quite different responses to *P. yoelii* infection. C57BL/6 mice showed the highest level against challenge with infected erythrocytes after immunization with recombinant proteins consisting of the PyMSP-1 C terminus in adjuvants. In this work, two strains of mice, BALB/c and C57BL/6, were used for oral

Coomassie brilliant blue-stained 12% SDS-polyacrylamide gel. lane 1, protein markers; lane 2, total protein of BL21 cells; lane 3, total protein of *E. coli* BL21 transformed with plasmid pGEX-5X-3 with IPTG induction; lane 4, total protein of *E. coli* BL21 cells harboring plasmid pGEX-MSP-1$_{19}$ after with IPTG induction. The arrows indicate the positions of GST and fusion protein GST-MSP-1$_{19}$.

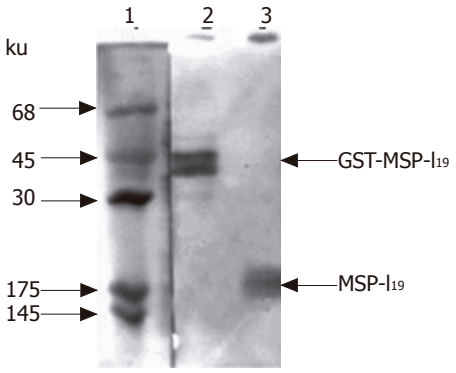

Figure 2 Immunoblotting analysis of MSP-1$_{19}$ expressed in *L. lactis*. Protein samples were first analyzed on 12% SDS-polyacrylamide gel and then transferred on nitrocellulose membrane followed by immunostaining with antiserum prepared by infecting mouse with *P. yoelii* parasites. lane 1, protein markers stained by amido black; lane 2, positive control of fusion protein GST-MSP-1$_{19}$ purified from *E. coli* cell lysate expressing the fusion protein by pGEX-MSP-1$_{19}$; lane 3, total protein of *L. lactis* cells harboring plasmid pL2-PSGT. The arrows indicate the position of fusion protein GST-MSP-1$_{19}$ and MSP-1$_{19}$.

immunization for comparison.

For BALB/c mice, two control groups were designed. Mice were administered with phosphate-buffered saline in control group 1, with 5×10^9 per dose of original *L. lactis* cells in control group 2, and with 5×10^9 per dose of *L. lactis* cells carrying pL2-PSGT construct in the test group, respectively. After seven doses of vaccination, each mouse was challenged with 1×10^5 asexual blood stage parasites. The parasitemias were measured from the next day of parasite challenging. The average and standard deviation of each group are shown in Figure 3. The peak p-arasitemias were 0.8±0.4% at d 4 for test group, 16.0±1.2% at d 8 for control group 1, and 12.0±0.8% at d 8 for control group 2, respectively. There was little difference between the peak parasitemias of the two control groups. Therefore, the non-specific immunity caused by the adjuvanticity of *L. lactis* was little. It should be noted that the appearance of parasitemia in the test group was one-day delayed compared with the control groups. None of the mice in any of the three groups died during the experiment. Overall, the BALB/c mice in all the three groups had the ability to scavenge *P. yoelii* parasites from their bodies by themselves.

For C57BL/6 mice, one control group and two test groups were designed. Mice were administered with 5×10^9 plasmid-harbored *L. lactis* cells per dose in test group 1, and 1×10^8 cells per dose in test group 2. Vaccination was performed by the same protocol for BALB/c mice, and the parasitemias were measured from the next day of parasite challenging. As shown in Figure 4A, the average peak parasitemias for the three groups were 60.8±9.6% for the control group, 41.6±8.8% for test group 1, and 20.8±26.5% for test group 2, respectively. Surprisingly, test group 2 administered with 1×10^8 bacterial cells per dose gained significantly stronger immune protection than test group 1, which was administered with 15 times more bacterial cells per dose. However, the standard deviation of test group 2 was remarkably bigger than the other two groups. This was largely due to the difference between individuals. Another important fact that should be noted was that all the mice in the control group died within 23 d after parasite infection, whereas all the vaccinated mice survived despite the high parasitemias (Figure 4B). After 30 d counting from the day of parasite challenging, malarial parasites were no more detectable in both of the two test groups (data not shown), implicating the complete elimination of the *P. yoelii* parasites.

We also checked the duration of recombinant bacteria in mice gut by investigation of the titers of recombinant bacterial cells in mice feces. After feeding of a single dose of 5×10^9 recombinant cells, the recombinant *L. lactis* reached a peak at 6 h with a density of 1×10^7 cells/g of feces, and then gradually decreased with time. The density of recombinant cells decreased to 1×10^4/g at 48 h, and 1×10^3/g at 72 h. Therefore, the interaction between the host and recombinant bacterial cell could be as long as 3 d per dose.

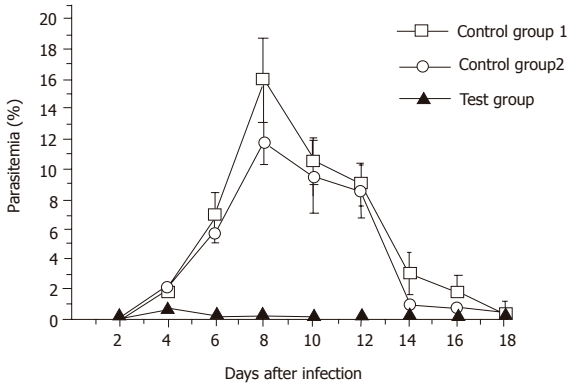

Figure 3 Blood-stage parasitemia of immunized BALB/c mice challenged with *P. yoelii* 265BY parasites. Mice were orally administered with PBS in the control group 1 (-□-), with 5×10^9 per dose of free *L. lactis* cells in the control group 2 (-○-), and with 5×10^9 per dose of *L. lactis* cells carrying pL2-PSGT construct in the test group (-▲-), respectively. Immunization procedure is described in Materials and Methods, and each mouse was challenged with 1×10^5 asexual blood-stage *P. yoelii* parasites.

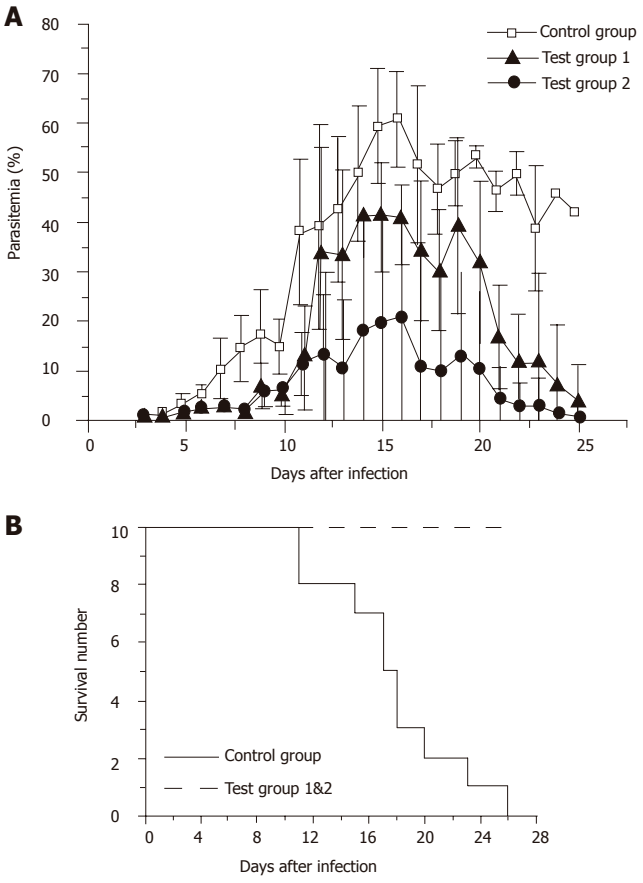

Figure 4 (**A**) Blood-stage parasitemia of immunized C57BL/6 mice challenged with *P. yoelii* 265BY parasites. Mice were orally administered with 5×10^9 per dose of free *L. lactis* cells in the control group (-□-), with 5×10^9 pL2-PSGT plasmid-harbored *L. lactis* cells per dose in the test group 1 (-▲-), and with 1×10^8 cells per dose of pL2-PSGT plasmid-harbored *L. lactis* cells in the test group 2 (-●-). Immunization procedure is described in Materials and Methods, and each mouse was challenged with 1×10^5 asexual blood-stage *P. yoelii* parasites. (**B**) Time course of survivals of the mice in the three groups is indicated in A.

DISCUSSION

It is known that the immunogenicity of soluble protein is low when administered orally but when expressed by genetically engineered bacteria and can be considerably enhanced. To achieve this goal, promoters that can drive the expression of a gene constitutively are essential. S-layer protein is a protein that forms regular crystalline arrays on prokaryotic cell surface. The *slp*A promoter can express the β-lactamase constitutively at a high level in *L. lactis*[27]. However, it failed to express MSP-1$_{19}$ with high efficiency in this study. The expression of MSP-1$_{19}$ in *L. lactis* could be detected only by immunoblotting; therefore, it was estimated at the level of several nanograms per 10^7 bacterial cells.

Unexpectedly, the low-level expression of MSP-1$_{19}$ in *L. lactis* was still able to elicit strong protection against *P. yoelii* infection on both BALB/c and C57BL/6 mice by oral administration. Although BALB/c mice seemed to be able to scavenge the malarial parasites by themselves, the parasitemia was reduced more than 10-folds (less than 1%) in the test group compared with the control groups. In the case of C57BL/6 strain, all the members in the control group died within 26 d after the infection, whereas all the members in the two test groups survived, and the parasites disappeared from both groups one month after the parasite challenging.

The different immune responses of the two C57BL/6 test groups also support the point of view that the expression level of MSP-1$_{19}$ is not critical for the elicitation of immune response, i.e., the group administered with a low dose of the recombinant bacterium gained stronger protection than the group administered with a high dose. The reason for the difference between the two groups is not clear at present; however, this might be partially due to immune tolerance caused by overdose. In the study by Robinson *et al*.[21], expression of tetanus toxin fragment C of *C. tetanus* in the intracellular accumulation of *L. lactis* was up to 3% of soluble cellular protein, and 5×10^9 cells were orally administered per dose to gain complete protection of mice from tetanus. Therefore, the optimal dose and the time schedule for oral administration should be carefully determined for each antigen.

It is striking to find the difference in immune response between the two strains of mice, BACL/c and C57BL/6. Our results partially support the report by Tian *et al*.[28] that C57BL/6 mice are most sensitive to *P. yoelii* infection. In most cases, BALB/c and C3H/He mice are used for protection test of a vaccine. Our results suggest that at least for protection experiments, C57BL/6 mice are better to be used in parallel.

In vaccination experiments with recombinant MPS-1$_{19}$ of *P. yoelii*, the protection effect has been found to be mediated by humoral immune response[15-17]. Robinson *et al*.[21] also reported high titers of IgG against tetanus toxin. We also tried immunoblotting and ELISA test with sera from the survivals of C57BL/6 mice in the test groups (data not shown). Nearly all the mice generated IgG against MSP-1$_{19}$, and there were no significant differences between the two test groups at the titers of IgG. In general, the titers were between 5×10^2 and 3×10^3, lower than the titers reported by Robinson *et al*. On the other hand, Lee *et al*.[23] measured the antigen-specific IgG titers in monkeys immunized with recombinant *L. lactis* bacterium expressing *H pylori UreB* gene, and titers as high as 1×10^5 were detected. However, despite the presence of high-titer antigen-specific IgG, all monkeys were infected after *H pylori* challenge, and there were no differences in the density of colonization. Taking our results obtained from low-dose test group of C57BL/6, we suggest that high-titer antigen-specific IgG should not be considered as the major indicator of the protective immune response. The role of cell-mediated immunity played in live bacteria vaccine should be focused.

Abstract

AIM: To detect the effect of acid fibroblast growth factor (aFGF) on P53 and P21WAF-1 expression in rat intestine after ischemia-reperfusion (I-R) injury in order to explore the protective mechanisms of aFGF.

METHODS: Male rats were randomly divided into four groups, namely intestinal ischemia-reperfusion group (R), aFGF treatment group (A), intestinal ischemia group (I), and sham-operated control group (C). In group I, the animals were killed after 45 min of superior mesenteric artery (SMA) occlusion. In groups R and A, the rats sustained for 45 min of SMA occlusion and were treated with normal saline (0.15 mL) and aFGF (20 μg/kg, 0.15 mL), then sustained at various times for up to 48 h after reperfusion. In group C, SMA was separated, but without occlusion. Apoptosis in intestinal villi was determined with terminal deoxynucleotidyl transferase-mediated dUTP-biotin nick-end labeling technique (TUNEL). Intestinal tissue samples were taken not only for RT-PCR to detect P53 and P21WAF-1 gene expression, but also for immunohistochemical analysis to detect P53 and P21WAF-1 protein expression and distribution.

RESULTS: In histopathological study, ameliorated intestinal structures were observed at 2, 6, and 12 h after reperfusion in A group compared to R group. The apoptotic rates were (41.17±3.49)%, (42.83±5.23)%, and (53.33±6.92)% at 2, 6, and 12 h after reperfusion, respectively in A group, which were apparently lower than those in R group at their matched time points (50.67±6.95)%, (54.17±7.86)%, and (64.33±6.47)%, respectively, (P<0.05)). The protein contents of P53 and P21WAF-1 were both significantly decreased in A group compared to R group (P<0.05) at 2-12 h after reperfusion, while the mRNA levels of P53 and P21WAF-1 in A group were obviously lower than those in R group at 6-12 h after reperfusion (P<0.05).

CONCLUSION: P53 and P21WAF-1 protein accumulations are associated with intestinal barrier injury induced by I-R insult, while intravenous aFGF can alleviate apoptosis of rat intestinal cells by inhibiting P53 and P21WAF-1 protein expression.

Key words: Acid fibroblast growth factor; Ischemia; Reperfusion; P53 gene; P21WAF-1 gene

INTRODUCTION

Intestinal ischemia-reperfusion (I-R) injury is characterized histologically by inflammation, villus abscission, and mucosal epithelial cell apoptosis[1]. Agents can modulate or prevent apoptosis after I-R[2-6]. Though the mechanisms of action are diverse, all these agents ultimately show their potent antiapoptotic properties that account, at least in part, for their protective effects. Accumulation of P53 protein, which is well known as a tumor suppressor gene product, plays a central role as the initiator of the intrinsic apoptotic cascade triggered by a wide variety of insults[7-10]. In addition, a role of P53 in regulating the extrinsic receptor-mediated apoptotic pathway has also been reported[11]. P21WAF-1, which is a downstream mediator of P53 function, plays a key role in determining the ultimate sensitivity of cells to myriad stimuli and insults that induce apoptosis[12-14]. Thus, P53 and P21WAF-1 are poised as the ideal candidates for mediating apoptosis after I-R, a setting

where many insults coexist.

Acid fibroblast growth factor (aFGF) is a mitogen *in vitro* for most of the ectoderm- and mesoderm-derived cell lines. In addition, this factor shows a wide range of endocrine-like activities[15,16]. As a multiple function growth factor, aFGF is involved in embryo development and tissue repair[17,18]. Previous studies have shown that intravenous administration of exogenous aFGF could improve the physiological functions of intestine after I-R injury[19,20]. Since the mechanism by which aFGF inhibits apoptosis is unknown, we investigated the effects of aFGF on gene expression and protein contents of P53 and P21WAF-1 underlying the protective mechanisms of aFGF against intestinal I-R injury.

MATERIALS AND METHODS

Animal model and experimental design

Healthy male Wistar rats weighing 220±20 g (Animal Centre, Academy of Military Medical Sciences, Beijing) were used in this study. Animals were housed in wire-bottomed cages placed in a room illuminated from 08:00 to 20:00 (12:12-h light-dark cycle) and maintained at 21±1 ℃. Rats were allowed free access to water and food. The animals were anesthetized with 3% sodium pentobarbital (40 mg/kg) and underwent laparotomy. The superior mesenteric artery (SMA) was identified and freed by blunt dissection. A micro-bulldog clamp was placed at the root of SMA to cause complete cessation of blood flow for 45 min, and thereafter the clamp was loosened to form reperfusion injury. The animals were randomly divided into four groups, namely intestinal ischemia-reperfusion group (R), intestinal ischemia group (I), reconstructive aFGF treatment group (A) and sham-operated control group (C). In group I, the animals were killed after 45 min of SMA occlusion. In groups R and A, the rats sustained for 45 min of SMA occlusion and were treated with 0.15 mL normal saline and 0.15 mL saline plus aFGF (20 μg/kg) injected from tail vein, then sustained for 15, 30 min, 1, 2, 6, 12, 24, and 48 h of reperfusion respectively. In C group, SMA was separated, but without occlusion, and samples were taken after exposure of SMA for 45 min. In groups R and A, rats were killed at different time points after reperfusion, and intestinal tissue biopsies were taken. Six specimens of the intestine were obtained at each time point from six rats. When any rat died during the study, additional rats were used until six specimens could be obtained from six rats at each time point. A small part of the intestine specimen was fixed with 10% neutral buffered formalin for immunohistochemical detections of intestinal epithelial apoptosis, and protein expression of P53 and P21WAF-1. The remaining tissue samples were placed in liquid nitrogen for RT-PCR to detect P53 and P21WAF-1 gene expression.

Histopathological study

Formalin-fixed, paraffin-embedded intestinal samples were cut into 5-μm-thick sections, deparaffinized in xylene, rehydrated in graded ethanol, and then stained with hematoxylin-eosin (HE) for histological observation under light microscope.

In situ detection of cell death

The apoptotic cells in intestinal tissues were detected by the terminal deoxynucleotidyl transferase (TdT)-mediated dUTP-biotin nick-end labeling (TUNEL) method. Specimens were dewaxed and immersed in phosphate-buffered saline containing 0.3% hydrogen peroxide for 10 min and then incubated with 20 μg/mL proteinase K for 15 min. Seventy-five microliters of equilibration buffer was applied directly onto the specimens for 10 min, followed by 55 μL of TdT enzyme and incubation, which were then incubated at 37 ℃ for 1 h. The reaction was terminated by transferring the slides to prewarmed stop/wash buffer for 30 min at 37 ℃. The specimens were covered with a few drops of rabbit serum and incubated for 20 min and then covered with 55 μL of anti-digoxigenin peroxidase and incubated for 30 min. Specimens were then soaked in Tris buffer containing 0.02% diaminobenzidine and 0.02% hydrogen peroxide for 1 min to achieve color development. Finally, the specimens were counterstained by immersion in hematoxylin. The cells with clear nuclear labeling were defined as TUNEL-positive cells. The results of positive cells and their distribution were observed under 400× microscope. Sixty intestinal villi per time point were required for counting, and then the apoptotic ratios were calculated and analyzed.

Immunohistochemistry

Immunostaining for proteins of P53 and P21WAF-1 was performed in paraffin sections with a high-temperature antigen-unmasking method in citrate buffer and ABC peroxidase, using P21WAF-1 monoclonal mouse antibody (Santa Cruz Cor, sc-6246) and P53 polyclonal rabbit antibody (Santa Cruz Cor, sc-6243) against antigens (1:100 in PBS). Tissues were fixed overnight in 4% paraformaldehyde, dehydrated, and embedded in paraffin. Five-micrometer thick sections were deparaffinized and rehydrated using graded alcohol concentrations. Antigen retrieval was performed by incubation in 100 mmol/L sodium citrate, pH 6.0, at 90 ℃for 20 min. Then, sections were blocked with 5% normal swine serum in PBS for 30 min at 25 ℃, followed by incubation with primary antibodies at a concentration of 5 μg/mL overnight at 4 ℃. Control slides were incubated with PBS without primary antibodies. Tissue sections were then incubated for 60 min with biotinylated secondary antibody. After being washed in PBS, the sections were exposed to acidin-biotin complex for 60 min, reacted with 0.05% (wt/vol) DAB in 50 mmol/L Tris-HCl (pH 7.4) with 0.1% (vol/vol) hydrogen peroxide for 5 min and counterstained with hematoxylin. The results of positive staining cells and their distribution were observed under 400× microscope. Sixty intestinal villi per time point were required for counting, and then the ratio of positive cells was calculated and analyzed.

RNA extraction and RT-PCR analysis

Tissue total RNA was extracted using TRIzol reagent

(Gibco BRL, USA). RNA was serially diluted with water containing 1 unit RNase inhibitor per μL and 3 mmol/L dithiothreitol (DTT). One microliter RNA, 1 μL oligo (dT12-18), 1 μL avian myeloblastosis virus reverse transcriptase (AMV-RT), 2 μL 10 mmol/L deoxynucleoside triphosphate (dNTP), 2 μL 0.1 mol/L DTT, 4 μL 5× buffer, and sterilized distilled water up to a total volume of 20 μL were incubated at 37 ℃ for 60 min. Subsequently, 2 μL of each reaction product was amplified in 50 μL of a PCR mixture. Then 29 cycles were performed with a Perkin-Elmer Cetus/DNA thermal cycler (Takara Shuzo Co., Tokyo, Japan) at 94 ℃ for 1 min, at 50 ℃ for 1 min, at 72 ℃for 1 min, and then at 72 ℃ for 10 min at the end of the procedure. In this study, β-actin, which is ubiquitously expressed, was used as a positive control in a pilot study before formal experimentation, and PCR reaction for each primer set was repeated four times to verify the reproducibility of results. After PCR, 5-μL sample aliquots was electrophoresed on a 2% agarose gel for 30 min, stained with ethidium bromide and photographed. Densitometry was done with a Bechman densitometer. The level of gene transcription was expressed as the ratio of gray density of the gene to β-actin.

Statistical analysis

All values were expressed as mean±SD. The statistical significance was determined by one-way analysis of variance (ANOVA) followed by the Student's and Newman-Keuls multiple comparison tests. $P<0.05$ was considered statistically significant.

RESULTS

Histopathological findings

After the SMA was clamped near its origin from the aorta, the entire small intestine showed a dark purple, cyanotic color within 45 min. The histological evaluation revealed that damage to the small intestine in I group was small, with slightly edematous villus tips and intact crypts just after the ischemic period. Two hours after reperfusion, partial loss of the mucosa could be observed. During 6-12 h after reperfusion, the damage of intestinal epithelial cells, hemorrhage and apoptosis could be found accompanied with inflammatory cells infiltrated into the intestinal wall, and the crypt-villus structure was seriously spoiled. In the period of 24-48 h after reperfusion, the mucosal integrity was partially restored. Histological structure of the intestinal mucosa was markedly improved after administration of aFGF. The protective function of aFGF on intestinal mucosa was very effective 2-12 h after reperfusion. The structures of crypt and villus were both guarded, with less damage of intestinal mucosa in A group compared to R group.

Change of cellular apoptotic rates

To quantify the extent of apoptosis after ischemia and reperfusion, TUNEL reaction was performed in serial sections prepared from the middle quarter of the small intestine (jejunum). The time, when the animals were killed after a 45-min SMA occlusion followed by reperfusion, varied to further define the apoptotic response. Statistically significant increase in TUNEL-positive cells was not detectable until 1 h after reperfusion and reached its peak at 12 h. The cellular apoptotic rate in intestinal mucosa at 12 h after reperfusion was 3.3 times of that in C group. After reperfusion for 24 and 48 h, the mucosal apoptotic rates were restored to the level of C group. Administration of aFGF resulted in statistically significant decrease of the apoptotic rates compared to R group 2-12 h after reperfusion ($P<0.05$). No statistically significant decrease of apoptotic rates was observed at 24 and 48 h after reperfusion (Table 1).

Expression characteristics of P53 and P21WAF-1 proteins

Quantitative immunohistochemical results for P53 and P21WAF-1 proteins are summarized in Table 2. Protein expression levels of P53 were weaker in the sham-operated intestinal and ischemic tissues, and positive particles were mainly located in the epithelial cells of the upper part of villi. However, the positive cellular rates elevated with the increment of duration after reperfusion injury. In the period of 1-12 h after reperfusion, P53 protein was expressed at a dramatically higher level in comparison to C group ($P<0.05$) and the maximum level was 2.1-fold of C group at 6 h after reperfusion. The positive signals of P53 were mostly distributed in the nuclei and cytoplasm of epithelial cells of villi and crypts. At 24-48 h after reperfusion, the positive cellular rates were not substantially changed compared to C group. Treatment with aFGF could apparently inhibit the protein contents of P53 in intestinal mucosal epithelial cells 2-12 h after reperfusion in comparison to R group at different matched time points ($P<0.05$, Figures 1A-1C). The levels of P21WAF-1 protein were also significantly increased 2-12 h after reperfusion with a peak at 12 h after reperfusion (1.5-fold of C group, $P<0.05$). The positive particles of P21WAF-1 were mainly localized in the cytoplasm and nuclei of intestinal epithelial cells (Figures 1D-1F). By 24-48 h after I-R, the P21WAF-1 levels tended to normalize back to baseline of C group ($P>0.05$). Compared to the saline-treated group, the positive cellular rates of P21WAF-1 were significantly

lower 2 to 12 h after reperfusion in aFGF-treated group ($P<0.05$, Table 2).

Expression characteristics of P53 and P21WAF-1mRNA

We investigated the gene expression of P53 and P21WAF-1 in differentially treated intestinal villi through RT-PCR analysis (Table 3). The P53 gene amplification product was composed of 266 bp (Figures 2A-2C). Expression of this gene was remarkably and rapidly increased in intestinal mucosa after ischemia during the whole period of reperfusion. After aFGF administration, the mRNA level of P53 in villus cells was lower than that in normal saline-treated group. Especially at 30 min, 6 and 12 h after reperfusion, the discrepancy of P53 expression levels between the two groups was apparent ($P<0.05$, Table 3). Figures 2D-2F show that the length of RT-PCR products of P21WAF-1 was 219 bp. The P21WAF-1 gene was expressed at a pronounced high level in villi compared to sham-operated group at 15 min, 6 and 12 h after reperfusion ($P<0.05$). After treatment with aFGF, although P21WAF-1 gene expression was not substantially decreased after reperfusion in A group compared to C group, the content of P21WAF-1 gene transcript were markedly reduced at 15 min, 6 and 12 h after reperfusion in A group compared to R group ($P<0.05$, Table 3).

DISCUSSION

The major clinical disorders involving gastrointestinal circulation are hemorrhage and ischemia. It is well recognized that the small intestine is extremely sensitive to the deleterious effects of I-R, and it has been clearly demonstrated that I-R causes both mucosal and vascular injury within the small intestine[21,22]. Intestinal I-R injury may also cause release of bacteria and toxins from the gut into the host blood circulation and changes of inflammatory factors, cytokines, and growth factors, resulting in damage to the intestinal barrier. In the current study, we found that I-R, following occlusion of the SMA, induced apoptosis in the intestinal mucosal cells. Results of TUNEL method displayed that the apoptotic rate increased during ischemia and peaked at 12 h after reperfusion. The locations of apoptotic cells were extended from villus tip in sham-operated rats to the whole structure of mucosa in rats insulted by I-R. The quantification of apoptosis was corroborated with histological examination using HE staining. It was also found that administration of exogenous aFGF could reduce the intestinal injury caused by I-R insult. The antiapoptotic effect of aFGF was achieved by inhibiting the expression of some apoptosis-related genes. Previous experimental data showed that the change of expression of apoptosis-related genes played a pivotal role in alleviating cardiac, myocardial[23], cerebral[24,25], muscular[26], cutaneous[27], and adrenal cortex[28] apoptosis induced by I-R, which was in agreement with our results that I-R promoted P53 and P21WAF-1 expression.

After 45 min of ischemia, although gene expression of P53 was quickly increased, and lasted for the whole period after reperfusion, P21WAF-1 gene was only strongly expressed at 15 min, 6 h, and 12 h after reperfusion. The difference of time in the kinetics between these two genes may indicate that P21WAF-1 gene transcription might be activated in a P53-independent manner. Moreover, although protein levels of P53 and P21WAF-1 accumulated after reperfusion, there was a time lag in the

onset of elevation and the peak time point between these two proteins. These results indicate that the P21WAF-1 translation is activated by the elevated P53 protein contents. In this current study, we also found that the kinetics between the levels of P21WAF-1 and P53 protein expression and the apoptotic rate were similar, suggesting that protein levels of P21WAF-1 and P53 might be related to cell apoptosis. When severe histological damage of intestinal villi 2-12 h after reperfusion is considered, DNA damage in the intestinal cells cannot be repaired, resulting in cell apoptosis. Our study also found that the rate of apoptosis in intestinal villi insulted by I-R was significantly decreased by aFGF administration. aFGF could inhibit the increments of P21WAF-1 and P53 protein expression 2-12 h after reperfusion in comparison to normal saline treatment, suggesting that the decrement of P21WAF-1 and P53 protein contents caused by aFGF might be one of the mechanisms attenuating ischemia-reperfusion-induced apoptosis.

Studies have demonstrated that the activated neutrophils and oxygen free radicals produced in ischemic tissue during reperfusion play an important role in developing the injury of the intestine[26,28]. Free radicals are produced mainly by the activated neutrophils and xanthine dehydrogenase/xanthine oxidase enzyme system after reperfusion, but the free radicals produced from the neutrophils play a more important role than xanthine oxidase in mediating tissue-destroying events[29]. Our histopathological study showed that leukocyte sequestration into the villi was evident 6-12 h after reperfusion, and exogenous aFGF could alleviate leukocyte infiltration into intestinal villi. It is well known that free radicals cause DNA damage, and the series of cell reactions mediated by P53 might be investigated by free radicals produced during the reperfusion process. The protective mechanism of aFGF might inhibit P53 and P21WAF-1 protein translation by scavenging free radicals. The current study also demonstrated that apoptosis occurred 1 h after reperfusion and returned to baseline values after 24 h, suggesting that I-R-induced intestinal apoptosis and mucosal recovery is a rapid process. The mechanism underlying this interesting kinetics of induction of mucosal cell apoptosis and restoration is unclear. A time-dependent increment in protein expression of apoptosis-promoting factors including P53 and P21WAF-1 during ischemia and early phases of reperfusion, and decrement with prolonged reperfusion might be an alternative cause. Therefore, the protective effect of aFGF against intestinal I-R insult might be not only associated with inhibiting epithelial cell apoptosis but also related to inducing mucosal cell restoration.

In conclusion, the protective effects of aFGF against I-R in rat intestinal villi might be partially due to its ability to inhibit I-R-induced apoptosis. aFGF exerts its antiapoptotic effect via regulating P53 and P21WAF-1gene transcription and translation. The precise mechanisms of aFGF underlying the inhibition of intestinal I-R injury and attenuation of apoptosis need further investigation.

Abstract

AIM: To investigate ASCA production over time in CD and murine colitis in order to further our understanding of their etiology.

MATERIALS AND METHODS: Sixty-six CD patients were compared to ulcerative colitis (UC) and irritable bowel syndrome patients with respect to ASCA production as measured by ELISA. ASCA IgG or IgA positivity as well as change in titers over a period of up to 3 years ($\Delta_{IgG/A}$) was correlated with clinical parameters such as CD activity index (CDAI) and C-reactive protein levels (CRP). Moreover, two murine models of colitis (DSS and IL-10 knock out) were compared to control animals with respect to ASCA titers after oral yeast exposure.

RESULTS: ASCA IgG and IgA titers are stable over time in CD and non-CD patients. Fistular disease was associated with a higher rate of ASCA IgA positivity (P = 0.014). Ileal disease was found to have a significant influence on the Δ_{IgG} of ASCA (P = 0.032). There was no correlation found between ASCA positivity or $\Delta_{IgG/A}$ and clinical parameters of CD: CDAI and CRP. In mice, neither healthy animals nor animals with DSS-induced or spontaneous colitis exhibited a marked increase in ASCA titers after high-dose yeast exposure. On the other hand, mice immunized intraperitoneally with mannan plus adjuvant showed a marked and significant increase in ASCA titers compared to adjuvant-only immunized controls (P = 0.014).

CONCLUSION: The propensity to produce ASCA in a subgroup of CD patients is largely genetically predetermined as evidenced by their stability and lack of correlation with clinical disease activity parameters. Furthermore, in animal models of colitis, mere oral exposure of mice to yeast does not lead to the induction of marked ASCA titers irrespective of concomitant colonic inflammation. Hence, environment may play only a minor role in inducing ASCA.

INTRODUCTION

Much attention has been focused on serologic markers in inflammatory bowel disease (IBD). The anti-*Saccharomyces cerevisiae* antibody (ASCA) is one such marker, which possesses an intermediate sensitivity and a high specificity for Crohn's disease (CD)[1-5]. Antibodies to *S cerevisiae* in CD were first described by Main *et al*.[6], using whole killed yeast cells as antigens. Sendid *et al*.[3] demonstrated greater diagnostic value for CD with *S cerevisiae* Su1, a strain of brewer's yeast, and identified the antigenic oligomannosidic epitopes of this organism. Subsequent work demonstrated that CD patients develop antibodies to a variety of baker's and brewer's yeast strains[4]. The antigen reacting with ASCA is a phosphopeptidomannan, a component of the *S. cerevisiae* cell wall[3].

Aside from the diagnostic role performed by ASCA, uncertainty remains as to whether they possess a pathophysiologic significance. One can argue for a genetic origin due to ASCA presence in 20-25% of unaffected first-degree family members[7-10]. Healthy monozygotic twins of CD patients also demonstrate increased IgA, IgG, and IgM ASCA levels[11]. In one study of non-IBD families,

ASCA were found to be familial with a vertical transmission pattern[12]. ASCA stability over time and independence from disease activity further indicate a genetic link[11,13]. Moreover, we have shown that T cells from ASCA-positive patients proliferated upon stimulation with mannan[14]. We were able to show that mannan binding lectin (MBL) deficient patients were significantly more frequently ASCA-positive and showed an enhanced T cell proliferation upon mannan stimulation compared to MBL wildtype patients[15]. These results further support the importance of genetic determination of ASCA.

Nevertheless, some of the familial studies have yielded conflicting data. For example, one group showed increased ASCA production in familial *vs* sporadic CD[7], but others have shown equal or increased ASCA prevalence for sporadic CD[9,16-18]. Thus, the case for an environmental etiology for ASCA has been articulated as well. For instance, a decline in ASCA levels has been observed post-surgically in a pediatric CD population[5]. Another group demonstrated lower ASCA titers in CD patients taking mesalazine than in CD patients not taking mesalazine[19]. Additionally, both brewing and baking strains of *S cerevisiae* provoke an antibody response in CD, implicating dietary antigens in disease pathogenesis[4]. One group has noted higher ASCA IgG antibody levels in patients with small bowel Crohn's disease *vs* those with colonic disease[18]. This same study found high levels of ASCA IgG but not IgA in celiac disease, indistinguishable from levels seen in CD. It was, thus, concluded that ASCA may result from a mucosal permeability defect. However, Vermeire *et al*.[20] were not able to show a correlation between ASCA and intestinal permeability.

In this study, our aim was to characterize ASCA over time in patients with IBD in order to further our understanding of their etiology. Furthermore, we assessed the possibility to induce an ASCA response in animal models.

MATERIALS AND METHODS

Patients

Sixty-six Crohn's disease (CD) patients, 29 ulcerative colitis (UC) patients, and 10 irritable bowel syndrome (IBS) patients with informed consent were enrolled in the study, and the study was approved by the ethical committee of the local authorities. Patient serum samples were drawn during routine outpatient visits (Gastroenterology clinic, University Hospital, Bern, Switzerland) for ASCA IgG and IgA analysis. Diagnosis of CD and UC was established by endoscopic, histological, and clinical criteria. Diagnosis of IBS was established by the Rome criteria[21].

A subgroup of CD (73 sera from 29 patients), UC (26 sera from 12 patients) and IBS (22 sera from 10 patients) patients, whose serum samples were drawn on at least 2 consecutive (maximally 4 consecutive) routine out-patient visits, were retrospectively selected for ASCA IgG and IgA titer analysis. An assessment of the Crohn's disease activity index (CDAI) was obtained at each CD patient's visit to the clinic[22]. The serum CRP levels were obtained at each clinic visit as well. Three patients with stoma were excluded from the CDAI analysis. One patient was excluded from the clinical analysis, since this patient's CDAI and CRP could not be obtained.

Mice

Four to six-weeks-old female interleukin-10 knockout mice (*Il10*^{tm1Cgn}; henceforth abbreviated as IL-10$^{0/0}$) on a C3H/HeJBir background were obtained from the University of Bern breeding facility (Bern, Switzerland) and housed under specified pathogen-free conditions. Four to six-week-old BALB/c mice were obtained from Harlan (Horst, The Netherlands). All procedures involving animals were performed in compliance with the local authorities on the use of animals in research.

ASCA ELISA for mouse and human sera

Investigators were blinded to disease status when performing the ELISA. Phosphopeptidomannans from baker's yeast (Hefe Vital Gold, Deutsche Hefewerke, Nürnberg, Germany) were extracted as previously described[8,23]. Ninety-six well ELISA plates (MaxiSorb, Nunc, Wiesbaden, Germany) were coated with 100 μL of 0.25 μg/mL phosphopeptidomannans in carbonate-bicarbonate buffer, pH 9.6 and incubated overnight at 4 °C. Serum diluted 1/1 000 was applied to the coated plates in triplicates. The plates were incubated for 1 h at 37 °C. Secondary antibody was added and plates were incubated for 1 h at RT. The secondary antibodies (Sigma, Buchs Switzerland) were as follows: goat anti-mouse polyvalent immunoglobulin peroxidase conjugate at 1/1 000; goat anti-human IgA (alpha-chain specific) peroxidase conjugate; and goat anti-human IgG (Fc specific) peroxidase conjugate, both at 1/5 000. The plates were developed using TMB substrate (Sigma) and the reaction was stopped with sulfuric acid. The absorbance at 450 nm (reference filter = 490 nm) was read by an EL 800 microplate reader (Bio-Tek Instruments, Winooski, Vermont). The mean absorbance value for the healthy control sera plus two standard deviations was used to discriminate between positive and negative subjects. Absorbance units equal to or above this value were considered positive for ASCA antibodies. A patient was considered ASCA$^+$, when positive for ASCA IgG, IgA or both.

For the human ELISA, one serum highly positive for ASCA was used to obtain a standard curve at dilutions ranging from 1/100 to 1/102 400. The curve was fitted using a four parameter logistic function to the logarithmically scaled dilutions. Human titers are expressed as dilution units from this curve. We computed the average change of IgG and IgA ($\Delta_{IgG/A}$) in human ASCA titer as our main variable of interest. An increase of $\Delta_{IgG/A}$ represents a decrease in ASCA levels and vice versa. Of the CD patients, two patient's IgG titer and one patient's IgA titer could not be reliably calculated from the standard curve after two repeated assays and thus were excluded from the IgG/A titer analysis. The murine ASCA titers are expressed as optical density (OD).

Preparation of yeast solution

Baker's yeast (Hefe Vital Gold, Deutsche Hefewerke, Nürnberg, Germany) was freshly grown in YPD broth

(Becton Dickinson, Le Pont de Claix, France) for 12 h at 30 ºC in a shaker at 200 r/min. The yeast solution was centrifuged at 2 000 r/min for 5 min. The cellular pellet was washed twice, resuspended in sterilized water and sonicated at 100 W for 2 min. Protein concentration was determined using the Bradford reagent (Sigma, Buchs, Switzerland).

Induction of chronic dextran sulfate sodium-induced (DSS) colitis, oral yeast administration and histological assessment

The previously described model of chronic DSS colitis was adapted from Mähler *et al*.[24]. Briefly, Balb/c mice were given three 5-day cycles of 3% DSS (DSS salt, MW= 36 000-50 000, ICN Biomedicals, Inc., Ohio), each interrupted by the 7th d without DSS. All mice received yeast *ad libitum* at a protein concentration of 100 or 500 μg/mL for the entire experiment. Murine serum samples were drawn on d 0 and the day of killing (d 36) for ASCA immunoglobulin analysis.

Mice were euthanized via CO_2 asphyxiation. Colons were harvested, fixed in 4% phosphate-buffered formaldehyde, embedded *in toto* and H&E-stained sections were examined by a pathologist (Mähler) blinded to the code. The sections were scored on a previously described[24] scale ranging from 0 (no inflammation) to 4 (severe inflammation). A total colonic inflammation score was obtained by averaging the individual scores of the proximal, middle, and distal colon.

Immunizations

Balb/c mice from our central animal facility were intraperitoneally injected with 50 μg phosphopeptidomannans or ovalbumin (Sigma, Gaithersburg, MD) mixed 1:1 (v/v) with GERBU adjuvant (GERBU, Gaiberg, Germany). Injection was repeated after two weeks and mice were killed for analysis one week later. Serum samples were obtained before primary immunization by tail tip bleeding and after euthanization by puncture of the caval vein.

Statistical analysis

We analyzed the CD population in regard to ASCA IgG and IgA positivity to test for a significant influence of the following patient variables: age, gender, anatomical location of disease, medication, fistulae, and extra-intestinal manifestations. Significance of each variable was computed via unpaired, two-tailed Student's *t*-test assuming equal variances if the additional *F*-test was non-significant. We analyzed the titer subgroup in respect to ASCA IgG and ASCA IgA positivity to test for a significant influence of the above-mentioned variables and additionally CD activity index (CDAI) and C-reactive protein (CRP) levels.

In order to qualitatively assess the amplitude and distribution of IgG and IgA, the respective $\Delta_{IgG/A}$ histograms for the CD, UC, and IBS titer subgroups were computed. The quantitative assessment is shown via the mean, SD and 95% confidence interval of each $\Delta_{IgG/A}$ distribution and via unpaired, two-tailed Student's *t*-tests. We also employed Student's *t*-tests for testing $\Delta_{IgG/A}$ differences with regard to gender, anatomical location of disease, fistulae, extra-intestinal manifestations, and medication. To assess the differences between the three patient groups with regard to IgG and IgA $\Delta_{IgG/A}$, we applied the one-way ANOVA test. The correlation coefficients between $\Delta_{IgG/A}$ and the two clinical parameters, change in CDAI (Δ_{CDAI}) and change in CRP (Δ_{CRP}), were also computed.

The differences between the mice groups on day 36 were statistically assessed using the unpaired, two-tailed Student's *t*-test. Significance level for all tests was 0.05.

RESULTS

ASCA positivity in the study population

Thirty-five of sixty-six CD patients, 4 of 29 UC patients and 3 of 10 IBS patients were ASCA positive. The sensitivity, specificity, and positive predictive value of the ASCA assay in distinguishing CD from UC are 53%, 86%, and 90%, respectively.

Fistular disease is associated with higher rate of ASCA IgA positivity

The baseline clinical characteristics of the patients and controls can be seen in Table 1. None of the following clinical characteristics had a significant effect on ASCA IgG and IgA positivity in the Crohn's disease patients: age, gender, anatomical locations of disease, medication, and extra-intestinal manifestations. Patients with fistular disease were significantly more likely to possess ASCA IgA positivity (P = 0.014, 71% *vs* 32%) than patients with non-fistular disease.

ASCA IgG and IgA titers are stable over time in CD and non-CD patients

ASCA IgG and IgA titers in the CD subgroup, expressed as logarithmically (ln) scaled dilutions of a high positive control, have been plotted over a time-period of up to 3 years (Figure 1). The change in titers did not vary significantly as can be seen in the Gaussian distribution in the histogram, which is centered close to zero for all patient groups with respect to both IgG and IgA titers (Figure 2). The means, standard deviations and 95% confidence intervals of $\Delta_{IgG/A}$ are shown in Table 2 and indicate stable titers over time. Nevertheless, the patient groups are significantly different in regard to Δ_{IgA} values (P<0.05, ANOVA), specifically between CD and UC patients (P<0.05, ANOVA *post hoc*). This suggests that patients with UC were more likely to experience a decrease in IgA ASCA levels over time than patients with CD. The patient groups are not significantly different with regard to Δ_{IgG} values.

Anatomic location of disease significantly influences the Δ_{IgG} of ASCA

Of the clinical parameters assessed upon entry, ileal disease was found to have a significant influence on the Δ_{IgG} of ASCA (Table 3). The mean Δ_{IgG} value for patients with ileal disease *vs* those without ileal disease was 0.13 and -0.34, respectively. This suggests that patients without ileal

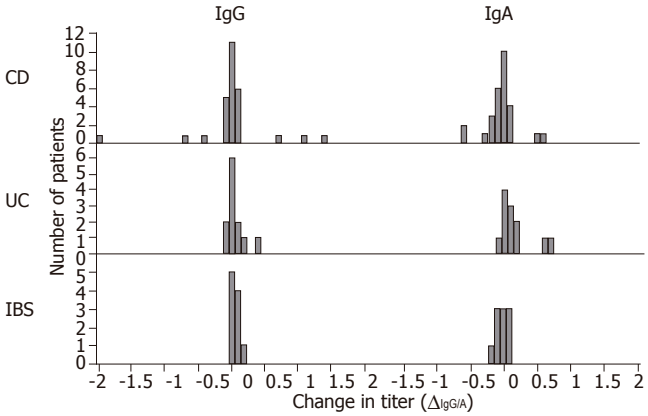

Figure 2 Histogram of change in ASCA IgA and IgG titers (ΔIgG/A) in patients with Crohn's disease (CD), ulcerative colitis (UC) and irritable bowel syndrome (IBS). CD patients demonstrate higher variability as compared to UC and IBS.

disease were more likely to experience an increase in ASCA level as opposed to patients with ileal disease. All other tested clinical parameters did not significantly influence the $\Delta_{IgG/A}$ of ASCA. Regarding the clinical parameters of disease, no strong corre=lation was found between the Δ_{CDAI} and Δ_{IgG} (c = -0.086) and Δ_{IgA} (c = -0.127). Moreover, no strong correlation was found between the Δ_{CRP} and Δ_{IgG} (c = 0.424) and Δ_{IgA} (c = -0.245).

Anti-S cerevisiae antibodies are not efficiently induced upon oral yeast administration, irrespective of concomitant induction of colitis in Balb/c or IL-10$^{0/0}$ mice

All mice given yeast lysate and unfed controls exhibited slightly increased ASCA titers at the end of the experimental period compared with values obtained at the beginning of the experiment. A slight increase in ASCA titers was observed in mice exposed to 500 μg/mL yeast lysate in their drinking water when compared with mice exposed to 100 μg/mL (Figure 3A). Concomitant DSS-

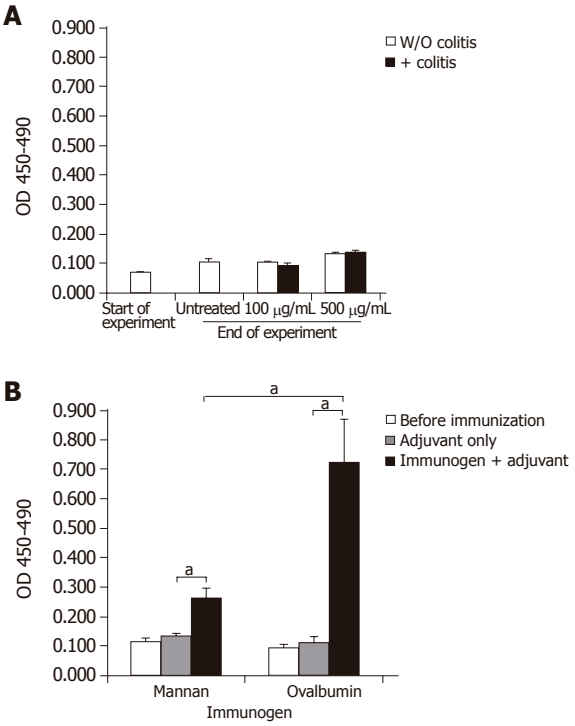

Figure 3 OD at 450 nm representing relative levels of polyclonal anti-*Saccharomyces cerevisiae* antibody (ASCA) (**A**) in control Balb/c mice (empty columns) or mice with DSS-induced experimental colitis (shaded columns). Basal ASCA titers were determined at the start of the experiment. During the experiment, mice received water containing 100 μg/mL or 500 μg/mL yeast solution *ad libitum*. (**B**) Balb/c mice were immunized with water or 50μg yeast mannan or ovalbumin mixed 1:1 (v:v) in GERBU adjuvant. After 2 wk, mice received a booster injection and ASCA or anti ovalbumin antibodies were determined 7 d later. [a]*P*<0.05.

treatment (Figure 3A) or onset of colitis in IL-10$^{0/0}$ mice (data not shown) did not lead to a further increase in ASCA titers. Development of colitis was evidenced by the observation of clinical signs such as soft stools and in some cases anal ulcerations and bloody stools. The average histological score±SD was as follows: 1.056±0.25 for the DSS-treated Balb/c group, 0±0 for the non-DSS-treated Balb/c group, and 1.5±0.19 for the IL-10$^{0/0}$ group.

ASCA titers are induced in mice after immunization with yeast mannan

Groups of Balb/c mice were immunized with adjuvant alone, or with adjuvant plus yeast mannan or, as a positive control, ovalbumin (Figure 3B). Mannan-immunized mice showed an average two-fold increase in ASCA titers when compared with mice receiving adjuvant only (P = 0.014). Mannan was poorly immunogenic compared to ovalbumin (P = 0.038) since specific serum antibody titers after ovalbumin plus adjuvant-immunization increased about seven-fold over adjuvant-only injected controls (P = 0.015).

DISCUSSION

Antibodies to the *S cerevisiae* cell wall mannans have been widely studied as a diagnostic tool to distinguish CD from UC. In this study, the rates of CD patient ASCA positivity correlate well with our previous results[8] as well as those cited in the literature[7,10,13]. Of all the clinical variables tested, fistular Crohn's disease was found to be associated with ASCA IgA positivity. This study is not the first to demonstrate such an association. Others have shown that the subgroup of CD patients with high levels of IgG and IgA ASCA has more aggressive, small-bowel fistulizing disease[25].

Our study was the first to assess time-period streamlined ASCA titers. We found no association between the change in ASCA titers and the following clinical characteristics: age, gender, presence of fistulae, medical therapy, CDAI or CRP levels. Of the clinical parameters tested, patients without ileal disease were more likely to encounter an increase in their ASCA titers over time as compared with CD patients with ileal disease. There is no good explanation why anatomic location of CD should provoke an increase or decrease in ASCA titers. It should be noted that Giaffer *et al.* noted increased ASCA IgG positivity association with small bowel disease as compared to

colonic disease[18]. Nevertheless, this study does not explain why these patient's titers were more likely to change over time. Also of special interest is the lack of association between Δ_{CDAI} and $\Delta_{IgG/A}$ and Δ_{CRP} and $\Delta_{IgG/A}$. ASCA stability over time in relation to the changes in CDAI was demonstrated by Landers *et al*.[13], utilizing a time period of at least 4 mo. Recently, Teml *et al*. established ASCA stability during a course of steroid or 5-ASA therapy[26]. Our data further strengthen this stability and lack of association with CDAI or medical therapy with the addition of CRP as a serologic marker of disease. This lack of association with clinical activity leads others and us away from thinking of ASCA as a subclinical marker of disease activity as it does not follow CD clinical status variations.

In line with the results obtained with human sera, the murine ASCA titers were rather stable, at least during the time of the experimental procedure (36 d). This is the first study to investigate murine ASCA production in the setting of DSS and IL-$10^{0/0}$ colitis. After oral treatment with a high antigen dose (500 μg/mL), we observed a slight increase of ASCA titers compared to untreated controls or mice treated with 100 μg/mL. Interestingly, we observed slightly lower ASCA titers in young untreated mice compared to untreated mice at the end of the experiment. It is very likely that ASCA titers in mice may slightly vary between the breeder company and our animal facility as a consequence of differential exposure to yeast-antigens depending on the hygiene status of the animal facility and/or the composition of food pellets. We did not, however, observe a further increase upon induction of colitis. Therefore, the impairment of mucosal barrier during inflammation and/or the enhanced presence of immune competent cells alone does not lead to markedly enhanced ASCA generation.

In contrast, systemic immunization of mice with phosphopeptidomannans in the context of appropriate adjuvant leads to a significant increase in ASCA titers. However, the increase of ASCA titers is much less pronounced than that of anti-ovalbumin antibodies after ovalbumin immunization. Thus, these data show that mannans are not very efficient antigens when used for immunization, further indicating that normally mice and human beings are tolerant to mannans. Local inflammation during colitis is not sufficient to break this tolerance. In our recent study we were able to show that ASCA positivity was associated with MBL deficiency[15]. Furthermore, family studies show an increased incidence of ASCA in healthy family members[7,8,20]. Thus, generation of ASCA in a subgroup of CD patients and healthy family members may be mainly a result of a genetic predisposition, although biochemical and genetic analyses supporting this notion are not currently available.

In conclusion, we have demonstrated the stability of the ASCA titers over time and their lack of association with clinical activity in the form of CDAI and CRP. These findings are in line with the observation that ASCA are only marginally inducible in mice via high dose oral exposure, and are not further influenced by concomitant induction of colitis. Hence, we speculate that the propensity to produce ASCA in a subgroup of CD patients is largely genetically predetermined and, thus, may reflect a predisposition of distinct genetic backgrounds to establish immune responses against normally tolerated antigens.

Abstract

AIM: To introduce a computer-aided morphometric method for quantifying the necro-inflammatory phase in liver biopsy specimens using fractal geometry and Delaunay's triangulation.

METHODS: Two-micrometer thick biopsy sections taken from 78 chronic hepatitis C virus-infected patients were immunohistochemically treated to identify the inflammatory cells. An automatic computer-aided image analysis system was used to define the inflammatory cell network defined on the basis of Delaunay's triangulation, and the inflammatory cells were geometrically classified as forming a cluster (an aggregation of a minimum of three cells) or as being irregularly distributed within the tissue. The phase of inflammatory activity was estimated using Hurst's exponent.

RESULTS: The proposed automatic method was rapid and objective. It could not only provide rigorous results expressed by scalar numbers, but also allow the state of the whole organ to be represented by Hurst's exponent with an error of no more than 12%.

CONCLUSION: The availability of rigorous metrical measures and the reasonable representativeness of the status of the organ as a whole raise the question as to whether the indication for hepatic biopsy should be revised by establishing clear rules concerning the contraindications suggested by its invasiveness and subjective interpretation.

Key words: Biopsy; Grading; Image analysis; Fractal geometry; Topography; Delaunay

INTRODUCTION

The antiviral treatment of chronic hepatitis C is expensive, efficacious in only 50% of cases, and has sometimes major undesired effects. The criteria for selecting the patients to treat are therefore a central problem and its solution is sought by evaluating the inflammatory lesions (grading) and fibrosis (staging) histologically observed in bioptic specimens.

A single bioptic sample is still the most effective means of obtaining the greatest amount of information for formulating a diagnosis of chronic hepatitis, excluding other diseases, hypothesizing the prognosis, and defining therapeutic indications[1-4]. However, taking a bioptic sample is expensive, carries a certain risk, and the results are not reliable insofar as they do not express real measures, but only semi-quantitative categories of severity, and its evaluation entirely depends on the subjective skill and experience of the pathologist[5-9]. It therefore follows that such semi-quantitative data cannot be used for statistical purposes[10,11].

The recently proposed alternative methods of estimating hepatic tissue inflammation by measuring the blood levels of molecules associated with the evolution of liver inflammation (including the extremely and widely used measurement of transaminase levels) have not shown any sure correspondence with actual tissue status[12-16].

It is therefore necessary to develop more rigorous and objective morphometric methods capable of providing scalars for the metrical quantification of inflammation structures within a liver biopsy sample. We have herein described the first results of our metrical measurements of the *fractal spaces* covered by necro-inflammatory lesions observed in the biopsies of consecutive chronic hepatitis C patients, and obtained by means of a totally computerized analysis that excludes any subjective influence.

The phase of inflammatory activity in the examined samples has been estimated using Hurst's exponent (*H*). *H* was first excogitated in the middle of the last century in order to study the local variations in water flow in the branches of the Nile delta during the construction of the Aswan dam[17]. Further refined in 1965 and 1969, it can

now be drawn from the fractal dimension (D)[18,19]. As it can describe even subtle quantitative differences in the smoothness of the configurations of natural objects with fractal properties, we used it to describe the phase of the inflammatory process on the basis of the fractal space occupied by inflammatory cells. In our case, a high H value indicates a small number of inflammatory cells within the tissue (i.e. the natural state), and a low value indicates the presence of many inflammatory cells (i.e. severe inflammatory states). H can be considered as a quantitative descriptor of the configuration pattern expressing the phase of the inflammatory process, and thus gives inflammatory cell density, the significance of a physical variable.

MATERIALS AND METHODS

Biopsy specimens

The study was conducted in accordance with the guidelines of the Ethics Committee of Istituto Clinico Humanitas, Rozzano, Milan, Italy.

The 72 liver specimens (>10 mm long) came from 43 male and 29 female chronic hepatitis C patients (mean age 50.3±14 years; range 25-77 years) admitted to our Hepato-gastroenterology Unit.

Histochemistry

Two consecutive 2-μm-thick sections were cut from the formalin-fixed and paraffin-embedded specimens. One was subsequently stained with hematoxylin-eosin (HE) solution, and the other was used for immunohistochemistry. HE stained sections were graded by two hepato-pathologists using a semi-quantitative scoring system.

Immunohistochemistry

In order to classify the inflammatory cells, the histological sections were treated with primary antibodies raised against human leukocyte common antigen (LCA, monoclonal mouse anti-LCA) for 1 h at room temperature, 1 mg/mL mouse IgG1 (Dako, Milan, Italy) was used as a negative control.

In order to distinguish settled macrophagic mesenchymal Kupffer cells from recruited inflammatory T cells, a further section was immersed in an antigen retrieval bath (Dako, Milan, Italy) for 30 min at 98 °C in 1 mmol/L of a freshly made EDTA solution. The inflammatory T cells were classified using primary antibodies raised against human CD3 (Dako, Milan, Italy), and the Kupffer cells by treatment with primary antibodies raised against human CD68 (Dako, Milan, Italy) at room temperature, or with 1 mg/mL mouse IgG1 (Dako, Milan, Italy) as a negative control.

The sections were then incubated with the DAKO Envision Doublestain System (Dako, Milan, Italy). Fast red was used as a chromogen to yield the red reaction products for CD68, and 3,3'-diaminobenzidine tetrahydrochloride (DAB, Sigma Ltd, MO, USA) to yield the brown reaction products for LCA and CD3.

The nuclei were lightly counterstained with Harris's hematoxylin solution (Medite, Bergamo, Italy).

Quantitative image analysis

The histological sections were digitized using an image analysis system consisting of a Leica DMLA microscope (Leica, Italy) equipped with an *x-y* translator table, a digital camera (Leica DC200, Leica, Italy), and an Intel dual Pentium IV, 660 MHz computer with incorporated *ad hoc* constructed image analysis software[20].

The computer program automatically selected the surface covered by the whole LCA-immunopositive inflammatory system. In this paper, the term *true area* indicates the surface of the liver tissue section without unfilled natural holes, vascular and biliary cavities, sinusoidal spaces or artificial spaces due to the needle excision and histological manipulations[20]. All the measurements were made at an objective magnification of ×20.

Determination of Hurst's exponent

This was obtained using the general relationship:

$$H=E+1-D \quad (1)$$

where E indicates the Euclidean topological dimension and D the fractal dimension of the surface covered by the whole LCA-immunopositive inflammatory system.

D was automatically estimated using the box-counting method and the formula:

$$D_B = \lim_{\varepsilon \to 0} \frac{\log N(\varepsilon)}{\log(1/\varepsilon)} \quad (2)$$

where D_B is the box-counting fractal dimension of the object, ε the side length of the box, and $N(\varepsilon)$ the smallest number of boxes of side ε required to cover the surface of the object completely, i.e. the whole LCA-immunopositive inflammatory system. As the zero limit cannot be applied to biological objects, the dimensions were calculated as $D=d$, where d is the slope of the graph of log $[N(\varepsilon)]$ against log $1/\varepsilon$. The log-log graphs were plotted and the linear segments were identified using least squares regression. Their gradients were calculated using an iterative resistant line method[20-28].

On the basis of the H value, two categories were considered. The first included all the samples characterized by $0.5<H<1.0$, and the second included all the samples verifying the relationship $0<H<0.5$.

Dynamic side of the shapes of chronic liver inflammation

The pictures indicating chronic liver inflammation appeared as portal, periportal, and perilobular aggregations of lymphocytes, plasma cells, and monocytes/macrophages (Figure 1). The extent of intralobular focal necro-inflammation varied with the severity of the disease, with confluent necrosis expressing its most severe clinical exacerbation[29-33].

These cell conglomerates arose when the viral etiological agent shaped critical points in the liver tissue consistent with hepatocyte necrosis. Each critical point acted as an attractor of the inflammatory cells naturally present within the liver tissue and recruited lymphocytes,

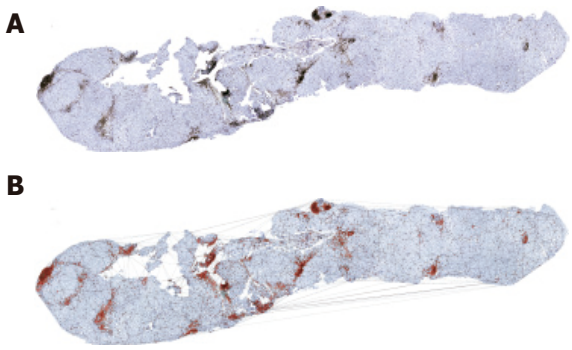

Figure 1 Liver biopsy section immunohistochemically treated with antibodies against LCA (**A**) and computer-aided recognition of the inflammatory cell network (**B**).

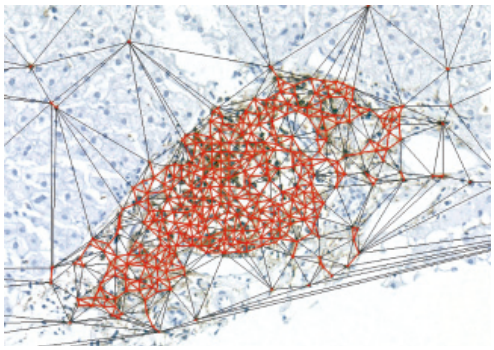

Figure 2 Border of clustered and non-clustered inflammatory cells.

plasma cells and other white blood cells. The trajectories of the inflammatory cells would die inside the attraction basin created by the necro-inflammatory process, where the motion of the recruited cells came to an end, and they formed a *cluster* marking the metrical space covered by the inflammation basin. The cell density of the cluster was transient and depended on the evolution of the inflammation connected to necrosis healing.

Definition of cluster outlines

As the cells of a cluster were not settled in tasseled forms, they were not bounded by a distinguishable contour. This meant that, in order to measure the fractal spaces they covered, the canonical step was to fix their bounds. To this end, we used a triangulation method based on the principles of Delaunay's tessellation[34-37], which can be very efficiently adapted to cluster geometry and involves the metrical measurement of the *distances* between the cells belonging to the whole inflammatory system.

Each inflammatory cell on the surface of the histological specimen was considered as a node of a continuous framework covering the entire section characterized by very irregular triangular windows in which any two triangles have one common side (Figure 1).

The border of the cluster (Figure 2) was arbitrarily fixed at the level of the continuous line formed by the set of the most external triangle sides with a length of ≤20 μm, corresponding to about twice the mean diameter of a lymphocyte (7-12 μm)[38]. All the points within this border were considered as belonging to the subset of cluster-resident cells, and those connected by longer segments as belonging to the non-clustered subset of inflammatory cells.

Geometrical structure of inflammatory clusters

The dynamics of the necro-inflammation shaping a cluster generate metrical spaces covered by two overlapping components. One belonged to the entire attraction basin of hepatocyte necrosis bounded by the cluster contour drawn by the triangulation, the other belonged to the sum of the surfaces of the inflammatory cells residing within the attraction (necro-inflammation) basin. The outline of the true area of the biopsy sample was indicated by the symbol A_B, the area of the triangulation-defined cluster (necrosis attraction zone) was indicated by the symbol A_C, and the sum of the areas of cluster-resident inflammatory cells was indicated by the symbol A_{CINF} (Figure 3). The dispersed cells were indicated by the symbol A_{PINF}, and their areas added to the area of resident inflammatory cells provided the area covered by the inflammation system as a whole, which was indicated by the symbol A_{TINF}

Physical parameters of inflammation

The physical parameters of inflammation were taken from analyses of the clusters consisting of at least three inflammatory cells. Smaller aggregates were considered as randomly united cells.

In the two dimensions of a histological section, we obtained the following physical parameters relating to the state of inflammation: (1) cluster extension: the area of the necro-inflammation basins identified by means of Delaunay's triangulation; (2) the area covered by the inflammatory cells resident within the cluster perimeter: i.e. the intracluster mass of inflammatory cells; (3) the whole area occupied by all the inflammatory parenchymal cells not residing inside the clusters; (4) the A_C/A_{CINF} ratio; (5) the extent of inflammatory tissue as a whole ($A_{CINF}+A_{PINF}$); (6) the discrimination of inflammatory T cells from Kupffer cells; (7) Hurst's exponent in order to evaluate the spatial heterogeneity of the chronic inflammatory process, i.e. the phase of the inflammatory process.

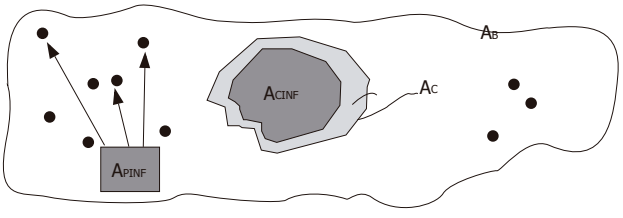

Figure 3 Geometrical structure of clustered inflammatory cells. A_B=true area of the biopsy sample; A_C=area of the triangulation-defined cluster (necrosis attraction zone); A_{CINF}=sum of the areas of cluster-resident inflammatory cells; A_{PINF}=dispersed non-clustered cells.

Statistical analysis

All the data were expressed as mean±SD.

RESULTS

Cluster extension

The area of the necro-inflammation basins obtained by Delaunay's triangulation ranged from 0.010% to 33.74% (mean 5.22±6.5%) of the area of the histological section. This area was a perceptible and measurable marker of the necrosis subtending each cluster. The sum of these areas could express the overall extension of the necrotic process in the evaluated section.

Area covered by clustered inflammatory cells

This area ranged from 0.021% to 15.36% (mean 2.22 ±2.9%) of the area of the histological section. As it represented effective inflammatory activity, its measure indicated the inflammatory potential of the set of clusters identified in the biopsy section.

Area of dispersed inflammatory cells

The area covered by the whole set of LCA-immunopositive inflammatory cells lying outside the clusters recognized in the histological sections ranged from 0.024% to 3.93% (mean 0.91±0.83%).

A_C/A_{CINF} ratio

This parameter, which expresses the density of the inflammatory cells lying within the clusters, ranged from 0.34 to 3.28 (mean 0.56±0.35).

Extension of inflammatory tissue

This area was drawn from the sum of the clustered and dispersed inflammatory cells immunopositive for LCA, and ranged from 0.045% to 18.58% (mean 3.13±3.30%).

Discrimination of recruited inflammatory T cells from resident macrophagic Kupffer cells

The whole LCA-immunopositive inflammatory area was shared by recruited blood cells (lymphocytes, monocytes, plasma cells, mast cells) and settled macrophagic Kupffer cells (Figure 4). The different range of the areas of Kupffer cells suggested that the number of Kupffer cells potentially capable of being activated might explain the distinction between fast and slow fibrosis. It is worth mentioning that this preliminary study found a high percentage of macrophages among the dispersed cells and a very low percentage in the clusters, which mainly consisted of lymphocytes and other recruited blood inflammation cells (Figure 4).

Quantification of spatial histological heterogeneity of chronic inflammatory process

This was evaluated using Hurst's exponent, the values of which range from 0 to 1 and indicate the actual phase of the inflammatory process. *H* coefficients of >0.5 were considered as belonging to tendentially less severe inflammatory pictures, and those of <0.5 as belonging to more severe pictures. The mean *H* value of all the cases was 0.67±0.14 (range 0.36-1).

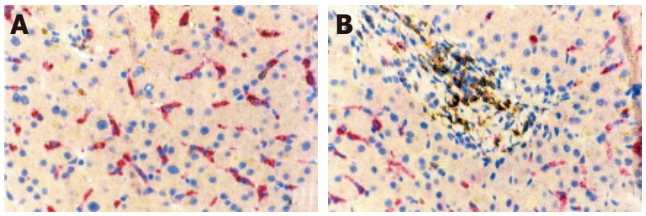

Figure 4 High percentage of macrophages among dispersed cells (**A**) and low percentage in clusters of lymphocytes and other inflammatory cells (**B**).

DISCUSSION

Given a hierarchy of logical concepts going from the purely qualitative or classificatory, to the semi-quantitative or ordering, and finally to the entirely quantitative or metrical (i.e. scientific variables), it is not a prejudice to consider that the maturity of a discipline is reflected by the number of quantitative concepts it adopts.

From this viewpoint, the phasing out of the clinical use of qualitative and semi-quantitative methods when evaluating the extension of chronic inflammatory lesions can be correlated with the maturity of hepatological disciplines. In this study, we used measurement theory, which forms the basis of our concrete knowledge of the real world and discriminates the specificity of its interrelationships, to construct a method of evaluating the different pictures of chronic liver inflammation.

Studying the measurement of inflammation (or the intensity of a process) obliged us to think in different terms from those that we were used to. In order to express new facts in intelligible terms, the confusion generated by the vague and emotive semi-quantitative definitions dictated by an observer's skill must be removed from every conceptual structure.

The method adopted by us is highly objective insofar as it is entirely computerized. Its foundations lie in the theory of measurement, a basic point of reference for all conceptual structures organizing knowledge[39].

The liver tissue lesions related to the inflammatory process at any given time caused variations in the concentrations of some specific blood molecules. These have been grouped and proposed as disease indices despite the fact that their concentrations depend not only on their production, but also on the rate of their metabolism in the bloodstream, thus depriving them of much of their significance as a quantitative index of the hepatic structure producing them. The changes in the concentrations of these blood indices over time can be described by the general equation:

$$dx_i/dt = f_i(x_1, x_2, \ldots, x_n) \quad (3)$$

where x_i denotes the blood concentration of the molecular species used, t is time, and the functions f_i are determined by the specific reactions of each x_i with the environmental factors in the bloodstream that affect their mean life (many

of which are unknown).

This makes these blood molecules independent variables that are incapable of expressing the state conditions of hepatic tissue even when the most sophisticated statistical methods are used. Similar conclusions can be made concerning the figured elements of blood (granulocytes, red cells, and platelets), and the characteristics of independent variables can also be found in the case of hepatofuge circulations (esophageal, gastric, hemorrhoidal, and umbilical varices). It therefore follows that the only variables describing the state of a chronic necro-inflammatory hepatic tissue lesion are those obtained by measuring their characteristics in the tissue in which they occur.

Since all theoretical hepatologists freely admit that the forms of chronic viral inflammation are so numerous and that they elude a complete verbal description, metrical measurements estimating the size of the true area covered by inflammatory cells and the density of the cells occupying it are the most real means of defining the stage of the process.

In practical terms, measuring chronic hepatitis B and C virus-related inflammation on the basis of a histological section of liver tissue is a problem of estimating the density of the points aggregated in clusters and those isolated in the interstitium of the hepatic parenchyma. As the points of the former (lymphocytes, monocytes, plasma cells) and the latter (which also include Kupffer cells) have the same mesenchymal nature and a similar capacity of activation during disease, it can be reasonably presumed that the degree of activity of the chronic viral process can be estimated by measuring the metrical spaces occupied by these cells and their density within them.

Whatever the method used, it is always difficult to determine the density of the punctiform particles representing the recruited inflammatory blood cells in a cluster because it depends on what is assumed to be the boundary of these basic elements of the chronic hepatitis virus-related process of liver tissue inflammation. After repeated tests (not described here), we decided to use cell sequences characterized by intercellular distances of $\leq$20 μm. Although this resolved our case, it certainly did not provide definitive solutions.

One basic question raised by our study is how much new knowledge of inflammation we have acquired after recognizing, measuring and classifying it. A first reply can be that we are able to acquire rigorous and repeatable metrical data concerning the anatomical (i.e. physical) state of the lesions induced by the etiological agent, which can be used as a reference point to give some significance to the hematological indices of disease whose uncertainty is always due to partially unknown factors. No other method of tissue or hematological analysis offers a result that is so near to reality.

Furthermore, using the same equation (4), we can now geometrically describe the morphometry of the histological picture offered by a liver biopsy. In this case, x_i represents the observable (i.e. measurable) quantities indicating the phase of the dynamic state of the inflammatory lesions that directly mark the evolution of the disease, t is time, and the functions f_i are determined by both viral and immune activity.

We included in x_i the observable, directly perceivable and metrically quantifiable measures that can change the blood concentrations of the individual molecules indicative of chronic liver disease.

Tissue and hematological indices can both be seen as dynamic variables and written using the same formula, but the hematological indices described by equation (3) are completely different functions (f_i) from those determining the dynamics of anatomical lesions. It therefore follows that blood indices cannot be used to validate the results of our method, and that the changes in hematological indices are due to the action of very different independent factors. At this point, it may be wondered what qualitative differences distinguish our method from previous recognition/classification and evaluation procedures. The most immediate reply is the rigorousness of the results expressed by scalar numbers, but it should also be added that our method allows the state of the whole organ to be represented by Hurst's exponent with an error of no more than 12% (manuscript in preparation).

The availability of rigorous metrical measures and the reasonable representativeness of the status of the organ as a whole raise the question as to whether the indication for hepatic biopsy should be reviewed by establishing clear rules in relation to the contraindications suggested by its invasiveness.

Abstract

AIM: To study the efficacy, safety, and feasibility of a granulocyte adsorptive type apheresis system for the treatment of patients with chronically active ulcerative colitis despite standard therapy.

METHODS: An open label multicenter study was carried out in 39 patients with active ulcerative colitis (CAI 6-8) despite continuous use of steroids (a minimum total dose of 400 mg prednisone within the last 4 wk). Patients received a total of five aphereses using a granulocyte adsorptive technique (Adacolumn®, Otsuka Pharmaceutical Europe, UK). Assessments at wk 6 and during follow-up until 4 mo comprised clinical (CAI) and endoscopic (EI) activity index, histology, quality of life (IBDQ), and laboratory tests.

RESULTS: Thirty-five out of thirty-nine patients were qualified for intent-to-treat analysis. After the apheresis treatment at wk 6, 13/35 (37.1%) patients achieved clinical remission and 10/35 (28.6%) patients had endoscopic remission (CAI<4, EI<4). Quality of life (IBDQ) increased significantly (24 points, $P<0.01$) at wk 6. Apheresis could be performed in all but one patient. Aphereses were well tolerated, only one patient experienced anemia.

CONCLUSION: In patients with steroid refractory ulcerative colitis, five aphereses with a granulocyte/monocyte depleting filter show potential short-term efficacy. Tolerability and technical feasibility of the procedure are excellent.

Key words: Steroid; Refractory colitis; Ulcerative colitis; Granulocyte; Apheresis

INTRODUCTION

Systemically acting corticosteroids are mainstay in the treatment of patients with severely active ulcerative colitis (UC). But steroid free remission cannot be achieved in up to 40% of these selected patients[1,2]. Thus, there is a need of alternative treatment options.

Etiology of inflammatory bowel disease (IBD) is still unknown, but the pathogenesis is thought to comprise interaction between genetic factors, intestinal flora, and immunomediated tissue injury[3] Extravasation of a large number of granulocytes and macrophages into the mucosa plays a major role in the release of proinflammatory cytokines[4,5], reactive oxygen derivatives[6-9], and degradative proteases[10]. Accordingly, immunosuppressive therapy has been introduced for refractory patients. Azathioprine/6-mercaptopurine, cyclosporin, and tacrolimus are widely used at present. But drawbacks such as delayed efficacy, adverse events, and costs are currently still limiting the clinical success in severely ill patients and proctocolectomy is necessary in about one-third of these patients. The search for a better treatment strategy has failed as yet. Trials with methotrexate, infliximab, and interferon have shown no convincing effects.

In view of the pathogenetic key role of granulocytes and macrophages, it makes sense to focus on therapeutic goals here. A recently developed adsorptive carrier-based granulocyte and monocyte apheresis device has demonstrated significant effects on inflammatory processes both *in vivo* and *in vitro*[11]. Preliminary data have shown promising therapeutic efficacy in IBD, rheumatoid arthritis, and other conditions[11]. Expanding on these findings, we have reported the results of an open label study on the efficacy of granulocyte apheresis treatment in severely ill patients with chronically active UC despite high doses of systemic corticosteroids.

MATERIALS AND METHODS

This was a prospective and open label trial investigating the efficacy, safety, and feasibility of therapeutic apheresis in patients with active UC despite chronic intake of high doses of systemic corticosteroids. The study was conducted in eight European gastrointestinal (GI) referral centers (Germany, Sweden, Italy, Spain) according to the Declaration of Helsinki (as amended in Edinburgh) and the good clinical practice (GCP) guidelines. The study was approved by the "Ethikkommission der Ärztekammer Nordrhein", Germany as well as local ethics committees of the participating centers. All patients received materials in their own language and gave written consent.

Patients were included if they were aged between 18 and 75 years and diagnosed with active disease (clinical activity index/CAI$\geqslant$6 and $\leqslant$8, and endoscopic index/EI>4)[12]. Additional inclusion criteria were as follows: patients who were dependent on steroids and relapsed despite continuous use of steroids (a minimum total dose of 400 mg prednisone or equivalent within the last 4 wk, dose of steroids was not changed 2 wk prior to the study), history of at least one previous attack with an unsuccessful attempt to taper corticosteroids, immunosuppressants, and aminosalicylates were constant, 3 mo and 4 wk prior to the study, respectively.

Exclusion criteria were patients with severe activity (CAI>8); pregnancy, nursing; arterial hypotension/systolic pressure <11.97 kPa and/or diastolic pressure <8.645 kPa or hypertension (systolic pressure >23.94 kPa or diastolic pressure >15.96 kPa); serious renal, hepatic or cardiovascular disease; laboratory abnormalities such as neutrophils $<1\times10^9$/L, platelets $<100\times10^9$/L, hemoglobin <10 g/L, aPT >1.25 times upper range, aPTT >1.66 times upper normal range, AST or ALT >3 times upper normal range, total bilirubin >2.5 times upper normal range, creatinine >1.8 mg/L; allergy to heparin; viral infection within 4 wk prior to the study; positive stool microbiology; major bowel resection.

Study treatment

Each patient was intended to receive a total of five apheresis sessions, each per week for 5 consecutive weeks. An apheresis session lasted for 60 min at a flow rate of 30 mL/min. Most treatments were performed in an outpatient clinic, partly in dialysis units and also in apheresis non-specialized settings.

The apheresis system used consists of a pump with an integrated monitor (Adamonitor®, manufactured by Otsuka Electronics, Japan) and a single use polycarbonate column (Adacolumn®, CE-Mark; EC certificate GI030136676005, TUV) with a capacity of about 335 mL, filled with 220 g cellulose acetate beads (about 35 000 pieces) of 2 mm in diameter (carriers) bathed in physiological saline and steam sterilized (manufactured by JIMRO, Japan).

Concomitant medication according to inclusion criteria was permitted.

Study design

The aim of this open label pilot study was to investigate the therapeutic effects of a granulocyte adsorptive type apheresis system in patients with chronically active UC despite high doses of corticosteroids. Clinical efficacy as well as feasibility and safety of the procedure were evaluated.

Clinical examination and laboratory tests

Assessments were performed at the beginning and end of the study as well as after 1, 2, 3, 4, and 5 wk of treatment. Clinical (clinical activity index, CAI) and endoscopic (endoscopic index, EI) findings were defined according to Rachmilewitz[12]. Endoscopies were performed at the beginning and the end of study. Histology was reviewed by pathologists who were blinded to the study. Clinical remission was defined by a score of CAI$\leqslant$4, while clinical response was defined as a drop of CAI$\geqslant$3. Endoscopic remission was defined by an EI$\leqslant$4, while endoscopic response was defined as a drop of EI$\geqslant$2. In addition, quality of life was assessed according to the IBDQ scoring system[13]. IBDQ was not assessed in Italian patients (n = 5). Physician's global assessment was asked for and the consumption of steroids was noted.

Laboratory tests included a differential blood count, hemoglobin, hematocrit, fibrinogen, aPT, aPTT, ESR, CRP, orosomucoid, calcium, sodium, potassium, phosphorus, creatinine, BUN/urea, uric acid, bilirubin, total protein albumin, alpha1-antitrypsin, haptoglobin, alkaline phosphatase, AST, ALT, GGT, LDH, and standard urine analyses.

Statistical analysis

The primary objective of this open multicenter study was to find the number of patients achieving clinical remission (CAI$\leqslant$4) at the end of the treatment (wk 6). Because of the uncontrolled pilot characteristics of the study, only descriptive statistical analyses were performed. Sample size was set at 35 patients. Two groups of patients were analyzed. The intent-to-treat (ITT) population consisted of all patients who experienced at least one complete (60 min) treatment of apheresis. Only patients who fulfilled the protocol without major violations were included into the per-protocol (PP) population. Comparisons were made using Wilcoxon signed rank test.

If not otherwise mentioned, data were expressed as mean$\pm$SE. P<0.05 was considered statistically significant.

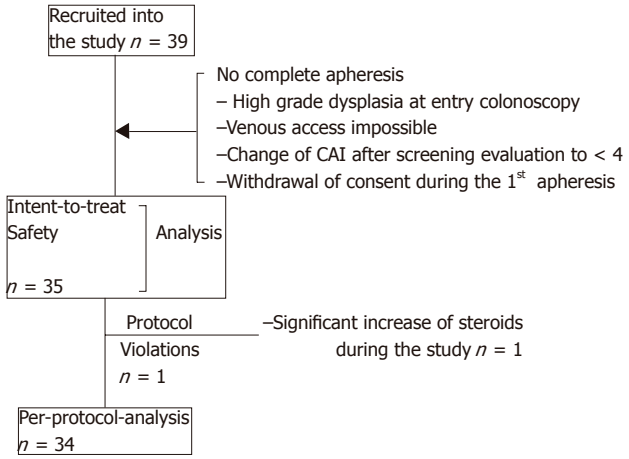

Figure 1 Patients: Analysis sets and drop outs.

Table 1 Biographical and clinical characteristics of the patients studied (intent-to-treat population[1])

Patients (ITT analysis)	*n* = 35	
Age: median/range (yr)	35	(20-72)
Female *n* (%)	10	(28.6)
Smoker *n* (%)	2	(5.7)
Ex-smoker *n* (%)	19	(54.3)
Disease: duration (mean+SE, yr) 7.2+0.8		
Site of disease: extent *n* (%):		
Proctosigmoiditis	3	(8.6)
Left sided	9	(25.7)
Pancolitis	23	(65.7)
Pretreatment (all patients had steroids)		
Aminosalicylates *n* (%)	25	(74.4%)
Immunosuppressants *n* (%)	13	(37.1%)

[1]Note: Per-protocol population comprised all but one ITT patient.

RESULTS

According to the inclusion criteria a total of 39 patients were recruited. Among the patients who underwent proctocolectomy, one patient received surgery before he started apheresis therapy because high grade dysplasia was found in the initial colonoscopy, the other two patients were operated upon because of refractory disease at wk 6 during the follow-up period. Figure 1 displays the different analysis sets and reasons for exclusion. Biographic and clinical characteristics are listed in Table 1. Suitable venous access could not be accomplished in one patient. All the other patients who started treatment received five treatments with apheresis. A total of 176 apheresis procedures could be performed without major technical difficulties. The majority of the patients (18/35) were treated in GI units, while 17/35 patients were treated in specialized dialysis units. Aphereses lasted for 60±3 min in 90.3% of the procedures and were prematurely stopped (50-55 min) in 1.7% procedures and the respective apheresis exceeded (65-91 min) in 8.0% procedures.

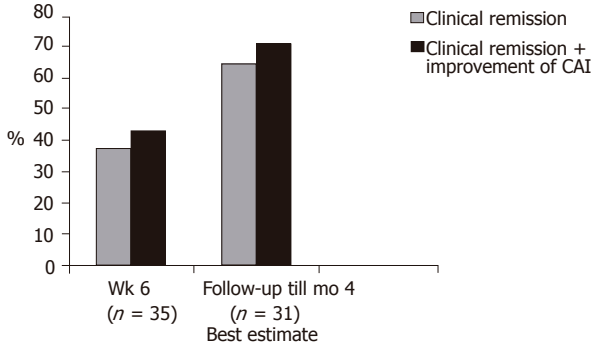

Figure 2 Patients (ITT analysis) in clinical remission or improved during a 4-mo follow-up period without additional apheresis therapy.

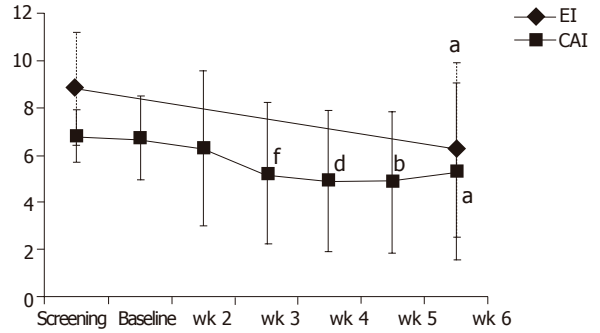

Figure 3 Course of clinical and endoscopic activity indices (CAI, EI) throughout the apheresis treatment. [a]*P*<0.05 *vs* Et at wk 6, [b]*P*<0.01 *vs* Et at wk 5, [d]*P*<0.01 *vs* Et at wk 4, [f]*P*<0.05 *vs* Et at wk 3.

Intent-to-treat analysis

At the end of the treatment period (at wk 6) 13/35 patients (37.1%) achieved clinical remission (CAI≤4). Remission or clinical improvement was observed in 15/35 (42.8%) of the patients. During a follow-up period (up to 4 mo), the number of patients achieving clinical remission increased to 20/31 patients (65%) (best estimate) (Figure 2). Except for doses of steroids no other relevant changes in medication occurred during the follow-up. Four patients lost the follow-up. The clinical remission rate of patients with concomitant immunosuppressants was 23% (3/13 patients) at wk 6 and 54.5% (6/11 patients) at the end of the follow-up. Figure 3 displays the course of clinical (CAI) and endoscopic (EI) activity. Both indices dropped significantly between the beginning and end (at wk 6) of the treatment period.

Endoscopic remission (EI<4) was observed at wk 6 in 10/35 (28.6%) patients. Mucosal healing (vulnerability of mucosa and mucosal damage scores) was improved in 19 patients, unchanged in 13 patients and deteriorated in 3 patients (P<0.001).

Between wk 0 and 6, changes in histology improved in 14 (44%) patients, no change in 16 (50%) and deteriorated in 2 (6%) patients (P<0.002).

Quality of life of the 30 non-Italian patients (IBDQ) improved rapidly by 17 points within 3 wk of treatment (P<0.01) and reached 162±6.4 points at wk 6 which was

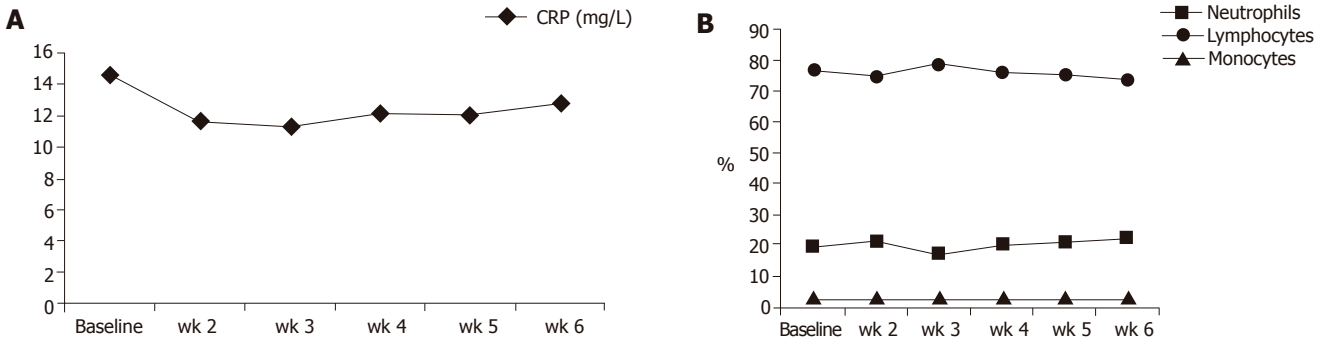

Figure 4 Course of neutrophil, lymphocyte, and monocyte counts as well as CRP between the beginning and wk 6 of the study (numbers are given as means; no significant differences).

significantly ($P<0.01$) better than that at the beginning of the study (138.1±4.8 points).

Physician's global assessment at wk 6 was 'very much improved' (11.4%), 'much improved' (37.1%), 'minimally improved' (25.7%), 'no change' (20.0%), 'minimally worse' (5.7%) and 'much worse' (0%).

Figure 4 displays the results of blood cell counts and CRP serum concentrations between the beginning and wk 6 of the study. With the exception of the lymphocyte count all other numbers dropped, but none of those changes reached statistical significance.

Consumption of systemic steroids decreased significantly ($P<0.05$) throughout the whole treatment period. The median total dose of systemic steroids was decreased from 20.0 mg/d at baseline to 15.0 mg/d at wk 6. The means were 26.1±18.04 mg/d and 16.5±15.56 mg/d, respectively. At the end of 4-mo follow-up period, the median daily dose of steroids was 6.5 mg (mean daily dose: 14.6±16.8 mg).

Per-protocol analysis

One patient of the ITT patient group experienced several changes of his dose of steroids (increase or decrease >10 mg) throughout the study. He was, therefore, excluded from the per-protocol analysis. The patient did not achieve clinical remission but had clinical improvement.

Safety analysis

No unexpected adverse events occurred. The 35 patients included experienced a total of 46 adverse events (AEs) in 65 episodes recorded. Three events were serious: thrombosis of the lower leg, worsening of UC, and a significant drop of hemoglobin which could not be explained despite extensive investigations (the patient recovered quickly). The causality was judged as unlikely, none and possible, respectively. All other AEs were judged as non-serious and mild or moderate. Ten had no causal relationship to the study treatment, 38 had a possible, and 3 had a probable relationship. The three AEs probably related to the therapy were finger edema, right arm phlebitis, and paresthesia of the left hand. All of them were classified as mild. The 38 events judged as possibly related were headache, abdominal disorder, dysesthesia, dizziness, nausea, flush, muscle cramps, fatigue, vegetative dystonia, mood alteration, prostate inflammation, and urinary tract infection. They were judged as mild (28) or moderate (10). Those events classified as unlikely related to the study treatment were oral aphthae, vertigo, headache, common cold, cramps, thrombosis, arthralgia, meralgia, ankle swelling, and bronchopneumonia. Laboratory testing as mentioned in Methods did not reveal any significant alterations.

DISCUSSION

Granulocyte apheresis application with five scheduled sessions strongly suggests efficacy in chronically active steroid refractory UC in the study reported here. A short treatment period of 5 wk resulted not only in significant clinical but also in significant endoscopic and histological improvements. Moreover, when aphereses were stopped, further beneficial effects could be observed. A follow-up period of 4 mo demonstrated carryover effects of the initial treatment leading to clinical remission in three out of four patients. Apheresis treatment was safe and well tolerated.

These very good results must be critically seen in the light of the open uncontrolled study design. Extracorporal treatment, apparently different from medicinal or surgical therapy, is a new method also for 'experienced' patients, a fact which may hold some placebo effects. Other studies demonstrated that the placebo effect is up to 30% in similar patient groups (e.g. 14) but to our knowledge, none of those trials allowed ongoing intensive treatment (dose of steroids, immunosuppressants) at entry to the study as in the present study. All patients kept on having their initial unsuccessful treatment with steroids and in part with immunosuppressants. Recent results of other studies support our findings. Yamamoto *et al*.[15] described 70% clinical remission in 30 patients with active distal UC and Naganuma *et al*.[16] found a remission rate of 55% in either steroid refractory or dependent patients. Both trials used a similar treatment protocol.

The apheresis system is used to remove excess and activated leukocytes from peripheral blood. The release of proinflammatory cytokines in the peripheral blood such as tumor necrosis factor-α (TNF-α), interleukin-1β (IL-

1β), IL-6, and IL-8 is suppressed as well as the leukocyte adhesion molecules (L-selectin) and neutrophil adhesion to IL-1β-activated endothelial cells are downregulated[17-20]. In addition, it exerts antioxidant effects[21] and the production of anti-inflammatory substances such as IL-1 receptor antagonist (IL-1ra), IL-10, and soluble TNF-α receptors I and II (sTNF-α RI and sTNF-α RII) is increased[22,23]. UC patients with high mucosal content of IL-8mRNA responding well to granulocyte apheresis and mucosal IL-8mRNA can be significantly reduced[24]. Granulocyte apheresis seems also to modulate apoptosis[17]. These far reaching interventions on inflammatory immune reactions may explain the carryover effects of granulocyte apheresis, when its application is stopped and standard treatment is continued.

Adsorption techniques may lead to a decrease of circulating blood cells. Indeed peripheral granulocytes decrease significantly by 22% after a 60-min apheresis application in UC patients, but no granulocytopenia occurs[18]. Measurements of pre- and post-column blood cell counts have demonstrated adsorption of 65% of granulocytes, 55% of monocytes, and 2% of lymphocytes, but the number of peripheral leukocytes does not fall below the normal level[19]. Flow cytometry has shown an increase in the number of immature circulating granulocytes (CD 10^- neutrophils) which should be less proinflammatory[17]. The modest effect of apheresis on blood cell counts may prevent dangerous immunosuppressive adverse events seen in systemically acting immunosuppressants.

The protocol of our study prescribed 5-wk apheresis sessions with a duration of 60 min and a flow rate of 30 mL/min, a procedure which is based on empiricism. Intensification of this low exchange technique might create more rapid and/or more favorable therapeutic results. In a large trial in patients with rheumatoid arthritis the protocol here was compared to apheresis twice per week and no therapeutic advantage of intense treatment could be observed[20]. In a small study in patients with UC, intensified apheresis revealed more rapid but not superior therapeutic effects[25]. As yet the most effective procedure remains unclear. Another way to intensify the effects of apheresis is to increase the exchange of blood per time by augmenting the flow rate during the procedure. This may create technical difficulties. The easy technical success of the protocol as it occurred in the present study is based on the low exchange protocol. Simple handling is a prerequisite of the method for its introduction to non specialized (apheresis) units.

In conclusion, granulocyte apheresis seems to be a very promising treatment, particularly in severely ill patients with UC. For patients refractory to standard therapies, it could offer an alternative which is safe and well tolerated. Controlled studies are urgently warranted.

Abstract

AIM: To assess the appropriateness of referrals and to determine the diagnostic yield of colonoscopy according to the 2000 guidelines of the American Society for Gastrointestinal Endoscopy (ASGE).

METHODS: A total of 736 consecutive patients (415 males, 321 females; mean age 43.6±16.6 years) undergoing colonoscopy during October 2001-March 2002 were prospectively enrolled in the study. The 2000 ASGE guidelines were used to assess the appropriateness of the indications for the procedure. Diagnostic yield was defined as the ratio between significant findings detected on colonoscopy and the total number of procedures performed for that indication.

RESULTS: The large majority (64%) of patients had colonoscopy for an indication that was considered "generally indicated", it was "generally not indicated" for 20%, and it was "not listed" for 16% in the guidelines. The diagnostic yield of colonoscopy was highest for the "generally indicated" (38%) followed by "not listed" (13%) and "generally not indicated" (5%) categories. In the multivariable analysis, the diagnostic yield was independently associated with the appropriateness of indication that was "generally indicated" (odds ratio=12.3) and referrals by gastroenterologist (odds ratio =1.9).

CONCLUSION: There is a high likelihood of inappropriate referrals for colonoscopy in an open-access endoscopy system. The diagnostic yield of the procedure is dependent on the appropriateness of indication and referring physician's specialty. Certain indications "not listed" in the guidelines have an intermediate diagnostic yield and further studies are required to evaluate whether they should be included in future revisions of the ASGE guidelines.

Key words: Colonoscopy; Indications; Diagnostic yield; Guidelines; Appropriateness

INTRODUCTION

Over the last two decades, there has been a remarkable advancement in gastrointestinal endoscopy, and colonoscopy has become the most commonly performed procedure for the diagnosis and treatment of diseases of the large intestine as well as screening for colon cancer[1,2]. The increasing availability of colonoscopy, however, has also led to an inappropriate referral and overuse of this procedure, which is reported to range between 15% and 35% in different studies[3-6]. Consensus-based guidelines for appropriate referral of both upper and lower gastrointestinal endoscopic procedures have been developed by several expert panels[7,8]. The American Society for Gastrointestinal Endoscopy (ASGE) has also developed and periodically reviews the guidelines on the appropriate use of these procedures with the latest update made in the year 2000[9].

The diagnostic yield of an endoscopic procedure is defined as its capacity for identifying a lesion that is potentially important to patient care and has been reported for both upper and lower endoscopy in relation to the appropriateness of the indication[8]. For colonoscopy, it is reported to range 40-45% for procedures that are referred for appropriate indications, and 15-20% for those with inappropriate indications[3,6,8,10].

The objectives of this study were to evaluate the appropriateness of referrals for colonoscopy based on

the 2000 ASGE guidelines on the appropriate use of gastrointestinal endoscopy, and to assess the diagnostic yield of the procedure according to these guidelines.

MATERIALS AND METHODS

For administrative purposes, Kuwait with its population of about 2.2 million is divided into six districts, each with a well-defined area and population. Medical services in each district comprise a network of primary care clinics and a general public hospital. In addition, there are a number of centralized specialty hospitals. Our study was conducted at the Thunayan Al-Ghanim Gastroenterology Center, which offers modern facilities in gastrointestinal endoscopy, and treatment and follow-up of gastroenterology and hepatology patients. The center provides open access endoscopy services for five out of six general public hospitals in Kuwait. Primary care physicians and specialists working in hospitals can directly refer patients for endoscopy. The majority of endoscopies are performed without prior consultation with a gastroenterologist.

This study was carried out prospectively between October 2001 and March 2002. Demographic data, in/outpatient status, specialty of the referring physician, indications for the procedure, and results of colonoscopy (including histologic reports, if any) were recorded in a standardized form specifically developed for this study. The year 2000 ASGE guidelines were used to determine the appropriateness of indication(s) for the procedure. These guidelines were printed on the form used for data collection, but the headings "generally indicated" and "generally not indicated" were omitted to avoid bias. Before starting the colonoscopy, the endoscopist obtained a brief history from the patient to confirm the indications for the procedure and to exclude any contraindications. If the indications were not listed in the ASGE guidelines, the endoscopist was asked to record it separately on the form. If the patient had more than one indication for colonoscopy and at least one of these was "generally indicated" by the guidelines, then the procedure was considered appropriate.

Diagnostic yield in relation to each indication was defined as the ratio between significant findings detected on colonoscopy and the total number of procedures performed for that indication. Based on the criteria followed in previous studies[3,6,11], the presence of any of the following lesions was considered as a significant finding on colonoscopy: a pre-malignant or malignant lesion, inflammatory bowel disease (IBD) (either newly diagnosed or a more precise diagnosis or determination of the extent of the disease that influenced immediate management of the disease), angiodysplasia, stricture (benign or malignant), other colitides (infectious, ischemic, eosinophilic, microscopic), and diverticulosis (as a definite or presumptive cause of acute hematochezia)[12]. The following were not considered as significant findings: normal colonoscopy, hemorrhoids, anal fissures, previously established IBD, uncomplicated diverticulosis, and nonadenomatous polyps. The study was carried out in accordance with the ethical standards of our institution and the Helsinki Declaration as revised in 1989.

We used Student's *t*-test to compare the difference between two means and the normal *Z* test to assess the significant difference between two proportions. Multiple logistic regression analysis was performed to study the clinical parameters independently associated with diagnostic yield of colonoscopy. $P<0.05$ was considered statistically significant. All *P* values presented are two sided. The data were analyzed using SPSS 13.0 for Windows software (SPSS Inc., Chicago, IL, USA).

RESULTS

A total of 759 patients were referred for colonoscopy during the study period. Colonoscopy could not be performed in 23 of these patients because of inadequate bowel preparation. None of the patients had any contraindications for the procedure. Table 1 shows the demographic and clinical characteristics of the 736 patients (415 males, 321 females) who were prospectively enrolled in the study. The mean age of the patients was 43.6±16.6 years (range 1-90 years), and the large majority (82.3%) were outpatients. The majority of the patients were referred by general physicians (34.6%) and surgeons (33.4%).

Table 1 Demographic and clinical characteristic of 736 patients undergoing colonoscopy in Kuwait

Characteristic	*n* (%)
Gender	
Male	415 (56.4)
Female	321 (43.6)
Age (yr)

Pediatric gastroenterologist	22 (3.0)
Other[1]	8 (1.1)
Clinical status	
Inpatient	130 (17.7)
Outpatient	606 (82.3)

[1]Oncologist (6), gynecologist (2).

Indications for colonoscopy

Of the 736 patients, 468 (63.6%) had colonoscopy for an indication that was considered appropriate according to the ASGE guidelines (Table 2). The two most common indications were "hematochezia" and "diarrhea of

Table 2 Indications for colonoscopy among 468 patients referred for reasons generally indicated according to the 2000 ASGE guidelines[1]

Indication	*n* (%)
1 Hematochezia	151 (20.5)
2 Clinically significant diarrhea of unexplained origin	65(8.8)
3 Irritable bowel syndrome or chronic abdominal pain: colonoscopy done once to rule out organic disease	48(6.5)
4 Chronic inflammatory bowel disease of the colon, if more precise diagnosis or determination of the extent of activity of disease will influence immediate management	34 (4.6)
5 Unexplained iron deficiency anemia	27 (3.7)
6 Following adequate clearance of neoplastic polyp(s) survey at 3-5 year intervals	24 (3.3)
7 Colonoscopy to remove synchronous neoplastic lesions at or around time of curative resection of cancer followed by colonoscopy at 3 years and 3-5 years thereafter to detect metachronous cancer	23 (3.1)
8 Evaluation of an abnormality on barium enema or other imaging study, which is likely to be clinically significant, such as a filling defect or stricture	19 (2.6)
9 Presence of fecal occult blood	12 (1.6)
10 Examination to evaluate the entire colon for synchronous cancer or neoplastic polyps in a patient with treatable cancer or neoplastic polyp	11 (1.5)
11 Excision of colonic polyp	9 (1.2)
12 Balloon dilation of stenotic lesions (e.g., anastomotic strictures)	9 (1.2)
13 Melena after an upper GI source has been excluded	8 (1.1)
14 In patients with ulcerative or Crohn's pancolitis eight or more years' duration or left sided colitis 15 or more years' duration every 1-2 years with systematic biopsies to detect dysplasia	8 (1.1)
15 Treatment of bleeding from such lesions as vascular malformation, ulceration, neoplasia, and polypectomy site (e.g., electrocoagulation, heater probe, laser or injection therapy)	7 (1.0)
16 Family history of sporadic colorectal cancer before the age of 60: colonoscopy every 5 years beginning at the age of 10 years earlier than the affected relative or every three years if adenoma is found	6 (0.8)
17 Intraoperative identification of a lesion not apparent at surgery (e.g., polypectomy site, location of a bleeding site)	3 (0.4)
18 Family history of hereditary non-polyposis colorectal cancer: colonoscopy every two years beginning at the age of 25, or five years younger than the earliest age of diagnosis of colorectal cancer. Annual colonoscopy beginning at the age of 40	2 (0.3)
19 Palliative treatment of stenosing or bleeding neoplasms (e.g., laser, electrocoagulation, stenting)	2 (0.3)

[1]According to 2000 American Society for Gastrointestinal Endoscopy (ASGE) guidelines on appropriate use of gastrointestinal endoscopy[9].

unexplained etiology". Whereas, 149 (20.2%) patients underwent colonoscopy for an indication, which was "generally not indicated" (Table 3), and for 119 (16.2%) patients the indication for colonoscopy was not listed in the guidelines (Table 4). The most common indications for patients in these two categories were "chronic, stable, irritable bowel syndrome or chronic abdominal pain", and "constipation", respectively.

Table 5 shows the appropriateness of indications for colonoscopy in relation to patients' gender, age, admission status, and specialty of the referring physician. There was no material difference in the appropriateness of indications between males and females or in- and out-patients. The mean age of patients who had colonoscopy for an indication that was "generally not indicated" was significantly lower than those who had the procedure for an indication that was "generally indicated" or "not listed" in the guidelines (38.2 *vs* 44.7 years, $P<0.0001$). Patients aged <15 years and those >50 years had a higher proportion of procedures for an indication that was considered "generally indicated" by the guidelines (77.4% and 74.6%, respectively). On the other hand, 29.5% of the patients aged 15-49 years had a significantly higher proportion of colonoscopies for an indication that was considered "generally not indicated" ($P<0.0001$). There was no real difference in the age groups when the procedure was performed for an indication that was "not listed" in the guidelines.

Pediatric gastroenterologists referred the highest proportion of patients (81.8%) for colonoscopy for an indication that was considered "generally indicated", followed by adult gastroenterologists (66.8%), surgeons (62.2%) and general physicians (60.4%). Among other specialists, general physicians referred the highest proportion of patients for colonoscopy for a reason that was considered "generally not indicated", while surgeons referred the highest proportion of patients for a "not listed" indication.

Diagnostic yield of colonoscopy

A total of 200 patients had one or more significant findings on colonoscopy giving an overall diagnostic yield of 27.2%. The most common significant findings were adenomatous polyps (29.5%), new diagnosis or more precise determination of the extent of IBD (23.5%) and colorectal cancer (12.0%). The yield of the procedures performed for "generally indicated" category was 37.8%, which was significantly higher than "generally not indicated" (4.7%, $P<0.0001$) and "not listed" (13.4%, $P<0.0001$) categories in the ASGE guidelines (Table 5). The yield of the procedures performed for "not listed" indications was also significantly higher than that for "generally not indicated" procedures (13.4% *vs* 4.7%, $P<0.05$). Inpatients had a higher diagnostic yield of

Table 3 Indications for colonoscopy among 149 patients referred for reasons generally not indicated according to the 2000 ASGE guidelines[1]

Indication	*n* (%)
1 Chronic, stable, irritable bowel syndrome or chronic abdominal pain	117 (15.9)
2 Routine follow-up of inflammatory bowel disease	15 (2.0)
3 Acute diarrhea	7 (1.0)
4 Metastatic adenocarcinoma of unknown primary site in the absence of colonic signs or symptoms when it will not influence management	6 (0.8)
5 Upper GI bleeding or melena with a demonstrated upper gastrointestinal source	4 (0.5)

[1]According to 2000 American Society for Gastrointestinal Endoscopy (ASGE) guidelines on appropriate use of gastrointestinal endoscopy[9].

Table 4 Indications for colonoscopy among 119 patients referred for reasons not listed in the 2000 ASGE guidelines[1]

Indication	*n* (%)
1 Constipation	71 (9.6)

[2]CI, confidence interval.
[3]According to 2000 American Society for Gastrointestinal Endoscopy (ASGE) guidelines on appropriate use of gastrointestinal endoscopy[9].

colonoscopy compared to outpatients (35.4% *vs* 25.4%, $P<0.05$). The highest diagnostic yield was obtained in those aged <15 years, and in those who were referred by a gastroenterologist.

Table 6 lists some of the significant findings on colonoscopy by appropriateness of referrals. Colorectal cancer, adenomatous polyps, and IBD were more likely to be detected, if the colonoscopy was performed for a "generally indicated" reason. The colon was reported as completely normal in 82.6% of the patients in the "generally not indicated" and 73.9% in "not listed" groups, compared to 51.7% in the "generally indicated" group.

Determinants of diagnostic yield

Table 7 shows the association between selected clinical parameters and diagnostic yield of colonoscopy. The probability of finding a clinically significant lesion was significantly higher in patients aged ⩾50 years (odds ratio = 1.6), inpatients (odds ratio = 1.6), those referred by gastroenterologists (odds ratio = 1.9), and those who had the colonoscopy for "generally indicated" (odds ratio = 12.3) or "not listed" (odds ratio = 3.2) categories. After adjustment for the other variables, appropriateness of indications for colonoscopy according to the ASGE guidelines and referrals by gastroenterologist were the two independent parameters associated with the diagnostic yield.

DISCUSSION

To our knowledge, this is the first study to assess the appropriateness of referrals for colonoscopy and to determine the diagnostic yield according to the year 2000 ASGE guidelines. About 64% of our patients had an indication for colonoscopy that was appropriate or

"generally indicated", according to the ASGE guidelines. This finding is similar to the 61-66% rate reported from open-access colonoscopy settings in the United States, Italy and Switzerland[3,5,6,8]. A higher rate (81%) has been reported in a study from the United States, where the referring physicians were instructed on the accepted indications for gastrointestinal endoscopy[4]. All these studies were based on the 1992 version of the ASGE guidelines. The year 2000 guidelines include several new conditions for which colonoscopy is now considered "generally indicated" such as all patients presenting with hematochezia, while the older guidelines only considered colonoscopy to be appropriate, if the hematochezia was not thought to be from the rectum or a perianal source. In addition, screening of asymptomatic, average risk patients for colonic neoplasia and seven new therapeutic indications have been included in the new guidelines. Inclusion of these additional indications means that a higher proportion of the patients referred for open-access colonoscopy should have an appropriate indication for the procedure. In our study, the overall rate of "generally indicated" colonoscopies was comparable to the studies based on the 1992 guidelines. It is noteworthy that our patients were relatively younger than those in other studies. Compared to an average age of 53-62 years in other studies, the average age of our patients was about 44 years and 60% were aged between 15 and 49 years. This may be the reason why we did not have a higher proportion of patients referred for appropriate indications even though we used more "liberal" ASGE guidelines. We did, however, observe a higher rate of "generally indicated" colonoscopy for patients aged <15 years (77%), which is not unexpected as colonoscopy is usually not performed in children unless an appropriate indication is present, and for those aged >50 years (75%).

We found no real difference between various specialties when patients were referred for a "generally indicated" colonoscopy. As for "generally not indicated" procedure, the rate was lowest for surgeons, while that for gastroenterologists was similar to general physicians. This finding is consistent with a study of open-access colonoscopy from Italy which reported similar rates of "generally not indicated" colonoscopy between gastroenterologists and family physicians[5], but is in contrast with studies of open access upper gastrointestinal endoscopy[13]. The majority (80%) of "generally not indicated" colonoscopies requested by gastroenterologists in our study were for chronic stable abdominal pain or irritable bowel syndrome (IBS), while the other 20% were for routine follow-up of IBD. This high referral rate of colonoscopy for chronic stable abdominal pain or IBS by gastroenterologists may be because in Kuwait many such patients after failing to respond to therapy are referred to the gastroenterology clinics by primary care physicians. When these patients were excluded from the analysis, the rate of "generally indicated" colonoscopy for gastroenterologists increased to about 83%, which was higher than that for all other specialties.

In our study, the definition of significant findings was based on certain positive results on colonoscopy. A normal colonoscopy was not considered significant, although this may be relevant to patient care as it may rule out a serious disease in the colon. Our results show that the diagnostic yield of colonoscopy was independently associated with appropriateness of indications and referrals by gastroenterologists. Our findings are consistent with studies conducted in Europe and the United States[3,6,11], but the difference between the yield of "generally indicated' and "generally not indicated' procedures (37.8% *vs* 4.7%) is much higher than reported in these studies. Charles *et al*.[3] reported that 40% of patients who have colonoscopy for an ASGE (1992 version) approved indication have a significant pathological finding compared to 22% of those who do not meet the guidelines. Similarly, Morini *et al*.[6] have reported a diagnostic yield of 43% for "generally indicated" and 16% for "generally not indicated" categories. De Bosset *et al*.[11], using the Swiss criteria developed by the Rand Corporation/University of California at Los Angeles (RAND/UCLA) panel, have reported a diagnostic yield of 26% for patients who have colonoscopy for an appropriate or uncertain indication and 17% for those with an inappropriate indication. The higher difference in the diagnostic yield of colonoscopy for a "generally indicated" and "generally not indicated" category seen in our study suggests that the 2000 ASGE guidelines for appropriate use of gastrointestinal endoscopy are more efficient in discriminating indications for colonoscopy than the earlier versions or the Swiss (RAND/UCLA) criteria.

The year 2000 ASGE guidelines clearly differentiate between the "generally indicated" and "generally not indicated" colonoscopies in terms of the diagnostic yield of the procedure. Clinicians can therefore predict the expected yield of colonoscopy as long as the indications for the procedure can clearly be classified as "generally indicated' or "generally not indicated". However, in clinical practice there are always some patients who undergo colonoscopy for indications that cannot be clearly classified into either of these two categories. It has been reported that about 12-28% of the patients undergoing colonoscopy have indications that are not listed in the ASGE guidelines[5,6,8]. In our study, the proportion of patients in "not listed' category was about 16% with a diagnostic yield of 13.4%, being about three times higher than the diagnostic yield of colonoscopy which is "generally not indicated". Among the patients in the "not listed' category, three were diagnosed with colorectal cancer compared to none in the "generally not indicated" group and the proportion of patients diagnosed with adenomatous polyps and IBD was also higher. The ASGE guidelines appear to be deficient with regard to these "not listed" indications, but it is acknowledged that clinical considerations may occasionally justify a course of action at variance with the recommendations of the ASGE. The two most frequent unlisted indications in our study were constipation and unexplained weight loss, and all three cases of colorectal cancer were found in patients who underwent colonoscopy for constipation. Clear recommendations are needed for such common unlisted

indications such as constipation as provided in the Swiss and American panel-based guidelines[8]. Further studies are needed to identify other common but unlisted indications that may be included in future versions of the ASGE guidelines.

In summary, the results of this prospective study demonstrate that a large proportion of colonoscopies performed in an open-access system in Kuwait is for the indications considered inappropriate by, or not listed in the 2000 guidelines of the ASGE on appropriate use of gastrointestinal endoscopy. The probability of identifying a significant finding on colonoscopy is particularly higher when the indications for the procedure are judged to be appropriate by the ASGE guidelines, but a proportion of patients who undergo colonoscopy for an unlisted indication also have significant findings. Further studies are required to evaluate these unlisted indications to determine whether they should be included in future revisions of the guidelines. General physicians need further edification for appropriate referrals of patients for colonoscopy.

Abstract

AIM: To evaluate the role of surgical treatment for isolated loco-regional recurrences of operated gastric adenocarcinoma.

METHODS: Among the 837 patients operated for gastric adenocarcinoma between December 1979 and April 2004, 713 (85%) underwent resection with curative intent. A retrospective review of a prospectively collected gastric cancer database was carried out. Overall recurrence rate was 44% (315 cases), with 75% occurring within the first 2 years from the operation. Isolated L-R recurrences were observed in 38 (12%) patients. Symptomatic lesions were observed in 27 (71%).

RESULTS: Six (16%) patients were macroscopically resected with curative intent. The recurrence was located in the gastric stump after a STG in three patients, in the esophagojejunal anastomosis after a TG in two patients and in the gastric bed after a TG in one patient. Surgical procedures consisted of three secondary TG, two esophagojejunal resection and one excision of an extraluminal recurrence. Postoperative complications occurred in two patients (33%), including one anastomotic leakage and one hemorrhage. The latter patient died of sepsis 35 d after the surgery (mortality rate 17%). All patients died of recurrent gastric cancer: 2 within 1 year from surgery (8 and 11 mo, respectively), 2 after 16 and 17 mo respectively and 1 after 28 mo from the second operation.

CONCLUSION: Surgery plays a very limited role in the treatment for isolated loco-regional recurrence of gastric adenocarcinoma.

INTRODUCTION

Despite the decreasing overall incidence, gastric adenocarcinoma is still one of the most common causes of death for cancer worldwide. Even after curative gastrectomy, disease recurrence occurs in 22-50% of patients, mostly within two years from the operation[1-5].

Loco-regional (L-R) recurrence results from lymphatic spread or direct tumor propagation within the abdominal cavity[6]. Several series tried to clarify the relationship between clinicopathologic features of the primary tumor and failure patterns[1-5,7-11]. In any case, effective therapies are lacking and surgical resection is only rarely possible.

The aim of this study was to retrospectively analyze our experience with the surgical treatment of L-R recurrence in patients operated for gastric cancer.

MATERIALS AND METHODS

Out of the 905 patients submitted to gastric resections between December 1979 and April 2004, 837 with adenocarcinoma were entered and followed in a prospectively recorded database. Among these, 713 (85%) underwent resection with curative intent, consisting of 392 total gastrectomies (TG) and 321 proximal or subtotal distal gastrectomies (STG). Standard D2 lymph node dissection was performed in most patients, with D3 dissection performed for curative intent in selected cases. Pathologic stage distribution, according to the 1997 TNM classification[12], included stages IA (11%), IB (13%), II (14%), IIIA (15%), IIIB (16%), and IV (31%). All stages up to IV were due to N category or T4 classification in the presence of positive nodes. The most common histological type was intestinal (53%), according to Lauren's criteria.

All patients were included in a prospectively collected database. Follow-up examinations were performed 1 mo

Table 1 Resected patients' background at the time of the primary operation

Sex	Age	Staging	Operation	Adjuvant therapy	Histology	Tumor-free interval (mo)
1 M	72	T3N2M0	STG	CHT	Diffuse	9
2 F	60	T3N0M0	STG	–	Diffuse	21
3 M	49	T3N2M0	STG	CHT	Intestinal	12
4 M	63	T3N2M0	TG	CHT	Diffuse	16
5 M	66	T4N1M0	TG	CHT	Diffuse	24
6 F	58	T2N1M0	TG	–	Intestinal	50

after the surgery, once in every 3 mo during the first 2 years, every 6 mo for the first 5 years and yearly thereafter. Follow-up program included physical examination, laboratory analysis including serum tumor markers (CEA, CA 19-9, and CA 72-4) at each visit, abdominal ultrasound or computed tomography (CT) and chest radiograph every 6 mo and endoscopy once a year. Follow-up information was regularly obtained from outpatient clinical visits, from the time of surgery to May 2004 or until death. Median follow-up was 13 mo (range 1 mo to 163 mo).

Recurrences were classified according to the definition of Lenhert *et al*. as distant metastasis and L-R recurrences, including local lymph nodes metastasis, extraluminal recurrence, recurrence within the gastric remnant after STG and esophagojejunal anastomosis recurrence after TG[6].

Overall recurrence rate was 44% (315 cases), with 75% occurring within the first 2 years from the operation. Disease recurrence was rare after 5 years (5%). Isolated L-R recurrences were observed in 38 (12%) patients, while distant metastasis only in 167 (53%) and combined in the remaining 110 (35%). Symptomatic lesions were observed in 27 (71%), mostly including upper digestive obstruction and pain. In the asymptomatic patients, the recurrence was incidentally discovered during routine follow-up, most commonly by CT scan and occasionally by endoscopy or tumor markers elevation.

RESULTS

Six (16%) patients were macroscopically resected with curative intent, representing 4% only of all observed L-R recurrences. The other 32 patients underwent conservative treatment in 25 cases (66%), laparotomy only in five cases (13%) and by-pass procedure in two cases (5%). Resected patients' background at the time of the primary operation is shown in Table 1. Mean tumor-free interval was 22 mo.

The recurrence was located in the gastric stump after a STG in three patients, in the esophagojejunal anastomosis after a TG in two patients and in the gastric bed after a TG in one patient. Surgical procedures consisted of three secondary TG, two esophagojejunal resection and one excision of an extraluminal recurrence. Postoperative complications occurred in two patients (33%), including one anastomotic leakage and one hemorrhage. The latter patient died of sepsis 35 d after the surgery (mortality rate 17%). Three patients received adjuvant chemotherapy (CHT) after the second operation, in two combined with intraoperative radiation therapy (IORT). Clinical course of the resected cases is described in Table 2.

Table 2 Clinical course in resected cases

Case	Recurrent site	Operation	Adjuvant therapy	Survival (mon)	Recurrence
1	Gastric stump	TG-liver segmentectomy	–	16	Distant
2	Gastric stump	TG-splenectomy	CHT+IORT	28	Distant
3	Gastric stump	TG-liver segmentectomy	CHT+IORT	17	Combined
4	Esophagojejunal anastomosis	Resection	–	1	–
5	Esophagojejunal anastomosis	Resection	–	8	Combined
6	Gastric bed	Excision	CHT	11	Loco-regional

All patients died of recurrent gastric cancer: 2 within 1 year from surgery (8 and 11 mo, respectively), 2 after 16 and 17 mo respectively and 1 after 28 mo from the second operation (Table 2). Mean survival of the palliated or non-resected patients was 8 mo.

DISCUSSION

Despite considerable improvement in the surgical treatment of gastric adenocarcinoma, recurrences still constitute the main cause of death in operated patients. Recent series showed overall incidence rates of 22-50% after curative surgery, mostly (75-80%) occurring within 2 years[1-5,7-11]. Our 44% recurrence rate is probably due to the high incidence (62%) of advanced operated gastric cancer cases, as for most Western experience. Moreover, our results confirm that recurrences beyond 5 years are rare (3-9%)[1,4,5,10,13]. Median survival from the time of recurrence is approximately 6 mo[1,2,7,10,13].

Gastric cancer recurrence include: L-R recurrence (regional lymph nodes, perianastomotic region, gastric bed, and stump), peritoneal recurrence and hematogenous metastasis (liver, lungs, bones, brain, and skin)[2,3,5,7-11]. As confirmed by our experience, combined recurrences are frequently observed and hematogenous or lymphatic spread without intra-abdominal metastases occur rarely[2,6-8]. An isolated L-R recurrence is reported in 6-46% of patients[1-3,7,8,10,11,13] and they were 12% in our series. Such differences may be explained by variations in the presentation of data, the definition of recurrence, as well as the mode and timing of detection[6,7,10,11].

Clinicopathologic features of the primary tumor that predict L-R recurrences are: proximal location, older age and male gender, advanced stage of disease (T3-4, N+), infiltrative growth, diffuse type and stromal reaction[2-5,7-11]. Although not statistically significant, almost all our cases were males, with advanced age (median 61 years), T4 N+ and diffuse type. Even though advanced stage of the disease is a common risk factor, early gastric cancer (EGC) may relapse in 1.4-6.4% of patients, mostly being hematogenous metastasis, but in approximately 20% of cases, L-R recurrences[2,14].

Diagnosis is improved with modern imaging and

mainly suggested by tumor markers elevation, endoscopy, and CT scan. As occurred in our experience, most patients are symptomatic and diagnosis is earlier in such cases[10,13]. Since early detection of recurrence do not improve overall survival of patients; however, according to some authors, until the development of a more effective treatment, routine follow-up is not indicated and should be reserved for symptomatic patients and to provide psychological support[1,13,15].

Some retrospective and small series showed the usefulness of CEA, CA 19-9 and CA 72-4 monitoring in detecting the recurrence of operated gastric cancer[16,17]. However, their elevation is often seen much later than detection of recurrence by imaging, especially in patients with low preoperative levels.

Endoscopic surveillance is the most accurate method to identify anastomotic or gastric stump recurrences after STG, allowing early diagnosis and radical treatment in highly selected cases[18], as it occurred for one patient of our series. Helical CT scan is the most commonly employed diagnostic tool in such cases, but its sensitivity is very low because of the limit in differentiating recurrent tumor from postoperative fibrotic and inflammatory changes[1,19,20].

Once the diagnosis of L-R recurrence has been made, curative surgical resection is only rarely possible. Available data in the literature do not allow a valid interpretation with respect to the different types of recurrence[6]. Excluding anecdotal cases of local lymph nodes or extraluminal recurrence excision[21-23], it appears that a curative resection is possible when a partial gastrectomy was previously performed. Approximately 20% of patients undergo surgical resection but in 2-6% only it may be considered curative, with a mean survival lower than 2 years[1,2,6,13,17,21]. In our series, the resection rate was extremely low. In fact, considering the 38 patients with isolated L-R recurrence, only six (16%) were resected. The remaining group was excluded from surgery mostly because the recurrences were not considered amenable to a curative resection or to the poor general condition. According to some authors, adjuvant chemoradiotherapy has a potential effect on improving prognosis[6,21,23].

Palliative resections are indicated in highly selected symptomatic patient, mainly to restore the food passage, while tumor reduction is of minor importance[2,6]. In those with poor general conditions and a short life expectancy, placement of covered expandable metallic stents is technically feasible and clinically effective[24,25].

In conclusion, surgery plays a very limited role in the treatment for isolated L-R recurrences of gastric cancer. In low-risk patients, especially if symptomatic, an attempt at resection may be justified in specialized center with acceptable postoperative mortality and morbidity, as there are no effective alternative therapies. At present, however, prevention or reduction of the frequency of recurrence, with more extended lymph nodal resection and the combination of perioperative adjuvant treatment[2,4,6,7,10,11], seem more important than the early detection and surgical treatment.

Abstract

AIM: To determine whether the hematocrit (Hct) at admission or at 24 h after admission was associated with severe acute pancreatitis (AP), organ failure (OF), and pancreatic necrosis.

METHODS: A total of 336 consecutive patients with a first AP episode were studied. Etiology, Hct values at admission and at 24 h, development of severe AP according to Atlanta's criteria, pancreatic necrosis, OF and mortality were recorded. Hemoconcentration was defined as Hct level >44% for males and >40% for females. The *t*-test and χ^2 test were used to assess the association of hemoconcentration to the severity, necrosis and OF. Diagnostic accuracy was also determined.

RESULTS: Biliary disease was the most frequent etiology (n = 148). Mean Hct levels at admission were 41±6% for females and 46±7% for males (P<0.01). Seventy-eight (23%) patients had severe AP, and OF developed in 45 (13%) patients. According to contrast-enhanced computed tomography scan, 36% (54/150) patients showed pancreatic necrosis. Hct levels were elevated in 58% (55/96) and 61% (33/54) patients with interstitial and necrotizing pancreatitis, respectively. Neither Hct levels at admission nor hemoconcentration at 24 h were associated with the severity, necrosis or OF. Sensitivity, specificity and positive predictive values for both determinations were very low; and negative predictive values were between 61% and 86%, being the highest value for OF.

CONCLUSION: Hct is not a useful marker to predict a worse outcome in acute pancreatitis. In spite of the high negative predictive value of hemoconcentration, the prognosis gain is limited due to an already high incidence of mild disease.

Key words: Acute pancreatitis; Hematocrit; Hemoconcentration; Severity; Necrosis

INTRODUCTION

Acute pancreatitis (AP) is an inflammatory process of the pancreas with variable involvement of peripancreatic tissues or remote organ systems. Mostly, it develops as a mild and auto-limited disease, but around 25% of patients present the severe form with an elevated mortality rate (30%), when compared with overall mortality (2-16%)[1,2]. This worrisome condition is due to the eventual development of organ failure (OF) and sepsis[3,4], both complications are associated with the concurrent development of necrotizing pancreatitis that occurs in 20-30% of the cases[2,5]. Severity is currently defined according to the Atlanta International Symposium on AP by the presence of local complications (pancreatic necrosis, pancreatic pseudocyst, and pancreatic abscess) and/or OF (cardiovascular, pulmonary or renal insufficiency, and gastrointestinal bleeding)[6]. Several efforts have been made to describe prognostic factors that could help for the identification of high risk patients in order to maintain a closer vigilance, thereby providing a more aggressive medical treatment and an earlier admittance to the intensive care unit[7].

The usefulness of multiple clinical and laboratory tests to predict severe and/or necrotizing pancreatitis has been studied[8]. Ranson's criteria are most widely accepted for the assessment of high risk patients; however numerous parameters need to be measured during the first 48 h after admission[9,10]. Other scales like Glasgow or APACHE II are commonly used, but these also require several measurements and have not been proven superior to Ranson's criteria[11,12]. More recently, biochemical

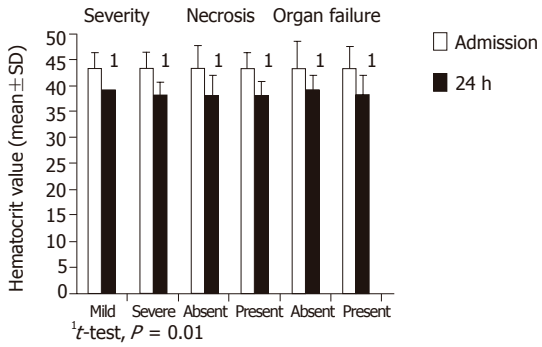

Figure 1 Mean hematocrit values at admission and 24 h later.

markers, such as C-reactive protein[13], polymorphonuclear elastase[14], interleukin-6 and trypsinogen activation peptide[15,16], have been used as predictors of severity in AP. C-reactive protein is a useful marker only 48 h after the onset of acute episodes[13,14] and overall usefulness of the remaining markers is restricted by their limited availability or elevated cost. Thus, so far, no early, accessible and economical predictive marker for severe AP has yet been described.

Hematocrit (Hct) is routinely assessed in every AP case at admission and is an accessible and low-cost test. Recent studies have proposed that hemoconcentration may constitute a good marker for severity of AP, but others were unable to find a significant correlation with the development of OF, pancreatic necrosis or death[17-20]. Thus, the value of hemoconcentration in the initial assessment of AP patients and its implications in prognosis remain controversial. We, therefore, aimed to determine whether hemoconcentration at admission and in the following 24 h was associated with the development of severe AP, pancreatic necrosis and/or OF.

MATERIALS AND METHODS

Patients with a first AP episode admitted consecutively to a tertiary medical center between June 1998 and December 2001 were included in this study. AP diagnosis was confirmed by typical clinical presentation and an increase in amylase or lipase concentration at least thrice the upper limit of normal, and/or evidence of pancreatic inflammation revealed by contrast-enhanced abdominal computed tomography[21]. Medical records of all the patients were reviewed retrospectively for the following variables: gender, age, etiology, Hct level at admission, Hct level at 24 h after admission, development of OF, and severity of AP (both defined according to Atlanta' s criteria)[6], evidence of necrosis in contrast-enhanced abdominal computed tomography, total hospital stay and mortality. Exclusion criteria included patients with previous AP episode(s) or with a first AP episode previously treated in other institutions.

Hematocrit levels at admission and 24 h later were compared with the severity of the pancreatitis, the presence of necrosis or OF. Categorical variables are expressed as absolute and relative frequencies and continuous variables as mean±SD. Receiver operator characteristic (ROC) curves were plotted for the range of Hct levels. Hemoconcentration was defined as an Hct level >44% for male and >40% for female patients[17-20]. The *t* test was used to analyze continuous variables, whereas the χ^2 or *F* tests were used on categorical variables, when appropriate. A *P* value <0.05 was considered statistically significant. Statistical analysis was performed using commercially statistical software SPSS 10 (SPSS, Chicago, IL, USA) and NCSS-2000 (NCSS, Kaysville, UT, USA).

RESULTS

Three hundred and thirty-six AP cases were included in the current study. Mean age was 45±17 (range, 15-90 years) years and 55% (*n* = 185) of patients were females. Sixteen patients (4.7%) were anemic according to reference values established for our population[22]. Mean Hct levels at admission were 41±6 for women and 46±7 for men (*P* = 0.00001). Biliary disease was the most common cause of the acute episode (*n* = 148, 44%), followed by alcohol abuse (*n* = 48, 14%). Other causes included: hypertriglyceridemia (9%), post endoscopic retrograde cholangiopancreatography (7%), drugs-induced (5%), post surgery (4%), obstructive disease (3%), hypercalcemia (1%), trauma (1%) and vasculitis (1%). Thirty-eight events were considered idiopathic (11%). When divided according to gender, biliary disease was more frequent in women and alcoholic pancreatitis was more frequent in men [odds ratio (OR) = 2.16; 95%CI 1.3-3.5 and OR = 40; 95%CI 9.7-243, respectively].

A mild AP episode was diagnosed in 258 (77%) patients, while the remaining 78 (23%) suffered from a severe attack. Organ failure developed in 45 (13%) patients. A contrast-enhanced abdominal computed tomography was performed during the first week after admission to assess the presence of necrosis in 150 cases. The Hct was determined in 233 (69%) patients 24 h after admission; of these, 183 patients (79%) presented with mild AP and 50 (21%) with severe AP. No differences were found in Hct levels at admission regardless of the presence of severe AP, necrosis or OF. A significant decrease in Hct levels was noted in all the patients at 24 h after admission, which was found to be independent of the severity status (Figure 1). There were no differences between the necrotizing and interstitial pancreatitis groups in terms of the fall in Hct levels after admission (7.5±4% *vs* 6.5±4%, respectively).

A ROC curve analysis for several cut offs of Hct levels at admission failed to show a single point combining good sensitivity, specificity, positive and negative predictive values for the detection of severe AP, necrotizing pancreatitis or OF (Figure 2).

However, the optimal cut-off values of Hct were similar to those used to define hemoconcentration (>44% for males and >40% for females). Neither the presence nor the absence of hemoconcentration at admission was associated to severity, necrosis or OF (Table 1). Hemoconcentration was present in 58% (55/96) and 61% (33/54) of patients with interstitial and necrotizing

pancreatitis, respectively. Hemoconcentration at 24 h was not associated to severity, necrosis or OF (Table 2). Hemoconcentration at admission and 24 h later had very low sensitivity, specificity, and positive predictive values for severity, necrosis or OF. Better results were obtained for negative predictive values (Table 3).

Hospital and intensive care unit stays were higher in patients with severe AP than mild cases (18±15 and 8±3 d *vs* 10±7 and 0.5±0.1 d, $P<0.05$). Mortality was significantly higher in patients with severe AP (13% *vs* 0.03%, $P = 0.001$).

DISCUSSION

One of the most important actions to cope with patients suffering from AP is to quickly and accurately assess the severity of the attack. Earlier identification of patients at risk of developing pancreatic necrosis and OF potentially improves their care via prompt admission to intensive care unit[23-25].

Besides the development of several prognostic systems for severity in AP, there are multiple biochemical tests[13-16] and clinical parameters[8,9,26-29] proposed as single markers for severe or necrohemorrhagic pancreatitis. Most of the laboratory assays have significant limitations in clinical practice mainly because they are expensive and not widely available. The clinical features might be the most economical and easily available parameters because they result from routine patient assessment. Among them, the presence of older age[8], alcohol etiology[9], time interval between onset of symptoms and admission[26], rebound tenderness/guarding[27], obesity[28], and android fat distribution[29] have been associated with the subsequent development of severe AP. The identification of these parameters as risk factors for the development of severe AP contributed to the understanding of the disease, but their impause of several drawbacks, such as biased clinical

data obtainment, controversial results and low sensitivity and/or specificity, and the results have been controversial.

AP is considered as a consequence from an insult to the pancreatic parenchyma that generates a local inflammatory reaction which then propagates and gives place to a generalized inflammatory response. Multiple studies have underlined the role of cytokines (e.g., tumor necrosis factor-α and interleukin-1, -6, and -8) and other inflammatory response mediators (e.g., platelet activating factor) in this propagating process[30]. Interestingly, the inflammatory response is always accompanied by the increase in vascular permeability that produces extravasation of

intravascular fluid into the peritoneal cavity[31,32]. The fluid loss significantly decreases the perfusion pressure into the pancreas leading to microcirculatory changes that contribute to pancreatic necrosis[33]. Thus, it has been proposed that hemoconcentration resulting from this fluid loss might well be associated with AP severity.

Gray and Rosenman[34] in 1965 reported that hemoconcentration at admission was a poor prognostic sign in patients with AP, but Talamini *et al*.[35] did not find significant differences of Hct levels obtained within 24 h of admission in survivors and non-survivors of AP. On the other hand, the classic study of Ranson[10] found that a fall in Hct level by greater than 10% during the initial 48 h of therapy correlates with severity and mortality. Thereafter, Baillargeon *et al*.[17] in a retrospective study reported that an admission Hct ⩾47% or, opposed to Ranson's finding, a failure of Hct to decrease at 24 h were predictive of necrosis but not of OF. The same group of authors in a subsequent prospective study of 128 patients with AP established an admission Hct ⩾44% and a failure to decrease after 24 h as the best binary predictor for necrosis and OF[18]. Both studies may have a referral bias in patient selection because the included patients transferred from other hospitals may correspond to sicker cases with a delay or less vigorous hydration. In some of the subsequent studies[36,37], elevated values of admission Hct were reported in necrotizing pancreatitis and also associated with serious complications but in all the studies, neither hemoconcentration at admission nor an Hct not decreasing after 24 h were able to predict severity (Table 4). In the current study, we could not find differences in the admission Hct between severe and mild cases. In every case, independently of the presence or absence of necrosis and/or systemic complications, there was a significant decrease in Hct levels at 24 h after admission. This finding might be explained by the common practice of aggressive fluid resuscitation in most of our patients with AP. The mean Hct fall at 24 h was under 10%, being non-significantly lower in necrotizing pancreatitis as expected in agreement with Ranson. According to our results, the accuracy of hemoconcentration at admission and at 24 h later as a marker for severe AP, necrotizing pancreatitis or OF lies in its high negative predictive value, mainly for OF (85% and 86%, respectively), as has been found in the previous reports (Table 4).

We analyzed a series of consecutive patients, including 4.7% of them with anemia, in order to test the utility of the Hct in a realistic clinical setting as was done by Khan *et al*.[16]. Our results were similar to those found by them, unlike our higher mean Hct levels. Admission Hct was analyzed separately in males and females as done by Lankisch *et al*.[20], but in addition to their approach, we also analyzed the Hct at 24 h after admission. Since Hct levels may differ according to atmospheric oxygen pressure (higher in high altitudes) and to gender (lower in females)[22], we constructed ROC curves that displayed cut-off values of Hct to define hemoconcentration at risk for severity in agreement with those previously reported by others[17-20]. Thus, anemia does not seem to play a role in the poor predictive accuracy of Hct in our study.

Our study is the only one that proves that hemoconcentration analyzed according to gender at admission and at 24 h is not a good predictor for severity in AP. We consider that our findings of the poor prognostic value of Hct at admission in AP cannot be attributed to sample bias. However, this is a retrospective study and only 69% of the patients had Hct determination at 24 h after admission; thus the lack of utility of the Hct at this time cannot be established strongly.

In conclusion, the sole clinical application that follows from the current study and several previous reports could be that patients without hemoconcentration have a very low likelihood of developing pancreatic necrosis or organ failure. However, we consider that in spite of the consistent findings of high negative predictive value of hemoconcentration for necrosis and/or OF, there is no prognostic gain because of the pre-existing 75% prevalence of mild AP.

Abstract

AIM: To estimate the incidence of catheter tract implantation metastasis among patients undergoing percutaneous transhepatic biliary drainage (PTBD) for extrahepatic cholangiocarcinoma, and to provide data regarding the management of this unusual complication of PTBD by reviewing cases reported in the literature.

METHODS: A retrospective analysis of 67 consecutive patients who underwent PTBD before the resection of extrahepatic cholangiocarcinoma was conducted. The median follow-up period after PTBD was 106 mo. The English language literature (PubMed, National Library of Medicine, Bethesda, MD, USA), from January 1966 through December 2004, was reviewed.

RESULTS: Catheter tract implantation metastasis developed in three patients. The cumulative incidence of implantation metastasis reached a plateau (6%) at 20 mo after PTBD. All of the three patients with implantation metastasis died of tumor progression at 3, 9, and 20 mo after the detection of this complication. Among the 10 reported patients with catheter tract implantation metastasis from extrahepatic cholangiocarcinoma (including our three patients), two survived for more than 5 years after the excision of isolated catheter tract metastases.

CONCLUSION: Catheter tract implantation metastasis is not a rare complication following PTBD for extrahepatic cholangiocarcinoma. Although the prognosis for patients with this complication is generally poor, the excision of the catheter tract may enable survival in selected patients with isolated metastases along the catheter tract.

INTRODUCTION

Percutaneous transhepatic biliary drainage (PTBD) has been widely employed as a biliary decompression procedure for malignant biliary obstruction[1-5]. It may cause implantation metastasis along the catheter tract, which has generally been considered as an unusual and lethal complication[6,7]. Although sporadic cases of such implantation metastasis have been reported[6-10], the incidence of this complication following PTBD is yet to be determined. Also, there is a paucity of data regarding the management of this complication. Taken together, these facts prompted us to conduct the current study.

The aims of this study were to estimate the incidence of catheter tract implantation metastasis among patients undergoing PTBD for extrahepatic cholangiocarcinoma, and to provide data regarding the management of this unusual complication by reviewing cases reported in the literature.

MATERIALS AND METHODS

Patient population

A total of 87 patients with carcinoma arising from the extrahepatic bile ducts (extrahepatic cholangiocarcinoma) underwent resection with curative intent at our department during the 15-year period between January 1988 and December 2002. Carcinoma arising from the cystic duct was categorized as extrahepatic cholangiocarcinoma according to the tumor-node-metastasis staging system[14]. Three patients who also had gallbladder carcinoma were excluded. Of the remaining 84 patients, 67 jaundiced patients underwent PTBD before the resection. They formed the basis of this retrospective study, and included 39 men and 28 women with a median age of 65 years (range: 35-88 years). All patients were Japanese.

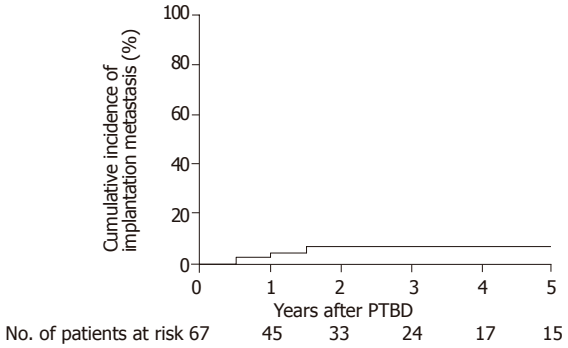

Figure 1 The cumulative incidence of catheter tract implantation metastasis after percutaneous transhepatic biliary drainage among 67 patients who underwent resection of extrahepatic cholangiocarcinoma.

Resectional procedure of the primary tumor

The resectional procedures were chosen according to the primary tumor location. Forty-one patients with hilar cholangiocarcinoma underwent a hepatectomy with bile duct resection, 12 with non-hilar tumor underwent a Whipple procedure or a pylorus-preserving pancreaticoduodenectomy, six underwent a bile duct resection, and eight underwent a combination of hepatectomy and pancreaticoduodenectomy. Regional lymphadenectomy was performed in all patients.

Pathologic examination

The resected specimens were submitted to the Department of Surgical Pathology at our hospital for histologic evaluation. The histologic findings were described according to the tumor-node-metastasis staging system[14]. The histologic grade was determined based on the areas of the tumor with the highest grade[14]. Adenocarcinoma was identified as the primary tumor in 64 patients and adenosquamous carcinoma was identified in three patients.

Patient follow-up

Patients were followed up regularly at outpatient clinics every 3 mo. The median follow-up period after PTBD was 106 mo (range: 4 to 186 mo). By the time of disease status assessment, 38 patients had died of tumor recurrence. Seven patients had died of other causes with no evidence of tumor recurrence. One patient was alive with recurrent disease, and the remaining 21 patients were alive without disease.

Review of the literature

The English language literature (PubMed, National Library of Medicine, Bethesda, MD, USA), from January 1966 through December 2004, was reviewed, and revealed that a total of seven patients undergoing resection of extrahepatic cholangiocarcinoma suffered from catheter tract implantation metastasis following PTBD[7-13].

Statistical analysis

Medical records and survival data were obtained for all the 67 patients. The causes of death were determined based on the medical records. The follow-up period was defined as the interval between the date of PTBD and that of the last follow-up. The Kaplan-Meier method was used to estimate both the cumulative incidence of catheter tract implantation metastasis and the cumulative patient survival rates. The differences in survival were evaluated using the log rank test. All statistical evaluations were performed using the SPSS 11.5J software package (SPSS Japan Inc., Tokyo, Japan). All tests were two-sided, and the differences with P values of <0.05 were considered statistically significant.

RESULTS

The incidence of catheter tract implantation metastasis after PTBD in the current series

Catheter tract implantation metastasis after PTBD presented as a subcutaneous nodule in 3 of the 67 patients during the follow-up period. The interval between PTBD and the detection of implantation metastases was 7, 14, and 20 mo for those 3 patients. The cumulative incidence of this complication reached a plateau (6%) at 20 mo after PTBD (Figure 1).

Of the three patients with implantation metastases, one underwent a resection of the catheter tract (patient 9 in Table 1), one underwent local radiation (patient 8), and the other received the best supportive care (patient 10). They died of disease at 3, 9, and 20 mo after the detection of this complication.

A review of the literature on catheter tract implantation metastasis from extrahepatic cholangiocarcinoma

An analysis of the 10 reported patients (including our three patients; Table 1) with catheter tract implantation metastasis revealed that the histologic grade of the primary tumor was well differentiated in four patients, moderately differentiated in three, poorly differentiated in one, and not documented in two. The median interval between PTBD and the detection of this complication was 14 mo (range: 3 to 45 mo).

Catheter tract implantation metastasis was isolated (without recurrences at other sites) in six patients, whereas it was non-isolated (with recurrences at other sites) in the other 4 patients (Table 1). Although the survival after the detection of implantation metastasis was generally poor, two patients who underwent excision of isolated implantation metastases survived for more than five years. Among the nine patients with documented outcomes, those with isolated implantation metastases survived longer than those with non-isolated implantation metastases ($P = 0.0457$; Figure 2).

DISCUSSION

The incidence of catheter tract implantation metastasis after PTBD has been reported to range from 0.6 to 6% in patients with malignant biliary obstruction due to tumors of various origins[7,11,15-17]. Nimura *et al*.[18] have reported

Table 1 Implantation metastases along the PTBD tract among patients who underwent a resection for extrahepatic cholangiocarcinoma

PTBD: percutaneous transhepatic biliary drainage; Adeno: adenocarcinoma; As: adenosquamous carcinoma; G1: well differentiated; G2: moderately differentiated; G3: poorly differentiated; Hx: hepatectomy; EAW: excision of the abdominal wall; RTx: radiotherapy; CTx: chemotherapy; ECW: excision of the chest wall, BSC: best supportive care; NED: (alive with) no evidence of disease; DOD: died of disease; nd: not documented. [1]Present case. [2]A PTBD catheter had been introduced transphrenically via the right pleural cavity in this patient.

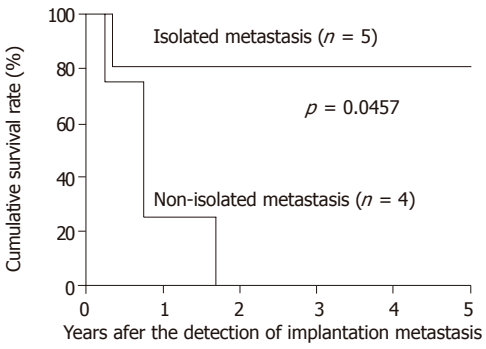

Figure 2 Kaplan-Meier estimates of survival after the detection of catheter tract implantation metastasis among nine patients with documented outcomes (Table 1). The median survival time was not reached with a cumulative 1-year survival rate of 80% in patients with isolated implantation metastasis, whereas it was 9 mo with that of 25% in patients with non-isolated metastasis. Patients with isolated implantation metastases survived longer than patients with non-isolated implantation metastases (P = 0.0457).

a 3% incidence of such implantation metastasis among 133 patients with hilar cholangiocarcinoma. In the current series, the cumulative incidence of this complication increased with time and reached a plateau (6%) 20 mo after PTBD (Figure 2). The above data suggests that catheter tract implantation is not a rare complication following PTBD for extrahepatic cholangiocarcinoma.

Uesaka *et al*.[19] have reported that catheter tract implantation metastasis from hilar cholangiocarcinoma occurred more frequently in patients with well differentiated tumors. Among the 10 reported patients with this complication (Table 1), only one had a poorly differentiated tumor, implying that differentiated tumors may be more related to the development of this complication than poorly differentiated ones. The association between implantation metastasis after PTBD and the histologic grade of extrahepatic cholangiocarcinoma warrants further investigation.

Although Sano *et al*.[7] have reported the occurrence of a late implantation metastasis arising 46 mo after PTBD for extrahepatic cholangiocarcinoma, most of our collected patients suffered from this complication within 21 mo after PTBD (Table 1). Thus, patients undergoing PTBD for extrahepatic cholangiocarcinoma should be monitored for catheter tract implantation for around 2 years.

The survival of patients with catheter tract implantation metastasis from extrahepatic cholangiocarcinoma was found to be generally poor (Table 1), as with our patients. Despite the metastatic nature of this condition, surprisingly, the outcome after the excision of the implantation metastasis was not so dismal in some patients with isolated implantation metastases (patients 1-4). The possibility that the course of deceased patients is unlikely to be reported (a publication bias) may, in part, explain this. In order to excise catheter tract metastases following PTBD, a hepatectomy is usually required, because the catheter tract runs through the liver parenchyma; in some patients, a local excision of the abdominal wall is also required. Two of the five patients who underwent a hepatectomy, with or without a local excision of the abdominal wall, for isolated implantation metastases (patients 1 and 2) survived for more than 5 years with no evidence of the disease. This clearly demonstrates that excision of the metastases offers the only chance for long-term survival.

The issue how to prevent catheter tract implantation metastasis following PTBD is yet to be resolved. Although excision of the catheter tract along with the resection of the primary tumor appears to be effective, it is practically difficult to excise the whole catheter tract between the surface of the skin and the punctured intrahepatic bile ducts. Some authors have advocated ethanol injection into the catheter tract to prevent cancer implantation[10,19,20]. However, Shimizu and colleagues have reported a case of implantation metastasis following ethanol injection[10]. Further investigation is warranted to conclude the effects of this procedure.

In conclusion, catheter tract implantation metastasis is not a rare complication following PTBD for extrahepatic

cholangiocarcinoma. Although the prognosis for patients with this complication is generally poor, excision of the catheter tract, which usually requires a hepatectomy, enables long-term survival in selected patients with isolated implantation metastases.

Abstract

AIM: This study shares Asian clinical experiences of carcinoid tumors that originated in the upper gastrointestinal tract.

METHODS: From May 1987 to June 2002, we had found only 13 cases of histologically confirmed carcinoid tumors in the upper gastrointestinal tract by endoscopic examinations. There were eight males and five females. The mean age was 53.16±20.51 years that ranged from 26 to 82 years. Each of their clinical presentations, locations, tumor morphology, and size and the treatment outcome were analyzed and discussed.

RESULTS: One patient had a polypoid lesion at the lower esophagus, nine were stomach lesions and three located at the duodenum. All patients with polypoid and submucosal tumor types were of small size (<1.7 cm) and all patients survived after simple excision or polypectomy. Four of the five patients in tumor mass forms died and the tumors were more than 2.0 cm in size.

CONCLUSION: Carcinoid tumors rarely originated from the upper gastrointestinal tract and are usually found accidentally after endoscopic study. Bigger size (more than 2 cm) tumor masses may indicate a more severe disease and poor prognosis.

Key words: Upper gastrointestinal carcinoid tumors; Tumor morphology; Sizes; Treatment courses; Prognosis

INTRODUCTION

Carcinoid tumors are a type of very slow-growing neuroendocrine tumors that originate from the embryonic neural crest. Their prominent feature is the production of multiple hormones[1]. The incidence is increasing at rates around 24.7-44.8 cases per million in the United States each year. Over 90% of all carcinoid tumors originate in the GI tract. Most carcinoid tumors are GI in origin, yet they only account for 1.5% of all gastrointestinal neoplasms. Most carcinoids are, in fact, found incidentally. Neither cytology nor histology can determine if the lesion is benign or malignant. Only the presence of distant metastases confirms malignancy.

However, all carcinoids must be considered malignant when found because of the high threat of metastasis. Although carcinoids <1 cm in diameter are unlikely to metastasize, a wide excision is recommended[1]. Five-year survival rates of patients with a local excision of carcinoid are >95%, metastases to the liver constitute a dismal 20% 5-year survival rate. Therefore, early detection as with most cancers is, desirable. In the past 15 years, we found only 13 cases of upper gastrointestinal tract carcinoid tumors by endoscopic examination. We tried to analyze and correlate the clinical settings, the sizes of tumors, their morphology, and the outcome of the disease.

MATERIALS AND METHODS

The medical records of these 13 patients who were diagnosed as upper GI carcinoid tumors at Chang Gung Memorial Hospital, Kaohsiung Center, Taiwan from May 1987 to June 2002 were reviewed. We excluded all the cases with an uncertain diagnosis, small-bowel cancers found in the GI tract but thought to have metastasized there from an extra-abdominal primary site, and patients were operated on for periampullary tumors. The final study population composed of 13 patients who were treated. There

were eight males and five females. The mean age was 53.15 ±20.51 years ranging from 26 to 82 years (Figure 1).

The morphology of the tumors observed by endoscopic examinations was divided into three main categories: polypoid (Figure 2A), submucosal (Figure 2B), tumor-like (Figure 2C) lesions. A single surgical pathologist reviewed pathological specimens and histological features. Routine hematoxylin-eosin stains, immunohistochemistry, or elevated urinary 5-hydroxyindole acetic acid levels established the diagnosis of carcinoid tumor. Survival duration was measured from the time of diagnosis to the last follow-up evaluation or death. The follow-up observations were obtained from the medical records of the patients or direct contact with the patients, their relatives, or primary care physician. The endoscopic observations of the lesions such as the morphologic appearance and the sizes were analyzed in correlation to the treatment course and prognosis of each recorded patient (Table 1).

RESULTS

This study group included eight men and five women, with the median follow-up duration of 36 mo. The most common symptom was abdominal pain (53%), followed by weight loss (38.5%), GI tract bleeding (23%) and jaundice (7.7%). Some patients had more than one symptom or physical finding, though no combination of signs, symptoms, or acuity of presentation was thought to have any influence on the prognosis.

Only one 26-year-old male patient had a 0.7-cm esophageal carcinoid lesion, polypoid in appearance and located at the lower esophagus. Polypectomy was done for him and no signs of recurrence for more than 5 years. Nine patients suffered from gastric carcinoid tumors and three of them died. All these three patients had gastric tumor masses of at least 4 cm in size found by endoscope. One patient had tumor involving colon, spleen, and pancreas, while the other had metastatic mesenteric lymphnodes. Both underwent surgery but still failed to survive due to sepsis and organ failure.

A 30-year-old female had a huge mass over the pelvis extended to almost the whole of the left side abdomen. Endoscope showed a 4.0-cm ulcerated mass over the cardiac portion and fundus. Carcinoid tumor was proven by snare biopsy. She also suffered from a septic right knee. Due to the poor general condition, she received supportive treatment only. One 68-year-old male patient had a 1.5-cm tumor mass at gastric antrum who received complete resection already and survived for 6 years. One 46-year-old male patient had been suffering from repeated gastroduodenal ulcers bleeding. Scope reviewed a more than 4 cm slightly elevated submucosal lesion at the antrum. Computer tomography and angiography showed a tumor mass bulging out posterior to the stomach. He had been well after surgical resection of the antrum.

All four patients who had gastric carcinoid lesions smaller than 1.0 cm survived, and the morphology were polypoid (n = 2) and appearance of submucosa (n = 2). Two received polypectomies and two mucosectomies and there are no signs of recurrence so far.

Three patients had duodenal carcinoid lesions, two located in the duodenal bulb and one in the second portion of the duodenum. One 64-year-old female patient had a 0.9-cm polypoid lesion at the bulb portion, and polypectomy was performed. The other 40-year-old male patient who had a 1.7-cm submucosal lesion at bulb received duodenectomy. Both of them are still alive and disease-free at 4 and 6 years status post therapy. However, one 82-year-old female patient who suffered from obstructive jaundice by a carcinoid tumor mass at the duodenal second portion was not as fortunate. Stent was placed by using endoscope to relieve her obstructive jaundice but she still died because of sepsis shortly after.

The cumulative 5-year survival rate was 64% in the carcinoid tumor. Gastric carcinoid had the worse prognosis in this study with 5-year survival of less than 40%. Duodenal carcinoid tumor had a 5-year survival of about 60%. Only one case was found with a carcinoid in the esophagus and the patient is still surviving but the total number of patients is too small to come to any conclusion.

DISCUSSION

Carcinoid tumor of the esophagus is exceedingly rare, and the knowledge about this tumor is based primarily on case reports[2]. Several case reports have emphasized that esophageal carcinoid tumors are associated with a poor prognosis[2]. Primary endocrine tumors of the esophagus are rare tumors that include small cell carcinoma, large cell neuroendocrine carcinoma, atypical carcinoid tumor, classical carcinoid tumor, and combined endocrine tumor and adenocarcinoma[2]. Small cell carcinoma of the esophagus accounts for 1% of all esophageal tumors, and the overall median survival is 3.1 mo[3]. The only one case, who had a small polyp at distal esophagus, still survives, 50 mo after endoscopic polypectomy. Although only one case was treated, it supported that esophageal carcinoid tumors are not always associated with a poor prognosis probably as a non-small cell carcinoma.

Three types of gastric carcinoids have been described[4,5]. Type I is associated with chronic atrophic body-fundus gastritis type A. Type II is seen in Zollinger-Ellison syndrome/multiple endocrine neoplasia type I (MEN-1) syndrome. Type III is a sporadic tumor[6]. Gastric carcinoids arise from endocrine cells in gastric mucosa and recent reports indicate that 10-30% of all gastrointestinal carcinoids occur in the stomach[6].

Type I gastric carcinoids is the most frequent type encountered in about 65% of cases[7]. The tumors are usually small (<1 cm) polypoid lesions located in the gastric body or fundus[8]. Adjacent atrophic mucosa contains foci of precursor lesions, which are at different stages of ECL cell hyperplasia, dysplasia, and neoplasia. Hypergastrinemia is usually present[6]. Nodal metastasis is reported in up to 16% of cases and hepatic metastasis, in up to 4%[9]. Endocrine symptoms are rare; 5-year survival is high in our series, four gastric carcinoids were less than 1.0 cm in size, either in polypoid or submucosal in morphology endoscopically. Polypectomies and endoscopic mucosectomy were performed smoothly and they still survive.

One of our patients who belonged to type II gastric carcinoids suffered from repeated GI bleeding and hypergastrinemia. After receiving operation, he is still healthy. The adjacent mucosa is non-atrophic and entirely comprised precursor lesions[6]. Prognosis is intermediate, between types I and III[7].

Type III gastric lesions make about 20% of gastric carcinoids[6]. Forty percent occur in the antropyloric area[6] when discovered; they are usually single tumor more than 2 cm. They arise from ECL, EC, or X cells. There is no hypergastrinemia and no precursor lesions. They can cause either a classic syndrome of facial flushing, abdominal cramps, diarrhea, left-sided endocardial fibrosis, and 24 h urinary 5-HIAA more than 10 mg, or an atypical carcinoid syndrome associated with vasoactive substances and

polypeptide hormone production[6]. Nodal metastasis is reported in 55% of patients and liver metastases, in 25% of patients[5]. Five-year survival is only 50%[7]. All the four of our patients with gastric tumor masses of more than 4 cm in size were associated with adjacent and distant metastasis. Two had carcinoid syndrome. Three received surgical intervention and one had supportive care. Three of them expired.

Schneider *et al*.[10] showed that the patients with gastric carcinoids had an eight times higher risk of developing a secondary malignancy as compared with the normal population. None of our gastric carcinoids had secondary carcinomas so far.

The management of gastric carcinoids depends on the type; presence of symptoms, or metastases spread, size, and number of tumors[6]. Although multiple studies have been published, the treatment in many cases still remains controversial. Most agreed on the management of type III (or sporadic) carcinoids, which have the worst prognosis and the highest rate of metastasis and associated carcinoid syndrome[6]. The recommended therapy is *en bloc* surgical resection with regional lymph node dissection, especially for lesions of more than 2 cm[5,11,12]. If the tumor penetrated the serosa, gastrectomy is also recommended[13].

For the patients with liver metastasis, surgical resection of tumor foci or selective hepatic artery ligation or embolization may reduce the symptoms and improve survival[6]. Chemotherapy of disseminated disease with streptozocin, 5-FU, cyclophosphamide, and doxorubicin were reported to produce a 20-40% response rate[6]. Leukocyte interferon produced a temporary response in some patients[5]. Somatostatin analogs, octreotide, and lanreotide have been used successfully in recent years to relieve the symptoms of carcinoid syndrome[14]. Recently, the results of trials with long-acting formulations octreotide-LAR (10, 20, or 30 mg every 28 d) and lanreotide-PR (30 mg every 2 wk) were published and demonstrated effectiveness and convenience of the treatment[15-18].

The optimal management of the types I and II gastric carcinoids is less clear[6]. Many authors base their recommendations on the size and number of the tumors[6]. For lesions less than 1 cm in diameter and less than 3-5 in number, endoscopic removal and semiannual EGD surveillance is recommended[6]. If there is a recurrence, or if the lesions are larger than 1 cm or more than 3-5 in number, then antrectomy with endoscopic excision is recommended[5,13].

Type I is considered as the most benign type of gastric carcinoids, rarely affecting the 5-year survival[8]. There are strong arguments supporting surgery[6]. Although type I carcinoid is the most benign type, it is still associated with some incidence of lymph node and liver metastasis[7,8]. Most gastric carcinoids regress after antrectomy[12,19-21]. In contrast, improved overall survival for metastatic neuroendocrine tumors after the complete resection of primary and hepatic metastases is accomplished, with an actuarial 5-year survival rate of 70%.

Carcinoid tumor was the most common small bowel tumor. It occurred in 24% of patients. Forty-six percent of patients were asymptomatic during life, the tumors being found either at autopsy or during other surgical procedures. Of those that were symptomatic, half presented with intestinal obstruction and the rest with long-standing symptoms. An abdominal mass, which occurred in 14% of cases, is an uncommon physical finding since the majority present as small submucosal tumors. Fifty-eight percent overall and 72% of those having surgery had evidence of regional spread, either by local invasion or in the form of regional nodal involvement. Seven percent of patients have died because of their disease. Excision surgery should be performed for all cases where feasible, and repeated for recurrent symptoms[22].

Ampullary carcinoids are rare tumors. Like the 82-year-old male in our series, they most commonly present with obstructive symptoms like jaundice and nonspecific abdominal discomfort. They are difficult to diagnose preoperatively secondary to their relatively small size and submucosal location. Rarely, ulcerated duodenal carcinoids can present as a source of significant gastrointestinal bleeding. Overall, approximately 80-90% of all carcinoids secrete serotonin or its precursor 5-hydroxy tryptophan, and other tumors rarely do so. Measurements of serotonin and its metabolites like urinary 5-hydroxy indole acetic acid (5-HIAA) have been described to be very helpful in the diagnosis and postresection follow-up of carcinoids. In our patient, those levels were not obtained preoperatively as the patient did not have any signs, symptoms, or histologic evidence to suggest a diagnosis of carcinoid tumor[23].

In conclusion, carcinoid tumors rarely originated from the upper gastrointestinal tract in the eastern countries and are usually found incidentally after endoscopic study. Bigger size (more than 2 cm) tumor mass form may indicate a more severe disease and poor prognosis.

Abstract

AIM: To evaluate the change of growth characteristics and radiosensitivity of irradiated primary cultured human hepatocarcinoma cells.

METHODS: All tumor tissue samples were obtained from 39 hepatocarcinoma patients with a mean age of 49.6 years (range 22-76 years). We divided the samples into irradiated group and non-irradiated group and measured their plating efficiency (PE), population doubling time (PDT), radiosensitivity index SF2 and cell cycle.

RESULTS: The PDT of primary culture of hepatocarcinoma cells was 91.0±6.6 h, PE was 12.0±1.4%, SF2 was 0.41±0.05%. The PDT of their irradiated progeny was 124.8±5.8 h, PE was 5.0±0.7%, SF2 was 0.65±0.09%. The primary cultured human hepatocarcinoma cells showed significant S reduction and G^2 arrest in a dose-dependent manner. The progeny of irradiated primary cultured hepatocarcinoma cells grew more slowly and its radiosensitivity increased.

CONCLUSION: The progeny of irradiated primary cultured human hepatocarcinoma cells grows more slowly and its radiosensitivity increases.

Key words: Hepatocarcinoma; Cell cycle; Population doubling time; Radiosensitivity

INTRODUCTION

Hepatocarcinoma cells have a better reaction to X-rays. The mechanism of radiosensitivity of hepatocarcinoma cells after radiotherapy is not very clear. In this study, we have used primary cultured human hepatocarcinoma cells *in vitro* to evaluate the change of growth characteristics and radiosensitivity of progeny of irradiated primary hepatocarcinoma cells.

MATERIALS AND METHODS

Specimens

All tumor tissue specimens were obtained from 39 hepatocarcinoma patients with a mean age of 49.6 years (range 22-76 years).

Cell culture

Primary hepatocarcinoma tissue specimens were obtained from hepatocarcinoma patients. The volume of the sample was 1.5 cm^3. Cells were grown in Dulbecco's minimal essential medium (DMEM) containing 25% fetal calf serum and incubated at 37 °C in 50 mL/L CO_2. Most cells were anchored after inoculation for 16 h and the cell growth could be seen after inoculation for 48 h. Then the primary cultured human hepatocarcinoma cells entered the experimental growth phase. The proliferation was very productive and ended 7-8 d after incubation. The density of cells was 50-95% in flask with a few fibroblasts. The time was the best opportunity for irradiation in flask.

Irradiation condition

The samples were divided into irradiated group and non-irradiated group. Cells in the experimental growth phase were irradiated with 2-8 Gy of X-ray at a dose rate of 200 cGy/min and divided into five groups (0-8 Gy). The lucite was placed in dishes.

Population doubling time (PDT)

Cells in the experimental growth phase were digested into single-cell suspension by 2.5 g/L trypsin. *In vitro* transduction was performed by plating 1×10^5 cells in 6-cm^2 flasks. Cells were digested after being irradiated for 48, 72, 96, 120, 144 h and counted. The experiment was repeated thrice. The cell growth curve was drawn and the cell PDT was calculated.

Table 1 PDT and PE between irradiated and non-irradiated human hepatocarcinoma cells (mean±SD)

Dose (Gy)	PDT (PDT) (t/h)	PE (%)
0	91.0±6.6	12.0±1.4
2	104.7±2.1	10.2±0.6
4	120.4±2.8	8.2±0.4
6	133.5±1.4	6.0±1.1
8	141.8±5.8[a]	5.0±0.7[b]

[a]P<0.05, [b]P<0.01 *vs* 0 Gy.

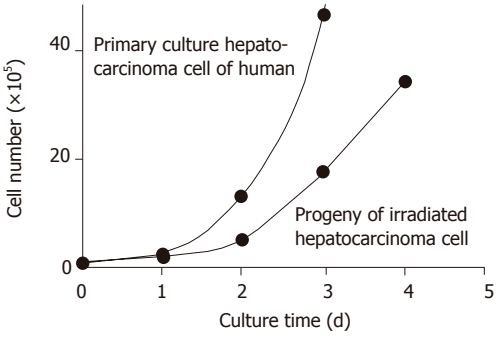

Figure 1 Cell growth curve and irradiated progeny of primary cultured human hepatocarcinoma cells.

Colony assay

Cells in the experimental growth phase were digested into single-cell suspension by 2.5 g/L trypsin. *In vitro* transduction was performed by plating 1×10^5 cells in 3-cm^2 flasks. Cells were irradiated with 2-8 Gy. After 12-15 d of plating, the culture was ended. Cells were fixed by formaldehyde and stained with Giemsa. The number of colonies exceeding 50 was defined as positive. The survival fraction rate was the colony rate. Three parallel samples were set in each dosage point and the experiment was repeated thrice. The formulations [SF2 = e-($aD+\beta D2$)] (the secondary equation) and [(S = 1-(1–e-KD)N)] (the multi-target click model) were used to simulate the cell survival curve of hepatocarcinoma cells. The radiosensitivity parameters such as SF2, α, D_0, and N were calculated.

Detection of cell cycle

Cells in the experimental growth phase were irradiated with 2-8 Gy (Linear Accelerator Saturn 43 type). Cells after being irradiated were retrieved at five time points (0, 6, 12, 24, 36 h) and centrifuged (800 r/min). Then the cells were washed twice with PBS. The single-cell suspension was fixed in 80% ethanol and then treated with RNase. At last, the cells were resuspended and incubated for 30 min at 4 ℃. Cellular fluorescence was measured by FASort flow cytometry (Becton Dickinson). The data were analyzed by CELLQuest software.

Statistical analysis

Using the SPSS 10.0 statistical analysis software, cell growth curve and cell survival curve were simulated by square regression. The cell cycle ratio and radiosensitivity parameters were expressed as mean±SD. Student's t-test was used to compare the difference between the two groups.

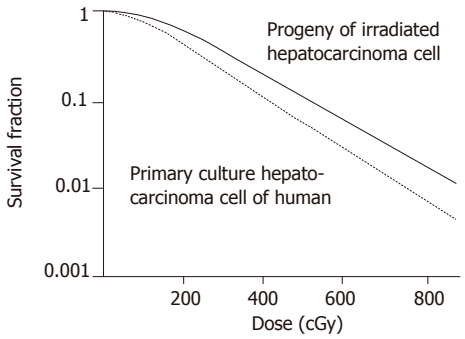

Figure 2 Cell survival curve of primary human hepatocarcinoma cells and irradiated progeny.

RESULTS

Plating efficiency (PE) and cell population doubling time of irradiated progeny

The plating efficiency (PE) of primary cultured human hepatocarcinoma cells was 12.0 ± 1.4%, the irradiated progeny was 5.0±0.7%, being significantly higher than that of non-irradiated cells (t = 8.547, P<0.01). The cell PDT of progeny of irradiated human hepatocarcinoma cells was longer than that of non-irradiated ones. The cell PDT of primary cultured human hepatocarcinoma cells was 91.0 ±6.6 h. The PDT difference between irradiated progeny and non-irradiated cells was significant (t = 3.672, P<0.05; Table 1 and Figure 1).

Radiosensitivity of irradiated progeny

The survival curve and irradiated progeny of human hepatocarcinoma cells are shown in Figure 2. SF2, α, D_0, and N of primary human hepatocarcinoma cells were 0.41±0.05, 0.37/Gy, 0.43 Gy, 2.52, respectively. SF2, α, D_0, and N of irradiated progeny were 0.65±0.09, 0.10/Gy, 0.61 Gy, 1.08, respectively (t = 3.863, P<0.05). The difference was significant. Both SF2 and radiosensitivity of hepatocarcinoma cells were increased in human hepatocarcinoma cells and irradiated progeny.

Detection of cell cycle

Cells in the experimental growth phase were irradiated with 2-8 Gy (Linear Accelerator Saturn 43 type). The cells decreased in S phase and increased in G_2/M phase in a dose-dependent manner (P<0.05). The DNA synthesis time was shorter and mitosis was delayed. The cells after mitosis entering G_0/G_1 phase decreased in a dose-dependent manner (Table 2).

DISCUSSION

The results of radiosensitivity *in vitro* of carcinoma cells are closely related with the clinical effect of carcinoma

Table 2 Cells in S and G2/M phase of irradiated progeny (mean±SD)

Dose (Gy)	SPF (%)	G2/M (%)
0	66.10±0.75	0.91±0.19
2	61.52±0.22	1.73±0.53
4	50.15±0.68	3.32±0.68
6	43.35±0.24	4.51±0.92
8	33.32±0.51[a]	6.48±0.57[a]

[a]$P<0.05$ *vs* oGy.

radiotherapy. But most studies showed that there have been great differences in radiosensitivity of identical carcinomas[1-2]. Studies indicate that radiation can lead to the instability of cell genes and survived progeny will occur[3]. It was reported that irradiated progeny produces resistance after radiation or DNA damage[4-5].

There is evidence that carcinoma is a cell cycle disease. The malignant level of carcinoma is closely related with cell cycle. The carcinoma cells in different cell cycle phases have different radiosensitivity to chemotherapy drugs. Proliferating cells have a good radiosensitivity. Radiotherapy can change the processes of cell cycle. It displays G_0, G_2/M, and S arrest. To study the alteration of cell cycle after radiation is of great significance in choosing suitable chemotherapy drugs after radiotherapy.

Our study indicated that the growth characteristics of progeny of human hepatocarcinoma cells were changed after being irradiated with 2-8 Gy. The growth speed was delayed, the PE was decreased and the radiosensitivity was increased. The radiosensitivity of irradiated progeny was related with G_2/M arrest and cells in S phase reduced in a dose-dependent manner. The radiosensitivity of cells in S phase was the highest due to decreased progeny of irradiated human hepatocarcinoma cells and PE as well as delayed PDT cell reaction in S phase and G_2/M arrest[6].

In conclusion, stereotactic radiotherapy can achieve better results in the treatment of hepatocarcinoma.

Abstract

AIM: To investigate the prediction value of radiosensitivity of hepatocarcinoma cells for apoptosis and micronucleus assay.

METHODS: Clonogenic assay, flow cytometry, and CB micronuclei assay were used to survey the cell survival rate, radiation-induced apoptosis and micronucleus frequency of hepatocarcinoma cell lines SMMC-7721, HL-7702, and HepG2 after being irradiated by X-ray at the dosage ranging 0-8 Gy.

RESULTS: After irradiation, there was a dose-effect relationship between micronucleus frequency and radiation dosage among the three cell lines ($P<0.05$). A positive relationship was observed between apoptosis and radiation dosage among the three cell lines. The HepG2 cells had a significant correlation ($P<0.05$) but apoptosis incidence had a negative relationship with micronucleus frequency. There was a positive relationship between apoptosis and radiation dosage and the correlation between SMMC-7721 and HL-7702 cell lines had a significant difference ($P<0.01$). After irradiation, a negative relationship between cell survival rate and radiation dosages was found among the three cell lines ($P<0.01$). There was a positive relationship between cell survival rate and micronucleus frequency ($P<0.01$). No correlation was observed between apoptosis and cell survival rate.

CONCLUSION: The radiosensitivity of hepatocarcinoma cells can be reflected by apoptosis and micronuclei. Detection of apoptosis and micronuclei could enhance the accuracy for predicting radiosensitivity.

Key words: Hepatocarcinoma cell; Micronuclei; Apoptosis; Radiosensitivity

INTRODUCTION

The prediction of cell radiosensitivity is a main content in radiobiology and carcinoma treatment. Apoptosis of carcinoma cells can be induced by radiotherapy. Micronucleus is a product of abnormal mitosis. Studies have verified that micronucleus analysis can predict radiosensitivity of cells[1,2]. It was reported that apoptosis is correlated with cell survival[3,4]. Apoptosis and micronuclei occur after the first mitosis and are related with the damage in heredity substance. To investigate apoptosis and micronucleus assay is of significance in predicting radiosensitivity.

This study focused on the relationship among apoptosis, micronuclei, and cell survival rate of three hepatic cell lines (HL-7702, HepG2, SMMC-7721). The prediction value of radiosensitivity for apoptosis and micronucleus assay of hepatocarcinoma cells was investigated *in vitro*.

MATERIALS AND METHODS

Three hepatic carcinoma cell lines (HL-7702, HepG2, SMMC-7721) were cultured at 37 ℃ in RPMI 1640 medium supplemented with 10% fetal bovine serum and divided into irradiated group and non-irradiated group. Cells in experimental growth phase were irradiated by X-ray at a dose of 2-8 Gy (Linear Accelerator Saturn 43 type) with a dose rate of 200 cGy/min. The lucite was placed in dishes.

Cells in the experimental growth phase were digested by 2.5 g/L trypsin into a single-cell suspension. *In vitro* transduction was performed by plating 1×10^5 cells in 3-cm^2 flasks. Cells were irradiated with 2-8 Gy. After 12-15 d of plating, the culture was stopped. Cells were fixed by formaldehyde and stained with Giemsa. The number

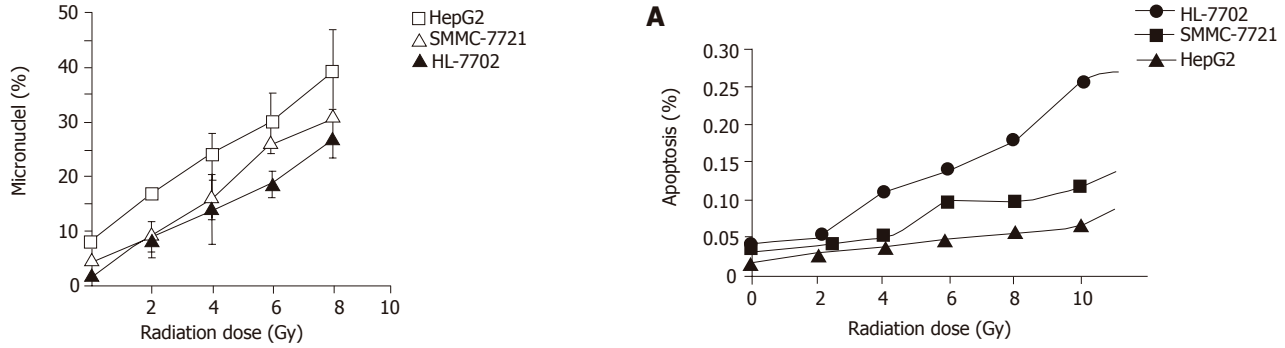

Figure 1 Micronucleus frequency of three cell lines.

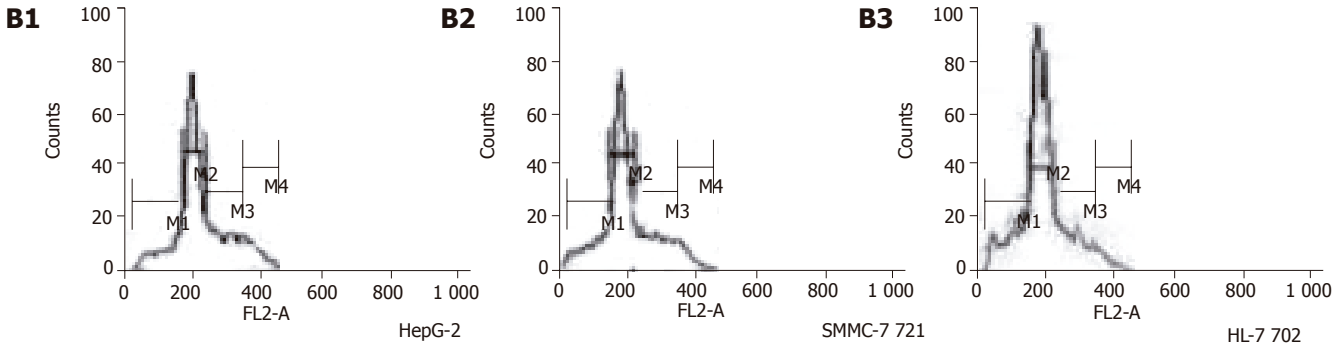

Figure 2 Apoptosis incidence (**A**) and DNA content (**B**) in three cell lines.

of colonies exceeding 50 was defined as positive. The survival fraction rate amounted to colony formation rate in irradiation group. Three parallel samples were set in each dosage point and repeated thrice.

Cells in the experimental growth phase were digested by 2.5 g/L trypsin into single-cell suspension at the concentration of 3×10^4 μg/mL and inoculated in petri dishes. When the cells were attached to the wall, they were cultured for 2 days and then irradiated with 2-8 Gy. After irradiation, samples were added in 2 μg/mL cytochalasin-B, and cultured for 48 h, and then stained *in situ*. The number of micronuclei in double nuclear cells was counted. At least 1 000 double nuclear cells were calculated. Each dosage had three parallel exponents and the experiment was repeated thrice.

Cells were centrifuged and washed 2-3 times with PBS and then fixed in 80% ethanol at -20 ℃. The samples were centrifuged for 5 min (800 r/min) and washed with PBS, mixed into mono cell suspension and diluted at 1:400 in PBS. The cells were treated with RNase for 30 min, resuspended in 10 μg/mL of PI and incubated overnight at 4 ℃. Cellular fluorescence was measured by FASort flow cytometry (Becton Dickinson, San Jose, CA, USA). We collected the data by CELLQuest software and analyzed the cell cycle by ModFit2.0.

Statistical analysis

Correlation analysis was made using the SPSS statistical analysis software.

RESULTS

After being irradiated with 2-8 Gy, the micronucleus frequency of HepG2, SMMC-7721, and HL-7702 was related with radiation dosage. The relationship between the micronucleus frequency of HepG2 and radiation dosage was significant ($P<0.05$, Figure 1).

After being irradiated with 2-8 Gy, a positive relationship was observed between apoptosis incidence and radiation dosages. The relationship between micronucleus frequency of HepG2, SMMC-7721 and radiation dosage was significant ($P<0.01$, Figure 2). But apoptosis incidence was negatively related with micronucleus frequency.

After being irradiated with 2-8 Gy, the cell survival rate of three cell lines was decreased ($P<0.05$, Tables 1 and 2).

After being irradiated with 2-8 Gy, a positive relationship was found between micronucleus frequency and cell survival rate ($P<0.01$, Figure 3) .

The relationship between micronucleus frequency and apoptosis of three cell lines was not significant ($P>0.05$).

DISCUSSION

Hepatocarcinoma is a common malignant tumor. Stereotactic radiotherapy of hepatocarcinoma can achieve better effects. Hepatocarcinoma cells may have corresponding radiosensitivity.

Micronucleus is a product of abnormal mitosis and consists of chromatosome fragments that cannot enter the

Table 1 Cell survival rate of three cell lines (mean±SD)

HL-7702	2.0	1.8	3.0	0.79±0.02

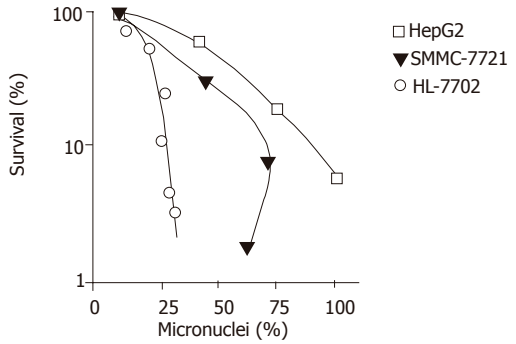

Figure 3 Relationship between micronucleus frequency and cell survival rate.

core nuclei when cells undergo mitosis. Micronucleus analysis is a method to detect cell radiosensitivity. Widel *et al*.[5] found that micronucleus frequency can be used as a marker to predict prognosis of hepatocarcinoma patients. Kolotas *et al*.[6] showed that the prognosis is better in patients with a higher micronucleus frequency than in those with a lower micronucleus frequency. But we found that micronucleus frequency of radiation-resistant cell lines was not related with cell survival rate. It is usually believed that micronuclei induced by X-ray express only in sensitive cells. Micronucleus frequency of sensitive cells is higher than that of radiation-resistant cells. Therefore, micronuclei as a marker to predict cell radiosensitivity of all cells needs to be studied further.

Apoptosis of carcinoma cells can be induced by radiotherapy. The sensitivity to apoptosis and X-ray of carcinoma cells is coincident. Studies showed that apoptosis index of carcinoma cells increases after radiation. The rate of apoptosis induced by radiotherapy increases after radiation, indicating that apoptosis can be used as a marker to predict radiosensitivity.

In this experiment, radiation dose was related with micronucleus frequency in three cell lines. There was a positive relationship between the micronucleus frequency and cell survival rate, suggesting that micronucleus frequency can be used as a marker to predict the radiosensitivity of hepatic carcinoma cells. Radiation dose was related with apoptosis incidence in three cell lines. The apoptosis incidence of HL-7702 and SMMC-7721 was higher than that of HepG2, suggesting that apoptosis incidence can be used as a marker to predict the radiosensitivity of hepatocarcinoma cells.

In this experiment, no significant difference was found between apoptosis incidence induced by radiotherapy and cell survival rate in three cell lines, indicating that the damage induced by radiotherapy is different from apoptosis of hepatic carcinoma cells and that response of radiation-resistant cells occurs due to apoptosis.

Masunaga *et al*.[10] showed that micronucleus frequency and apoptosis incidence can predict radiosensitivity of carcinoma cells. Our study confirmed that micronucleus frequency was negatively related with apoptosis incidence of three cell lines. Apoptosis resulted from cell damage. The impaired cells express apoptosis or micronuclei. This result supports that once apoptosis occurs, the cells lose the segregating opportunity, thus affecting micronucleus formation. Apoptosis may be an important factor affecting micronucleus frequency.

Abstract

AIM: To establish the cell survival curve for primary hepatic carcinoma cells and to study the relationship between SF_2 of primary hepatic carcinoma cells and radiosensitivity.

METHODS: Hepatic carcinoma cells were cultured *in vitro* using 39 samples of hepatic carcinoma at stages II-IV. Twenty-nine samples were cultured successfully in the fifth generation cells. After these cells were radiated with different dosages, the cell survival ratio and SF_2 were calculated by clonogenic assay and SF_2 model respectively. The relationship between SF_2 and the clinical pathological feature was analyzed.

RESULTS: Twenty-nine of thirty-nine samples were successfully cultured. After X-ray radiation of the fifth generation cells with 0, 2, 4, 6, 8 Gy, the cell survival rate was 41%, 36.5%, 31.0%, 26.8%, and 19%, respectively. There was a negative correlation between cell survival and irradiation dosage (r = -0.973, P<0.05). SF_2 ranged 0.28-0.78 and correlated with the clinical stage and pathological grade of hepatic carcinoma (P<0.05). There was a positive correlation between SF_2 and D0.5 (r = 0.773, P<0.05).

CONCLUSION: SF_2 correlates with the clinical stage and pathological grade of hepatic carcinoma and is a marker for predicting the radiosensitivity of hepatic carcinomas.

Key words: Hepatocarcinoma; SF_2; Radiosensitivity; D0.54

INTRODUCTION

Hepatic carcinoma is the most common malignant tumors in China. Radiotherapy is its main therapy. But owing to the influence of radiosensitivity and other factors, the effect of radiotherapy on hepatic carcinoma is not obvious. About 40% of hepatic carcinoma patients do not respond to radiotherapy.

The cell survival curve is a curve that describes the relationship between radiation dose and survival cells.

In general, the proliferation ability of survival cells decreases with the increasing of radiation dose. Detecting the SF_2 is a reliable index to predict the radiosensitivity of tumors.

In this experiment, we used the primary cell culture and the clone-formation technique to establish the reliable cell survival curve for hepatic carcinoma. By application of the multi-target click model and calculation of SF_2, we studied the relationship between SF_2 and D0.5. The value of SF_2 for the prediction of the prognosis of hepatic carcinoma was evaluated.

MATERIALS AND METHODS

Source of samples

Thirty-nine fresh specimens were taken from hepatic carcinoma patients at stages II-IV. All the patients had their final diagnosis in Tongji Hospital and did not receive any therapy. Their average age was 49.6 years (22-76 years). All the cases were diagnosed by pathology. Twenty-four specimens of hepatocellular carcinoma and 15 samples of bile duct epithelial carcinoma were taken. Nine were in stage IIB (23%), 25 in stage IIIB (64.1%) and 5 in stage IV (12.9%). The maximum diameter of local carcinoma was <4 cm in 22 specimens (56.9%) and >4 cm

in 17 specimens (43.1%). The specimens were put into RPMI-1640 medium containing 25% fetal calf serum.

Reagents

RPMI-1640 medium, bovine trypsin (1:250), insulin, poly-lysine, and hydrocortisone were purchased from JingMei Company, Shenzhen, China. Agarose was purchased from DIFCO Company.

Irradiation condition

The specimens were irradiated by 6 MV X-ray at the doses of 0, 2, 4, 6, and 8 Gy. The irradiation field was 10 cm ×10 cm. The source skin distance (SSD) was 100 cm. The absorbed dose was 200 cGy/min. The culture bottle was covered with 1.5-cm lucite plate.

Primary culture of hepatic carcinoma cells

The specimens were rinsed 2-3 times with PBS containing streptomycin and penicillin. Blood, fibrous and necrosed tissue were removed. Then a small quantity of PBS was added and the tissue was cut into micro-blocks. The micro-blocks of tissue and PBS were left in the plate and incubated in a 50 mL/L CO_2 incubator. The plate was kept in inversion status for 4-6 h. The anchoring condition of cells was observed under a microscope. If the cells in the tissue were in good condition, RPMI-1640 medium containing 15-25% fetal calf serum was added. The anchoring condition of cells was observed under a microscope on the next day and poly-lysine was added. The poly-lysine promoted the anchoring of cells. In order to provide the cells a better growing condition, we could also add some stimulation factors such as hydrogenated cortadren (4 μg/mL) and insulin (4 μg/mL) on the third and fourth culture days. The culture medium was changed after 5 d, and then every 2-3 d. After incubation for about 14 d, the cultured cells were digested for future generation.

Clone formation rate of hepatic carcinoma cells detected by soft agarose cloning technique[1]

The fifth generation of hepatic carcinoma cells in logarithmic growth phase was digested by 0.25% trypsinogen and counted. Then the cells were inoculated into cell suspension containing 35% soft agarose. According to the irradiation dosage, the cell suspension was put into glass plates. The culture medium was changed after irradiation for about 12 h. The inoculated cells were divided into five groups and irradiated, and then cultured for 10-14 h. The surface culture medium of the plate was stained with hematoxylin and observed under invert microscope and the number of colonies was more than 50. The clone formation rate (SF) after irradiation was assayed thrice to obtain the mean value.

Drawing cell survival curve for hepatic carcinoma cells

Three petri dishes were selected from each dosage group to obtain the mean value. O Gy group was used in every experiment and the colony formation rate (SF) was calculated. On the basis of different dosage irradiation and different incubation time, the cell number was used as the ordinate and the irradiation dosage as the abscissa to draw the growth curve for hepatic carcinoma cells. SF_2 was calculated by the formula [$SF = 1-(1-e^{-D/D_0})^N$] (the multi-target click model)[2].

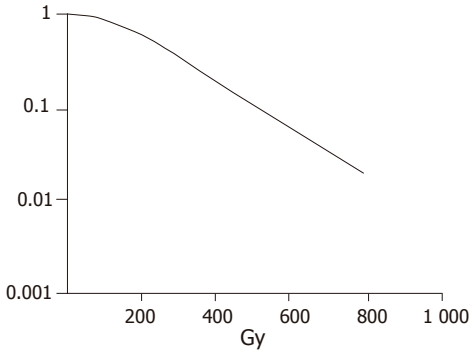

Figure 1 Survival curve of hepatic carcinoma cells.

Regression of hepatic carcinoma in vivo

The patients were examined once a week before and during radiotherapy. The stage plate was used to measure the size of carcinoma. The volume of tumor was calculated to describe the volume-dosage curve and the dosage decreasing tumor size of 50% (D0.5) was calculated.

Determination of colony formation

The fibroblasts were diffusely distributed in petri dishes after the culture medium was changed before one week. A small quantity of colony formation was also seen. The cell distribution in the center of colony was close. The surrounding cells were distributed outward. The cell density decreased. Different cell colonies had different sizes. Only a few cells could be seen in some new colonies. After 14 d, the fibroblasts in petri dishes increased and their diameter became bigger. The cell distribution in the center of the colony was dense. The diameter of the biggest colony was 8 mm.

Statistical analysis

Student's *t* test was used for the statistical analysis using SPSS 10.0.

RESULTS

After hepatic carcinoma tissue was primarily cultured for about 14-20 d, primary cell culture technique was established in 29 of 39 samples.

The survival curve was drawn after different dosage irradiation of hepatic carcinoma cells. The hepatic carcinoma cells were moderately radiosensitive cells (Figure 1).

The cell survival rate was 41%, 36.5%, 31.0%, 26.8%, and 19%, respectively, after irradiated at the dose of 0, 2, 4, 6, and 8 Gy, respectively. The survival rate of hepatic carcinoma cells had a significantly negative relationship with the irradiation dosage ($r = -0.973$, $P<0.05$, Figure 2).

SF_2 of hepatic carcinoma cells was 0.28-0.78, which

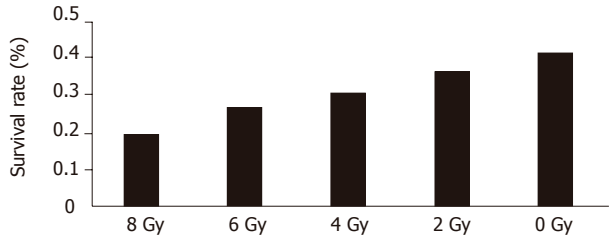

Figure 2 Relationship between survival rate of hepatic carcinoma cells and irradiation dosage.

Table 1 SF_2 of hepatic carcinoma in different clinical stages and pathological types

	Clinical stage		
	IIb	IIIb	IV
Pathology typing			
Hepatocellular carcinoma	0.28	0.47	0.61
Bile duct epithelial carcinoma	0.41	0.57	0.78

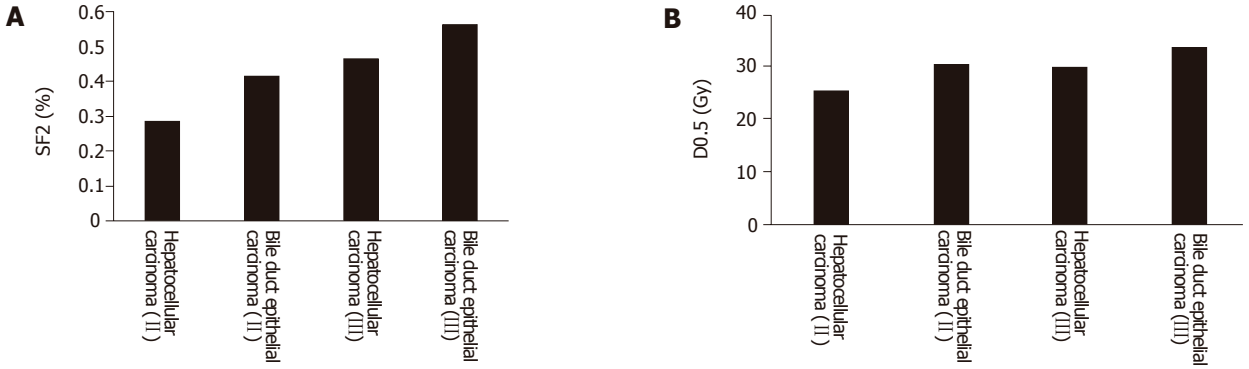

Figure 3 Relationship between the SF2 (**A**) and D0.5 (**B**) in different clinical stages and pathological typing.

was related with the clinical stage of hepatic carcinoma. The more advanced the clinical stage was, the higher the SF_2. SF_2 was also related with the pathological typing of hepatic carcinoma. SF_2 of bile duct epithelial carcinoma was higher than that of hepatocellular carcinoma (Table 1).

SF_2 had a positive relationship with D0.5 ($r = 0.773$, $P<0.05$). SF_2 in different clinical stages of hepatic carcinoma was also related with D0.5. SF_2 in different pathological types of hepatic carcinoma was correlated with D0.5 (Figures 3A and 3B).

DISCUSSION

The determination of radiosensitivity for tumor cells is an important component of tumor radiobiology. The final objective of tumor radiotherapy is to eradicate tumor. But the objective of clinical radiotherapy is to prevent tumor from growth and to eradicate the tumor. Based on the definition of cell survival, the judge of radiotherapy result is based on whether the cells proliferate or not. The survived cells are the main factor for the failure of radiotherapy[3].

Radiosensitivity of hepatic carcinoma cells is a main factor influencing the prognosis of radiotherapy for hepatic carcinoma. To predict the radiosensitivity of hepatic carcinoma cells before and during the therapy, individualization of reasonable and effective therapy is always the direction of tumor investigation.

Primary tumor cell culture *in vitro* has some difficulties such as longer time consumption, high cost, and easy contamination. Based on the past experience, the chief key point to the success of this technique is to draw the materials from tissue because it is closely related with the culture. Aseptic technique is one of the important factors for the success of culture.

It was reported that radiosensitivity is different in different hepatic carcinoma cells and that the local control rate of hepatic carcinoma with its SF_2 <0.55 is higher than that with its SF_2 >0.05[4,5]. SF_2 is related with the staging and pathological typing of tumor but not related with the age of patients and the diameter of tumor. SF_2 is also correlated with pathological typing and clinical stage of tumor. SF_2 for hepatic carcinoma cells in different clinical pathological typing and clinical stage has some differences. It is due to the necessity for individualized treatment of hepatic carcinoma in different clinical pathological typing and clinical stages.

The reports regarding the relationship between SF2 and radiosensitivity have different conclusions. But most experiments showed that SF_2 is negatively related with cell radiosensitivity[6]. SF_2 can be used as a marker for predicting the local control of head and neck tumor. It was reported that SF_2 can predict the reaction after radiotherapy[7]. SF_2 is related with the clinical prognosis of tumor[8]. In our study, SF_2 was significantly related with the radiosensitivity of hepatic carcinoma cells, suggesting that SF_2 can reflect the radiosensitivity of hepatic carcinoma cells.

In conclusion, SF_2 is a reliable marker for predicting the radiosensitivity of hepatic carcinoma cells before and during the therapy.

Abstract

Schistosomiasis is a chronic worm infection caused by a species of *trematodes,* the *Schistosomes*. We may distinguish a urinary form from *Schistosomes haematobium* and an intestinal-hepatosplenic form mainly from *Schistosomes mansoni* characterized by nausea, meteorism, abdominal pain, bloody diarrhea, rectal tenesmus, and hepatosplenomegaly. These infections represent a major health issue in Africa, Asia, and South America, but recently *S mansoni* has increased its prevalence in other continents, such as Europe and North America, due to international travelers and immigrants, with several diagnostic and prevention problems. We report a case of a 24-year-old patient without HIV infection, originated from Ghana, admitted for an afebrile dysenteric syndrome. All microbiologic studies were negative and colonoscopy revealed macroscopic lesions suggestive of a bowel inflammatory chronic disease. Since symptoms became worse, a therapy with mesalazine (2 g/d) was started, depending on the results of a bowel biopsy, but without any resolution. The therapy was stopped after 2 wk when the following result was available: a diagnosis of "intestinal schistosomiasis" was done (two *Schistosoma* eggs were detected in the colonic mucosa) and this was confirmed by the detection of *Schistosoma* eggs in the feces. Therapy was therefore changed to praziquantel (40 mg/kg, single dose), a specific anti-parasitic agent, with complete recovery. Schistosomiasis shows some peculiar difficulties in terms of differential diagnosis from the bowel inflammatory chronic disease, as the two disorders may show similar colonoscopic patterns. Since this infection has recently increased its prevalence worldwide, it has to be considered in the differential diagnosis of our patients with gastrointestinal symptoms.

INTRODUCTION

Schistosomiasis or Bilharziasis is a chronic worm infection caused by a species of t*rematodes*, the *Schistosomes*, which are blood flukes that parasitize the venous channels of definitive human hosts. The infection is transmitted by fresh-water snails. Based on their organ localization, we may distinguish a urinary form from *Schistosomes haematobium*, and an intestinal or hepatosplenic form from *Schistosomes mansoni*, *Schistosomes japonicum*, *Schistosomes mekongi,* and *Schistosomes intercalatum*[1,2].

S mansoni, a main agent of the intestinal form, is a *trematode* which infects human beings more frequently and also infects other primates too. Adult females of *S mansoni* deposit the eggs in the small veins around the large intestine of infected individuals. Some of the eggs may be trapped in the gut wall or break loose into it and are then eliminated by defecation. The eggs trapped in the gut wall are responsible for inflammatory and immunopathologic responses, leading to erythema, edema, granulomas, ulcerations, hemorrhages, and fibrosis. The infection is characterized by nausea, meteorism, abdominal pain, bloody diarrhea, rectal tenesmus, and hepatosplenomegaly[3,5].

Infection with *S mansoni* is still a major health issue in Africa, Asia, and South America[6-10], but recent epidemiological studies showed that its prevalence increases in Europe[11-15] and USA[16,17], due to international travelers and immigrants. In our country, the presence of acute *S mansoni* infection with progression to chronic lesions has been reported in a group of Italian travelers returning from Africa, showing both diagnostic and preventive problems[18].

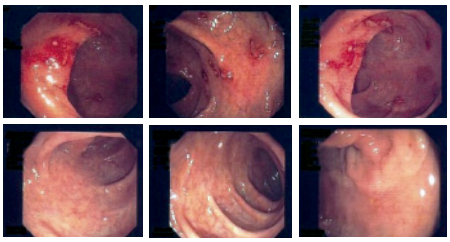

Figure 1 Colonoscopy before (**A**) and after (**B**) therapy.

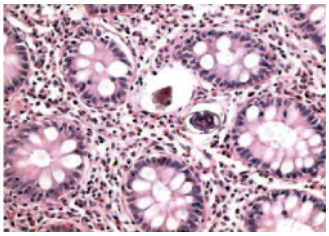

Figure 2 *Schistosoma* eggs detected in colonic mucosa.

Therefore, this infection was considered in the differential diagnosis of our patient with gastrointestinal symptoms. In particular, it is often hard to distinguish this infection from the bowel inflammatory chronic disease, since these two disorders may show similar colonoscopic patterns[19,20]. However, the contemporary presence of the two disorders (usually a chronic schistosomiasis precede the inflammatory disease in the same patient) represents a rare event[21,22].

We report a case of a 24-year-old patient without HIV infection, living in our region who immigrated from Ghana, and was admitted for an afebrile dysenteric syndrome. All microbiologic studies were negative and colonoscopy revealed macroscopic lesions suggestive of a bowel inflammatory chronic disease, and then treated with mesalazine, but without resolution. Further studies by bowel biopsy and feces examination revealed a *Schistosoma* infection, which was treated with praziquantel, a specific anti-parasitic agent and had a complete recovery.

CASE REPORT

A 24-year-old non-HIV patient immigrated from Ghana for economic reasons. He had pain in the left testicle 2 years ago and was hospitalized in his own country, where he was wrongly diagnosed and was given an unknown therapy. However, the pain occasionally recurred with exacerbation after the therapy. The patient was admitted to our hospital for diffuse abdominal pain with occasional bloody diarrhea and vomiting. Hematologic laboratory tests revealed no abnormalities; chest X-ray, and hepatosplenic ultrasonography were normal. The patient had no signs of distress but pain in epigastric and mesogastric regions. Small lymph nodes were observed in the latero-cervix area. All microbiologic studies were negative and colonoscopy revealed macroscopic lesions suggestive of a bowel inflammatory chronic disease reacutization (Figure 1A), like ulcerative colitis or a Crohn's disease. During the colonoscopy, a bowel biopsy was done. Since symptoms became worse, we started a therapy with mesalazine (2 g/d), pending the results of the intestinal biopsy. One week later, a second colonoscopy documented a minor improvement in the endoscopic pattern and the therapy with mesalazine was continued.

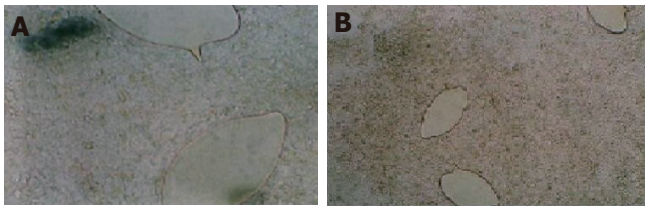

Figure 3 *Schistosoma mansoni* isolated in feces.

Two weeks later, the result of the bowel biopsy was available but did not support a diagnosis of a bowel inflammatory chronic disease, as suggested by the endoscopic patterns. The histopathological findings in colonic biopsies were negative for a bowel inflammatory chronic disease. Glands were regular in shape, with a normal amount of cytoplasmic mucous and without crypt abscesses. By contrast, the number of inflammatory cells increased in the *Lamina propria*, mostly eosinophils. These aspects, together with the clinical symptoms and the nationality of the patient, suggested that a searching for a parasitic infestation should be made. We were able to detect two *Schistosoma* eggs in the colonic mucosa, both of them were surrounded by a granuloma's reaction (Figure 2). Therefore, a diagnosis of "intestinal schistosomiasis" was made and was confirmed by the detection of *S mansoni* eggs in the feces (Figure 3).

On this basis, after two weeks, mesalazine was changed to praziquantel (40 mg/kg, single dose). Three weeks later, a third colonoscopy documented a significant improvement (data not shown). Therefore, the therapy with praziquantel was continued at the same dosage, and further improvement of the colonoscopy pattern was documented one month later (Figure 1B). Nothing was found in the other laboratory or radiographic tests, except of a weak plasma eosinophilia.

DISCUSSION

Schistosomiasis is an infectious disease, which affects more than 200 million people worldwide. Since it is endemic in at least three continents, Africa, Asia, and South America, it represents the most important public health problem of the tropical and sub-tropical areas[1,2]. In particular, Ghana is one of the African countries where schistosomiasis is more prevalent in both the urinary and intestinal forms[23,24].

Since the transmission of schistosomiasis is linked to the intermediate snail hosts, in the endemic countries the disease is more prevalent in subjects whose skin is more susceptible to contacts with water in rivers, lakes, swamps or artificial irrigation systems. This may occur frequently

in water-related activities of boatmen, fishermen, and rice workers. The infection is also promoted by unsanitary disposal of urine and feces and can occur in animals, such as dogs and cows[3,4,25].

S mansoni, a main agent of the intestinal form, together with *S japonicum*, *S mekongi,* and *S intercalatum*, is a trematode which parasitizes in human beings and also in other primates. *Schistosoma* eggs, upon deposition in the feces, mature in suitable environmental conditions (such as fresh water), giving rise to its larval forms (miracidia). These swimming forms reach and infect snails, species of the genus *Biomphalaria* (intermediate hosts), and mature in cercarie[26,27]. The cercarie are the infective forms for human beings and come out from the snails under specific conditions of light and temperature and infect men through the skin. During penetration, the cercarie shake off their tails and change into the next stage of the life cycle, the schistosomula, that reach the lungs and the liver. In the intrahepatic portal system, the worms complete the sexual stages of their development. Then, the adult females deposit the eggs in the small veins around the large intestine. Some of the eggs may be trapped in the gut wall or break loose into it and are then eliminated by feces. The eggs trapped in the gut wall are responsible for the inflammatory and immunopathologic responses, leading to erythema, edema, granulomas, ulcerations, hemorrhages, and fibrosis[28,29]. Regarding the pathogenesis of the disease, recent studies have dramatically changed the acknowledgment in this field. The T helper (Th) CD4+/CD8- cells, derived from hepatic granulomas of infected mice, may produce cytokines such as interleukin-2, interleukin-4, interferon-γ, with a type Th0 immunomediate response. After a longer period of infection, the murine models could show a type Th2 response[30-33].

The symptoms of our patient included nausea, meteorism, abdominal pain, bloody diarrhea, rectal tenesmus, and hepatosplenomegaly, which are consistent with those already reported[5]. The case showed some difficulties in terms of differential diagnosis of a chronic inflammatory bowel disease, since anatomical pathologic reports, in relation to the immediate endoscopic evidence, were not available.

Previous studies stated that colonoscopic findings are suggestive of schistosomiasis in about 45.3% of patients, but *S mansoni* eggs in feces are detectable in only 11.1% of the patients with colonic biopsies positive for *S mansoni*[34,35]. Endoscopic findings may not be typical and it is often hard to distinguish *Schistosoma* infection from a chronic inflammatory bowel disease, since these two disorders may show similar patterns, as shown in our patient[19,20].

Moreover, cystoscopy or rectosigmoidal endoscopy may be useful. In our case, the first probable diagnosis of bowel schistosomiasis was made by the detection of two *Schistosoma* eggs in the colonic mucosa, surrounded by a granuloma's reaction. During the disease's acute phase, the histological examination may show the presence of eggs on the ulcerated lesions as well as polyps-like forms on the bowel mucosa[36,37]. However, these aspects may be macroscopically and microscopically evocative of other disorders, such as chronic inflammatory bowel disease and infective colitis[38,39]. Therefore, diagnosis of schistosomiasis can be made by urine and feces examination and isolation of the agent.

When the correct diagnosis is made, the complete recovery of the patient can be achieved using a specific anti-parasitic therapy with praziquantel[40,41]. The intimate relationship between human beings and infected water leads to schistosomiasis elevated prevalence. Elimination of the intermediate hosts and avoiding the contact with infected water sources are the measures to prevent schistosomiasis[42]. For the treatment, current drugs include praziquantel, metriphonate[43], and oxamniquine[44].

We reported in this paper a case of an unsuspicious schistosomiasis, initially treated with mesalazine, for its peculiar difficulties in terms of differential diagnosis from a chronic inflammatory bowel disease. We suggest that the detection of the *Schistosoma* eggs in feces should always anticipate the colonoscopy examination. Since the prevalence of schistosomiasis has been increasing in Europe and USA, due to international travelers and immigrants[16-18,45], schistosomiasis should be considered in the differential diagnosis of patients with gastrointestinal symptoms.

Abstract

Plummer-Vinson syndrome (sideropenic dysphagia) is characterized by dysphagia due to an upper esophageal or hypopharyngeal web in patients with chronic iron deficiency anemia. The main cause of dysphagia is the presence of the web in the cervical esophagus, and abnormal motility of the pharynx or esophagus is also found to play a significant role in this condition. This syndrome is thought to be precancerous because squamous cell carcinoma of hypopharynx, oral cavity or esophagus takes place in 10% of those patients suffering from this malady, but it is even more unusual that Plummer-Vinson syndrome should be accompanied by gastric cancer. We have reported here a case of a 43-year-old woman with Plummer-Vinson syndrome who developed stomach cancer and recovered after a radical total gastrectomy with D2 nodal dissection.

Key words: Plummer-Vinson syndrome; Gastric cancer; Esophageal web

INTRODUCTION

Plummer-Vinson syndrome is characterized by dysphagia due to upper esophageal or hypopharyngeal web in patients with chronic iron deficiency anemia[1,2]. It is also combined with iron deficiency anemia, mucosal lesion of oral cavity or pharynx. This syndrome has been reported since 1893 in various literatures describing its specific symptoms. In 1926, Sir Arthur Hurst designated this symptom complex as Plummer-Vinson syndrome[1]. This syndrome is also referred to as Paterson-Kelly syndrome or sideropenic dysphagia. The main cause of dysphagia is the presence of a web in the cervical esophagus, and the abnormal motility of pharynx or esophagus is also found to play a significant role in the above causes[1,2]. It is well known that this syndrome is associated with an increased incidence of hypopharyngeal or cervical esophageal cancer. However, it is even more unusual that this syndrome is combined with gastric cancer[3]. So, we have reported a case of a 43-year-old woman who was initially diagnosed as Plummer-Vinson syndrome 2 years ago, and recently developed stomach cancer, which was managed successfully by surgery.

CASE REPORT

A 43-year-old woman was admitted to our hospital with symptoms of nausea, dysphagia and general weakness. She was diagnosed as Plummer-Vinson syndrome in April 2002, and has been managed conservatively on routine follow-ups. In August 2003, her nausea and dysphagia were aggravated. Her past history and family history were not specific. On admission, she complained about general weakness, mild abdominal pain and vomiting. The blood pressure was 0.247 kPa, pulse rate 90 bpm and body temperature 36.4 °C. The laboratory findings were consistent with microcystic, hypochronic iron deficiency anemia with 62 g/L hemoglobin, 22.2% hematocrit, 76.8 fL MCV, 21.5 pg MCH, 279 g/L MCHC, 325 000/μL platelet, 46 μg/dL serum iron, 271 μg/dL total iron binding capacity (TIBC), and 11.33 ng/mL serum ferritin. Urine analysis, serum liver function test (LFT), and serum electrolytes were unremarkable.

A gastrointestinal radiographic series indicated a linear filling defect (1.5 cm length) in the upper esophagus, which suggested an esophageal web (Figure 1). Contrast-enhanced abdominal CT scan showed diffuse irregular wall thickening with multiple calcifications at the body and antrum of the stomach. The CT scan also showed lymph node enlargement in the perigastric area and a mild enlargement of the spleen (Figure 2).

Esophagogastroduodenoscopic findings showed a web at 16 cm from the incisors. Upon endoscopic procedure for esophageal bougienage, we found a lesion at the cardia suspecting gastric cancer involving the upper body and the esophagogastric junction. Endoscopic biopsy proved to be a poorly differentiated adenocarcinoma. On surgical exploration, the serosa of the stomach was not invaded

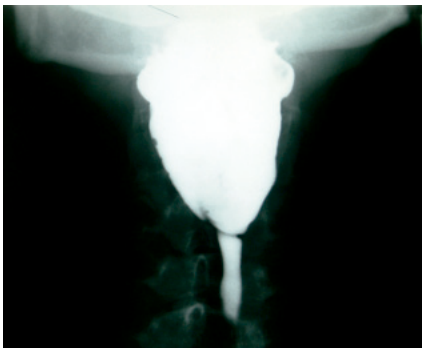

Figure 1 Esophagography showing a linear filling defect (1.5 cm length) at the upper esophagus, suggesting esophageal web.

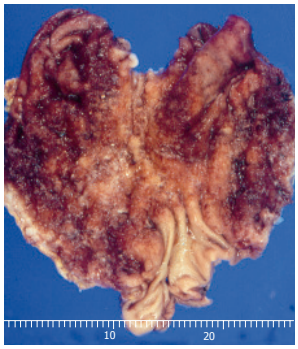

Figure 3 Macroscopic appearance of resected stomach showing a diffuse large Borrmann type 4 cancer in the whole body and cardia.

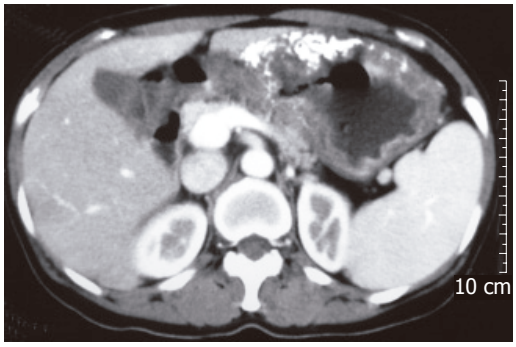

Figure 2 Contrast-enhanced abdominal CT scan showing diffuse irregular wall thickness with multiple calcifications at the body and antrum of the stomach.

macroscopically by cancer, but hilar lymph nodes of the spleen were grossly enlarged, suspecting tumor metastasis. The patient underwent a radical total gastrectomy with D2 nodal dissection. The spleen was taken out along with lymph node #10 and lymph node #11 d. No transfusion was required during and after the surgery. Excised surgical specimen demonstrated that the tumor size was 22 cm×18 cm, and both resection margins were tumor-free. The lesion was histologically confirmed as mucinous adenocarcinoma, Borrmann type IV, and it had infiltrated into the serosa with nodal metastasis of 33 out of 62 nodes. The TMN stage was T3N3M0 (Stage IV) (Figure 3). Iron supplemented soft diet was commenced on the 6th postoperative day. Peripheral blood findings improved within 2 wk after the surgery: 87 g/L hemoglobin, 28.5% hematocrit, 81.9 fL MCV, 25.0 pg MCH, 30.5 g/dL MCHC, and 1 186 000/μL platelets. The patient was discharged on the 19th postoperative day with no remarkable surgical complications except a mild nausea and surgical wound discomfort.

DISCUSSION

Plummer-Vinson syndrome, also known as Paterson-Kelly syndrome or sideropenic dysphagia[1], is characterized by dysphagia, iron deficiency anemia, and mucosal lesion of the oral cavity or pharynx. In 1893, Blackenstein reported a case with anemia, spasmodic stenosis of cervical esophagus and dysphagia[1]. The patient's symptoms were improved by endoscopic bougienage. In 1911, an another case with dysphagia due to upper esophageal web was reported, which was also alleviated by endoscopic bougienage. In 1912, Plummer[2] also reported cases with upper esophageal rigidity that the patients had iron deficiency anemia and splenomegaly. In 1922, Vinson named a series of patients with dysphagia, anemia, and splenomegaly as hysterical dysphagia[1]. In 1926, Sir Arthur Hurst designated similar cases of the syndrome as Plummer-Vinson syndrome[1].

The incidence of the Plummer-Vinson syndrome has recently decreased because of nutritional improvement, advanced health care, a decreased incidence of pregnancy and improved care programs for pregnant women. Moreover, this syndrome is now thought to be associated with the deficient intake of vitamins and iron[1,3,4]. Most patients are women aged over 40 years, and this group accounts for 75% in number[5,6]. The syndrome is usually asymptomatic, but the patients sometimes develop dysphagia, weight loss, and weakness. Other symptoms may include nail deformation of the hand and foot, cheilosis, atrophic glossitis, early loss of teeth, conjunctivitis, dermatitis seborrheica, hyperkeratosis, keratitis, blepharitis, visual disturbances and 30% of cases accompany splenomegaly[1]. The diagnosis of upper esophageal web is confirmed by radiologic methods or endoscopy. The radiologic method, however, is more suitable because endoscopy can sometimes miss the point of benign stricture, and does not verify most of the motility disorders[7]. On esophagography, the web is usually detected at the upper esophagus below the cricoid by showing a thin membrane across esophagus[8]. Pathologic finding of upper esophageal web shows hypertrophy or atrophy of squamous cells and it is sometimes combined with chronic inflammation[1].

Plummer-Vinson syndrome is known to be associated with an increased risk of upper alimentary tract cancers, and the incidence rate of upper esophageal cancer in this syndrome is 3-15%[6]. In Sweden, the incidence of upper alimentary tract cancer and hypopharyngeal cancer in Plummer-Vinson syndrome is decreasing along with that of the syndrome itself[3]. However, it is more unusual for

this syndrome to be accompanied by gastric cancer. Only two cases were reported in the literature, in which gastric cancer developed in the lower portion of the stomach[9,10]. In our case, the gastric cancer developed in the upper portion of the stomach involving esophagogastric junction.

It is not clear why Plummer-Vinson syndrome can exceptionally be associated with stomach cancer. However, it is widely accepted that atrophic mucosal change of alimentary tract due to iron deficiency anemia may lead to cancer development of the upper esophagus or hypopharynx. Therefore, careful examinations of hypopharynx, upper esophagus and stomach are of crucial importance for early detection of cancer development in this syndrome.

Abstract

Studies reported that there is a close relationship between hepatocellular carcinoma (HCC) and testis carcinoma. Both tumors can be presented as synchronal tumors, or as testicular metastases of HCC or as hepatic metastases of testicular tumor[7]. HCC is one of the most common malignancies worldwide and the incidence of HCC increases with age[8]. The relationship between hepatitis B incidence and HCC rates is also well recognized. Alpha fetoprotein (AFP) is produced by 70% of HCC. Though a level of AFP >400 ng/mL is diagnostic for HCC, in the presence of active hepatitis B infection, the cut-off level should be considered to be at least 1 000-4 000 ng/mL. Like HCC, germ cell tumors of the testis also release AFP; but it is shown that some of Sertoli cell tumors of testis can also release AFP[10]. Herein we have reported about the first case of HCC in the literature which is presented concomitantly with Sertoli-Leydig tumor of testis, leading to extremely high level of AFP in a 21-year-old man.

INTRODUCTION

Studies have reported that there is a close relationship between hepatocellular carcinoma (HCC) and testis carcinoma. Both tumors can be presented as synchronal tumors[1,2], or as testicular metastases of HCC[3-5] or as hepatic metastases of testicular tumor[6,7].

HCC is one of the most common malignancies worldwide and the incidence of HCC increases with age[8]. Alpha fetoprotein (AFP) is produced by 70% of HCC. Like HCC, germ cell tumors of the testis also release AFP[9]; but it is shown that some of Sertoli cell tumors of testis can also release AFP[10]. Herein we have reported the first case of HCC in the literature which is presented concomitantly with Sertoli-Leydig tumor of testis, leading to extremely high level of AFP in a 21-year-old man.

CASE REPORT

A 21-year-old man was admitted to our clinic in May 2002, with complaints of fatigue, nausea, vomiting, abdominal distention and weight loss. The patient was well before two months. His mother died of cirrhosis due to hepatitis B. His two sisters were HBsAg seropositive. On physical examination minimal ascites was detected and the abdomen was tender on palpation. The liver was palpated under the rib margin as 10 cm and was also tender. The spleen was palpated as 6 cm. Other systems were normal on examination. On admission, laboratory tests performed reported ALT: 64 IU/L (0-41), AST: 44 IU/L (0-37), fasting plasma glucose: 94 mg/dL, urea: 21 mg/dL, serum creatinine: 0.65 mg/dL, LDH: 500 IU/mL (240-480), GGT: 161 U/L (0-49), ALP: 372 U/L, T prot: 67 g/L, alb: 36 g/L, glob: 31 g/L, D bil: 0.76 mg/dL, I bil: 1.09 mg/dL, total cholesterol: 463 mg/dL, triglyceride: 130 mg/dL, LDL: 413 mg/dL, HDL: 24 mg/dL, VLDL: 38.2 mg/dL, Na: 138 mmol/L, K: 3.9 mmol/L, Ca: 9.4 mmol/L, Fe: 43 μg/dL, total iron binding capacity: 396 μg/dL, hemoglobin:11.5 g/dL, hematocrit: 34.8%, white blood cell: 2 700, platelet: 215 000, MCV: 83 fL, erythrocyte sedimentation rate: 12 mm/h. Markers of viral hepatitis were HBsAg (+), antiHBs (-), antiHCV -), HbeAg (-), antiHBe (-).

On ultrasonographic examination, the liver was heterogenous and there were multiple hypodense lesions in the right and left liver lobes. Thromboses were seen in both hepatic and portal veins in Doppler ultrasound. The AFP level was 5 181 000/mL (0-10) and beta-HCG was 0.5 mIU/mL (normal range: 5-10 mIU/mL). Computerized abdominal tomography showed that the craniocaudal sizes of the liver and spleen were 25 and 22 cm respectively. The liver margin was irregular, the right and

left lobes of the liver contained multiple hypodense lesions resembling metastasis or primary HCC. A liver biopsy was done to identify the hypodense lesions of the liver. Diffuse fibrosis and HCC were reported from the histopathological examination. Hepatocytes were positive for keratin and AFP, but negative for vimentin. Because of the young age of the patient, the presence of multiple hepatic hypodense lesions resembling metastasis and the extremely high AFP level, an examination of the testis was also done to exclude a testicular tumor. Physical examination of the testis revealed a painless mass on the left testis. Ultrasound sonography showed a hypoechoic lesion (19 mm× 18 mm×17 mm in size) in the left testis. High inguinal orchiectomy was performed. The tumor within the testis was histopathologically diagnosed as Sertoli cell testis tumor. Leydig cells were negative for keratin but positive for vimentin. Finally, the patient who had primary HCC and primary Sertoli cell tumor of the testis (two primary tumors concomitantly presented) was referred to the oncology clinic for further evaluation and therapy.

DISCUSSION

HCC is one of the commonest malignant diseases in the world and the majority of cases of HCC arise in individuals with chronic hepatitis B or C virus infections[11]. All ages can be affected by HCC. The mean age at diagnosis is 53 years in Asia and 62 years in the United States. Recently, an analysis of 76 HCC cases investigated by Butt *et al*.[8] showed that the mean age is 52.2±11.3 years and the mean AFP level is 142±155 ng/mL. In contrary, our patient was very young and the AFP level was very high. Transmission of hepatitis B virus from his mother at the very early time of his life might be the cause of HCC development at the very young age.

AFP continues to be the best marker for early diagnosis of HCC. In adults the value of AFP up to 20 ng/mL is considered to be normal. Patients with hepatitis B virus-related cirrhosis having AFP level greater than 100 ng/mL are in the very high risk group for HCC. The AFP level usually correlates with tumor size[12]. Thus, the very high level of AFP in our patient may be due to the large tumor size, which was multifocal in both lobes of the liver.

Extremely high AFP levels are found in endodermal sinus tumors (yolk sac tumors) also[13]. Such neoplasms occur in testis, ovary and extragonadal sites. Typically they occur in young subjects. Hence we also examined the testis in our patient and performed orchiectomy after we palpated a testicular mass. The histopathological result was a Sertoli cell tumor of the testis, which was a testicular gonadal stromal tumor. Sertoli cell tumor (SCT) is very rare among testis tumors accounting for lower than 1% of primary testicular neoplasms. It is subclassified into three groups: classic, large cell calcifying (LCCSCT), and sclerosing. Most SCTs are benign, metastases are the only reliable indicator of malignancy, occurring in lower than 10% of cases. The most common sites for metastatic spread are retroperitoneal lymph nodes, lungs, liver, and bone. LCCSCT and sclerosing SCT have minimal metastatic potential[14].

The risk for liver cancer is very high in cirrhotic liver. There is also evidence that the risk for extrahepatic cancers increases in patients with cirrhosis. The reason of the increased extrahepatic malignancy risk in cirrhosis is not clear but may be due to many abnormal and metabolic alterations in cirrhosis like hyperestrogenism, alterations in metabolism of lipid and water-soluble drugs and other chemicals, alterations in immune functions and risk of infections in cirrhosis[15]. In this cohort study, Sorensen *et al*.[15] also reported that the occurrence of liver cancer, tobacco- and alcohol-related cancers, testicular cancer, stomach and colon cancer is significantly higher in cirrhosis than expected. This study may explain two primary cancers in our young patient which were thought to be cirrhotic due to chronic hepatitis B infection.

Though our case was in a state of decompensated liver failure, he had hypercholesterolemia which was parallel to the change in serum AFP. Hwang *et al*.[16] also observed that HCC patients with hypercholesterolemia have significantly higher mean serum levels of albumin, triglyceride, and AFP compared with age-sex-tumor volume-matched HCC patients without hypercholesterolemia. It was reported that 11% of HCC patients have hypercholesterolemia, which can be explained by the possible result from the absence of dietary cholesterol suppression feedback regulation in the damaged liver[17].

In conclusion, this case is an example showing the increased risk of hepatic and extrahepatic tumors in cirrhosis. In the presence of HCC in a cirrhotic patient, there might be multiple primary cancers. The possibility of second primary malignancy in a patient with HCC should be kept in mind especially when a very high level of AFP is encountered and this second primary malignancy may be a kind of a very rare tumor. However, the co-existence of HCC and testis tumor is very rare. As far as we know, this is the first case report showing the co-existence of HCC and SCT in a young boy presented with an extremely high level of AFP.

Abstract

Mast cell (MC) is so widely recognized as a critical effector in allergic disorders that it can be difficult to think of MC in any other context. Indeed, MCs are multifunctional and recently shown that MCs can also act as antigen presenters as well as effector elements of human immune system. First observations of their possible role as anti-tumor cells in peri- or intra-tumoral tissue were mentioned five decades ago and a high content of MCs is considered as a favorable prognosis, consistent with this study. Believers of this hypothesis assumed them to be inhibitors of tumor development through their pro-apoptotic and -necrolytic granules e.g., granzymes and TNF-α. However, some still postulate them to be enhancers of tumor development through their effects on angiogenesis due to mostly tryptase. There are also some data suggesting increased MC density causes tumor development and indicates bad prognosis. Furthermore, since MC-associated mediators have shown to influence various aspects of tumor biology, the net effect of MCs on the development/progression of tumors has been difficult to evaluate. For instance, chymase induces apoptosis in targets; yet, tryptase, another MC protease, is a well-known mitogen. MCs with these various enzyme expression patterns may mediate different functions and the predominant MC type in tissues may be determined by the environmental needs. The coexistence of tryptase-expressing MCs (MC_T) and chymase and tryptase-expressing MCs (MC_{TC}) in physiological conditions reflects a naturally occurring balance that contributes to tissue homeostasis. We have recently discussed the role and relevance of MC serine proteases in different bone marrow diseases.

LETTER TO THE EDITOR

I read the article by Tan *et al*.[1] describing `prognostic significance of cell infiltrations of immunosurveillance in colorectal cancer with great interest. My interest in this study is that we have recently demonstrated human mast cell (MC) mediated cytotoxicity against different human leukemia and lymphoma tumor cells *in vitro*[2-4]. Our *in vitro* results seem to support their study conclusion of MC cytotoxicity against tumor cells that might contribute to immunosurveillance *in vivo*. The genuine role of MC in tumor stroma has been a very controversial topic for the past five decades and needs still further clarification. Here, I have discussed further primarily the anti-tumor effects of MC in the light of recent literature and our findings.

MC is so widely recognized as a critical effector in allergic disorders that it can be difficult to think of MC in any other context. Indeed, MCs are multifunctional and recently shown that MCs can also act as antigen presenters as well as effector elements of human immune system. First observations of their possible role as anti-tumor cells in peri- or intra-tumoral tissue were mentioned five decades ago and a high content of MCs is considered as a favorable prognosis, consistent with this study[1,5,6]. Believers of this hypothesis assumed them to be inhibitors of tumor development through their pro-apoptotic and -necrolytic granules e.g. granzymes and TNF-α. However, some still postulate them to be enhancers of tumor development through their effects on angiogenesis due to mostly tryptase. There are also some data suggesting that increased MC density causes tumor development and indicates bad prognosis[7,8]. MCs with these various enzyme expression patterns may mediate different functions and the predominant MC type in tissues may be determined by the environmental needs. Furthermore, since MC-associated mediators have shown to influence various aspects of tumor biology, the net effect of MCs on the development/progression of tumors has been difficult to evaluate. For instance, chymase induces apoptosis in targets; yet, tryptase, another MC protease, is a well-known mitogen. We have recently discussed the role and relevance of MC serine proteases in different bone marrow diseases[9]. The coexistence of tryptase-expressing MCs (MC_T) and chymase and tryptase-expressing MCs (MC_{TC}) in physiological conditions reflects a naturally occurring balance that contributes to tissue homeostasis.

In the past two decades, it was believed that murine MC has natural cytotoxicity in the long term (>24 h) against murine tumor cells (WEHI-164, L929, etc.) by different mechanisms e.g. TNF-α dependent and non-TNF-α dependent[10]. Recent studies suggested that MC

can kill targets through degranulation of serine proteases, cathepsin G, leukotrienes and NO. Lately, MCs have been shown to contain granzyme B[11] and express Fas ligand[12], which are the most important components of cell mediated cytotoxicity. Chymase was also demonstrated to induce apoptosis in neonatal rat cardiomyocytes and human vascular smooth muscle cells[13]. Thus, MC mediated cytotoxicity seems to be operated by at least 2 pathways: by secretory pathways via exocytosis of granules containing serine proteases such as granzymes, chymase and soluble TNF-α; and nonsecretory (cell-to-cell contact) pathways via membranous TNF-α and FasL. We are the first to show human MC cytotoxicity against NK-sensitive/resistant human leukemia/lymphoma cells in short and long term by our established flow cytometric method[2-4]. Our studies suggested that increased chymase content of MCs in long-term culture could have played a role to mediate cytotoxicity.

Tan *et al.* demonstrated in this study that both MCT and MCTC may equally proliferate or infiltrate in colorectal cancer similar to hepatocellular carcinoma and intrahepatic cholangiocarcinoma, consistent with some earlier literature[14]. In contrast to these reports, in some malignant lesions, MCT`s were found to be concentrated at the tumor edge, i.e., the "invasion zone," whereas MCTCs were not increased in this area[15-17]. For instance, a significant increase of MCT phenotype was observed in the invasive carcinoma of the cervix throughout the different stages of malignant transformation. Furthermore, an abundant MCT (but not MCTC) increase was detected infiltrating the tumors in sections of invasive carcinoma although the number of MCT was shown to be similar to that of MCTC in benign lesions. Malignant tumors had 2 to 3 times more MCT than MCTC and the number of MCT was noted to be significantly higher in malignant than benign lesions.

Our studies and past literature review suggest that increase of MC density in tumor stroma is as important as the phenotypic change[18,19] causing predominance of one phenotype. Consistent with this study, if chymase containing MCs (MCTC/MCC) were dominant over MCT in tumor stroma, this would usually be predictor of good prognosis such as in localized bronchioloalveolar carcinoma[20] and human renal tumors[21]. In contrast to this opinion, there are a few data suggesting that MCTC/MCC are related to a bad prognosis e.g. lip and some gastrointestinal cancers[22,23]. Nevertheless, overall chymase content of granules in MCs as well as timing of biopsy and other factors could be also important in these exceptional cases. If MCT`s were dominant over MCCT/MCC, this would be a bad prognostic factor such as in cervix cancer, B-cell non-Hodgkin's lymphoma and others[24,25]. Mounting evidence certainly indicates that MCs accumulate around the tumors and could either promote or inhibit tumor growth depending on the local stromal conditions[26]. These findings overall emphasize the role of MCT type in the tumor development rather than chymase containing MCs (MCC and/or MCCT) but this requires further studies and clarification. My personal conclusion is that inhibitory or proliferative effects of MCs depend on multiple interactions among MC, tumor type and the environment.

TO THE EDITOR

We read with great interest the article by XP *et al*.[1] They reported the results of their experience with transcatheter arterial chemoembolization (TACE) and systemic chemotherapy for forty-five patients with liver metastases from breast cancer and evaluate the prognostic factors. In their study, the response and survival rates were significantly better in TACE group than in chemotherapy group. The lymph node status of the primary cancer, the clinical stage of liver metastases, the Child-Pugh grade, loss of weight were found to be significantly associated with survival in both univariate and multivariate and analyses. However, they did not mention hormone receptor status of the patients that might have an effect on the survival rate. Elias *et al*.[2] in their study evaluated 54 breast cancer patients with liver metastases as the sole site of metastatic disease (except for bone metastases in 3 patients) that underwent hepatectomy. They showed that the only factor influencing survival in both the univariate and multivariate analyses was the hormone receptor status ($P = 0.03$), and the relative risk of death increased by 3.5-fold when hormone receptor was negative. Moreover, Mack *et al* [3] reported excellent local tumor control and survival rates achieved by laser induced interstitial thermotherapy (LITT) in breast cancer patients with liver metastases. Regarding the prognostic and predictive factors related to primary tumor, they found no statistically significant difference in terms of mean survival between the patients with N0-N1 lymph nodes and N2-N3 lymph nodes. However, they found that the hormone receptor status is a significant ($P<0.05$) prognostic factor on both mean and median survival. The mean survival in patients with positive hormone receptor status was 5.5 years (95%CI: 4.8-6.3 years, median survival 4.7 years) starting the calculation at the date of diagnosis of the metastases treated with LITT. The mean survival in patients with negative hormone receptor status was 3.7 years (95%CI: 2.8-4.6 years, median survival 5.1 years)[4].

In the light of the above information, hormone receptor status of primary tumor should also be evaluated as a prognostic factor in patients with breast cancer and liver metastases treated with TACE and systemic chemotherapy.

World J Gastroenterol 2005;11(44):7060-7061
World Journal of Gastroenterology ISSN 1007-9327

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG,* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc*., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Published jointly by
The WJG Press and Elsevier Inc.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297×210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures and Figure Legends. Neither the Editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and Elsevier Inc., and may not be reproduced by any means, in whole or in part without the written permission of both the Authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations.

Online submission
Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com for assistance. If you submit manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission
Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4(297×210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

World Journal of Gastroenterology
Apartment 1066 Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors originating from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page
Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be involved. Titles should be concise and informative (removing all unnecessary words), emphasize what is NEW, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initials and/or first name, middle name or initial(s) and full family name.

Abstract
An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc*. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words
Please list 3-10 key words that could reflect content of the study.

Text
For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the body text or Figures and Tables, not both.

Illustrations
Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should add into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) and not RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126× 76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by Freehand and Illustrator, or TIFF from Photoshop. EPS files must be accompanied by a version in native file format for editing purposes. Scans of existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size at which they will appear when printed, not smaller. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...;C: ...; D: ...; E: ...; F: ...; G: ...

Tables
Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be involved under the tables. This part should add into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data which is not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used; Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or some other symbols with a superscript (Arabic

numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*. in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

References

Cited references should mainly be drawn from journals covered in the Science Citation Index (http://www.isinet.com) and/or Index Medicus (http://www.ncbi.nlm.nih.gov/PubMed) databases. Mention all references in the text, tables and figure legends, and set off by consecutive, superscripted Arabic numerals. References should be numbered consecutively in the order in which they appear in the text. Abbreviate journal title names according to the Index Medicus style (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=journals). Unpublished observations and personal communications are not listed as references. The style and punctuation of the references conform to ISO standard and the Vancouver style (5th edition); see examples below. Reference lists not conforming to this style could lead to delayed or even rejected publication status. Examples:

Standard jounal article (list all authors and include the PubMed ID [PMID] where applicable)

1 **Das KM,** Farag SA. Current medical therapy of inflammatory bowel disease. *World J Gastroenterol* 2000; 6: 483-489 [PMID: 11819634]

2 **Pan BR**, Hodgson HJF, Kalsi J. Hyperglobulinemia in chronic liver disease: Relationships between *in vitro* immunoglobulin synthesis, short lived suppressor cell activity and serum immunoglobulin levels. *Clin Exp Immunol* 1984; 55: 546-551 [PMID: 6231144]

3 **Lin GZ,** Wang XZ, Wang P, Lin J, Yang FD. Immunologic effect of Jianpi Yishen decoction in treatment of Pixu-diarrhoea. *Shijie Huaren Xiaohua Zazhi* 1999; 7: 285-287 [CMFAID:1082371101835979]

Books and other monographs (list all authors)

4 **Sherlock S,** Dooley J. Diseases of the liver and billiary system. 9th ed. Oxford: Blackwell Sci Pub, 1993: 258-296

Chapter in a book (list all authors)

5 **Lam SK.** Academic investigator's perspectives of medical treatment for peptic ulcer. In: Swabb EA, Azabo S. Ulcer disease: investigation and basis for therapy. New York: Marcel Dekker, 1991: 431-450

Electronic journal (list all authors)

6 **Morse SS.** Factors in the emergence of infectious diseases. Emerg Infect Dis serial online, 1995-01-03, cited 1996-06-05; 1(1):24 screens. Available from: URL: http//www.cdc.gov/ncidod/EID/eid.htm

PMID requirement

From the full reference list, please submit a separate list of those references embodied in PubMed, keeping the same order as in the full reference list, with the following information only: (1) abbreviated journal name and citation (e.g. *World J Gastroenterol* 2003;9(11):2400-2403; (2) article title (e.g. Epidemiology of gastroenterologic cancer in Henan Province, China; (3) full author list (e.g. Lu JB, Sun XB, Dai DX, Zhu SK, Chang QL, Liu SZ, Duan WJ; (4) PMID (e.g. 14606064). Provide the full abstracts of these references, as quoted from PubMed on a 3.5 inch disk or CD-ROM in Microsoft Word format and send by post to The *WJG* Press. For those references taken from journals not indexed by *Index Medicus*, a printed copy of the first page of the full reference should be submitted. Attach these references to the end of the manuscript in their order of appearance in the text.

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean±SD and mean±SE.

Statistical expression

Express *t* test as *t*(in italics), *F* test as *F*(in italics), chi square test as χ^2(in Greek), related coefficient as *r*(in italics), degree of freedom as γ (in Greek), sample number as *n*(in italics), and probability as *P*(in italics).

Units

Use SI units. For example: body mass, m(B) = 78 kg; blood pressure, p(B)=16.2/12.3 kPa; incubation time, t(incubation)=96 h, blood glucose concentration, c(glucose) 6.4±2.1 mmol/L; blood CEA mass concentration, p(CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23,243,641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italicization

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc*.

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc*.

Biology: *Helicobacter pylori, H pylori, E coli, etc*.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the WJG Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

It is the policy of WJG to acquire copyright in all contributions. Papers accepted for publication become the copyright of WJG and authors will be asked to sign a transfer of copyright form. All authors must read and agree to the conditions outlined in the Copyright Assignment Form (which can be downloaded from http://www.wjgnet.com/wjg/help/9.doc).

Final check list for authors

The format is at: http://www.wjgnet.com/wjg/help/13.doc

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: http://www.wjgnet.com/wjg/help/10.doc

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Publication fee

Authors of accepted articles must pay publication fee.

PO Box 2345, Beijing 100023, China

Abstract

Although various animal models have been developed to clarify gastric carcinogenesis, apparent mechanism of gastric cancer was not clarified in recent years. Since the recognition of the pathogenicity of *Helicobacter pylori* (*H pylori*), several animal models with *H pylori* infection have been developed to confirm the association between *H pylori* and gastric cancer. Nonhuman primate and rodent models were suitable for this study. Japanese monkey model revealed atrophic gastritis and p53 mutation after long-term infection of *H pylori*. Mongolian gerbil model showed the development of gastric carcinoma with *H pylori* infection alone, as well as with combination of chemical carcinogens, such as *N*-methyl-*N*-nitrosourea and *N*-methyl-*N*-nitro-*N*'-nitrosoguanidine. The histopathological changes of these animal models after *H pylori* inoculation are closely similar to those in human beings with *H pylori* infection. Eradication therapy attenuated the development of gastric cancer in *H pylori*-infected Mongolian gerbil. Although several features of animal models differ from those seen in human beings, these experimental models provide a starting point for further studies to clarify the mechanism of gastric carcinogenesis as a result of *H pylori* infection and assist the planning of eradication therapy to prevent gastric carcinoma.

Key words: *Helicobacter pylori*; Gastric carcinoma; Animal model; Japanese monkey; Mongolian gerbil

INTRODUCTION

Gastric cancer is one of the main causes of cancer-related mortality, especially, in East Asia. To clarify the mechanism of gastric cancer development, many experimental models have been used. However, almost all experimental animals, that showed spontaneous gastric cancer were very rare[1]; therefore several animal models were established using chemical carcinogens, such as *N*-methyl-*N*-nitrosourea (MNU)[2,3] and *N*-methyl-*N*-nitro-*N'*-nitrosoguanidine (MNNG)[4,5], which showed a high rate of gastric cancer development, especially in the antrum.

Since Warren and Marshall[6] revealed the microorganism which inhabits the stomach, *Helicobacter pylori* (*H pylori*) was considered as the major factor of many kind of gastroduodenal diseases, such as acute gastritis[7-9], chronic atrophic gastritis[9,10], intestinal metaplasia[11], peptic ulcer[12,13], mucosal associated lymphoid tissue lymphoma[14], gastric cancer[15-18], and others[19,20].

Previously, a large number of epidemiological studies indicated that *H pylori* infection has a close relation with gastric cancer[15-18]. Therefore, the International Agency for Research on Cancer (IARC) conference of the World Health Organization (WHO) defined *H pylori* as a definite carcinogen (Group I) to the human stomach based on three prospective case-control studies[15-17] reported in 1991[21].

However, the mechanisms by which *H pylori* infection develop gastric cancer are not defined in detail. In further studies, attempts have been made to reveal the possible mechanisms by which *H pylori* contributes to the development of gastric carcinoma and many researchers have developed animal models of infection using *Helicobacter* species.

Previously, a large number of animal experimental models have been developed to define the association between *H pylori* infection and gastroduodenal disease, such as piglet[22], beagle dog[23], mice[24], rhesus monkey[25], Japanese monkey (*Macaca fuscata*)[9,26,27], Mongolian gerbil[28], and others. In the beginning of the development of experimental models, only a few models had long periods of infection.

We have reported the results of a 5-year study on *H pylori* infection using Japanese monkeys (*Macaca fuscata*)[27]

and have obtained the findings that advance gastric mucosal atrophy, increase proliferation and mutation of p53 in gastric epithelial cells[29,30].

Several experiments, which demonstrated that chronic *H pylori* infection models of Mongolian gerbils developed gastric carcinoma, were conducted[31-33]. In these experiments, the animals were mainly divided into two groups: one group was infected with *H pylori* alone and the group was given a known carcinogen such as MNU and MNNG in addition to persistent *H pylori* infection. The results of these experiments revealed that animals in different groups developed different histopathological types of gastric carcinoma. These results will be very useful to elucidate the mechanism of gastric carcinogenesis due to *H pylori* infection.

GASTRIC CANCER AND JAPANESE MONKEY

The nonhuman primate animals are useful to clarify the relationship between *H pylori* and gastric diseases. Their stomachs are similar to those of human beings anatomically, physiologically, and dietary, compared with rodent animals. They have 10-20 years of long life span, which enables long-term follow-up with endoscopy and repeated histological examinations of the stomach using biopsy or endoscopic resected specimens. Several primate animals have been reported to be successful in experimental transmission of *H pylori* in chimpanzees (*Pan troglodytes*)[34], and species of macaques: rhesus monkey (*M. mulatta*)[25], cynomolgus monkey (*M. fascicularis*)[25], and Japanese monkey (*M. fuscata*)[9,26,27]. In these animals, some kinds of *Macaque* species are available for a wide variety of research field. We have established the Japanese monkey model with *H pylori* infection. This experimental model is very useful and a promising nonhuman primate model[9,26,27].

The methods of development of this monkey model are described briefly. The bacterial strains used were *H pylori* MCO 88155, MCO 88099, MCO 88142, and MCO 88156, isolated from two patients with duodenal ulcers and two with gastric ulcers. The colonies were suspended in 5 mL of sterile saline, and the bacterial concentration was adjusted to 10^9 CFU/mL. These were resuspended in 8 mL of sterile saline, and 5 mL of the final resuspension was used in each monkey. The animals were given ampicillin orally to eradicate spiral bacteria other than *H pylori*. After treatment with ampicillin, spiral bacteria were not found in any of the stomachs. The monkeys were sprayed with 5 mL of a mixed suspension of four bacterial strains endoscopically around their antrum. The gastric mucosa was examined endoscopically, and endoscopic mucosal resection was performed repeatedly during 6 years of observation.

One week after inoculation, all infected monkeys showed endoscopic acute gastritis accompanied by marked erythema and edema. These findings were consistent with the acute gastric mucosal lesion observed in the human stomach. Infection of *H pylori* was recognized by culture, the rapid urease test, histology, and the elevation of *H pylori*-specific IgG in plasma. In the early phase of infection, infiltration of monocytes and polymorphonuclear leukocytes were marked in the edematous lamina propria and superficial erosions were evident. After 3 mo of inoculation, infiltration of mononuclear cells and plasma cells were predominant in the lamina propria layer. However, no superficial erosions and atrophic changes were observed.

In the infected group, the gastritis score which was evaluated by a scoring system based on the method of Rauws *et al*[35]. were markedly increased in the antral mucosa 1 wk after inoculation ($P<0.001$). The score then gradually decreased throughout the whole investigation period, but remained significantly higher ($P<0.01$) than that of the control group.

Six months after inoculation, the pyloric glandular height was apparently lower in the infected animals than in controls. Furthermore, the atrophic change advanced gradually throughout the 5-year observation period[27]. Endoscopically, according to the endoscopic-atrophic-border scale described by Kimura and Takemoto[36], gastric atrophy also gradually advanced for more than 3 years. These findings indicated evidently that *H pylori* infection caused atrophic gastritis in the Japanese monkey model. Cell proliferation activity, which was revealed with immunohistochemical detection of Ki-67 in the antral mucosa of infected animals, was significantly accelerated throughout the entire observation period (Figure 1). Immunohistochemical detection of p53 and point mutation of *p53* was exhibited in the gastric mucosa[29,30] of this model. Genetic alterations in exons 5-8 of the p53 gene were uncommon in the *H pylori*-uninfected monkeys, whereas a higher prevalence of missense mutations in the p53 gene appeared in association with *H pylori* infection (Table 1). The number of mutations in the p53 gene increased as the gastric atrophy score increased, which depends on the duration of *H pylori* infection[30]. These findings of Japanese monkey model may explain the potential mechanism for the causal role of *H pylori* in the chain of events leading to gastric carcinoma. This monkey model facilitates investigation of the correlation between the long-term sequence of *H pylori* infection and gradual gastric mucosal change. Although many pathophysiological changes were seen in *H pylori*-infected gastric mucosa, this Japanese monkey model did not show the development of gastric carcinoma. In their long life span, which is similar to human beings, further continuous infection may be needed to the more dramatic histological change.

DEVELOPMENT OF THE RODENT MODEL

Several rodent models were established for examining the etiological feature of *Helicobacter* species infection, such as mice[24,37], rat[38], and Mongolian gerbil[28]. Compared with nonhuman primate models, rodent models are treated easily, and are economical.

Marchetti *et al*[39]. reported the several clinical isolates colonized the stomach of SPF conditioned mice (CD1 mice) and Balb/c mice; however, colonization was very

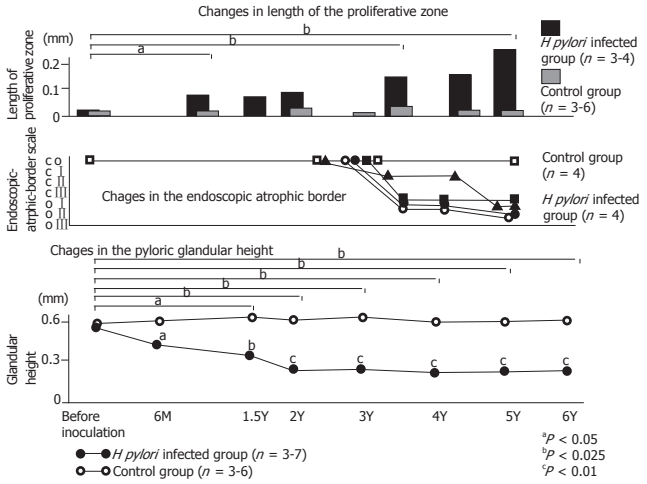

Figure 1 Gastric mucosal alteration of Japanese monkey model with *H pylori* infection. Upper graph showed the gradual increase of the proliferative zone of *H pylori*-infected Japanese monkey model. Middle graph showed the alteration of endoscopic-atrophic-border scale of this model. Macroscopically, gastric atrophy advanced for more than 3 yr. Lower graph showed the alteration of the pyloric glandular height. Six months after inoculation, the pyloric glandular height was apparently lower in the infected animals than in controls. Furthermore, the atrophic change advanced gradually throughout the 6-yr observation period.

Table 1 Duration of *H pylori* infection and number of point mutations in exon 5-8 of the p53 gene

Monkey	Duration of *H pylori* infection (yr)	Number of nucleotide (amino acid) substitutions in p53				Atrophy score[1]	Intensity of p53 immunostaining[2]
		Ex 5	Ex 6	Ex 7	Ex 8		
A	1.5	0 (0)	2 (1)	0 (0)	1 (1)	2	-
B	2	4 (0)	2 (2)	5 (4)	4 (3)	3	-
C	3	4 (2)	1 (0)	2 (2)	2 (2)	4	+
D	3	2 (1)	1 (0)	1 (1)	4 (2)	5	+
E	3.5	5 (2)	2 (1)	5 (4)	6 (4)	4	+
F	4.5	5 (1)	3 (1)	4 (3)	5 (4)	6	-
G	5	4 (1)	3 (1)	2 (1)	8 (6)	8	+
H	7.5	8 (5)	2 (1)	5 (4)	8 (4)	12	++

[1], The atrophy score was calculated as the sum of the histological evaluations of five gastric specimens according to Updated Sydney System. [2], The intensity of p53 immunostaining was classified into four grades: -, no staining; +, mild staining; ++, moderate staining; +++, intense staining.

low. Lee *et al*[40]. reported the quite good colonization by using the Sydney strain of *H pylori* (strain SS1), which is cagA and vacA positive.

These rodent models showed meager development of spontaneous gastric cancer. Cui *et al*[41]. reported the development of spontaneous gastric carcinoma, classified as malignant enterochromaffin-like (ECL) carcinomas in female cotton rats (*Sigmodon hispidus*). Previously, chemical carcinogens such as MNNG and MNU have been often used in the rodent species for the investigation of experimental gastric cancer[2-5].

From the recognition of *Helicobacter* species' pathogenicity, Fox *et al*[42]. reported a possible carcinogenic role for *Helicobacter* species in the gastric mucosa after oral administration of MNNG in ferrets infected with *Helicobacter mustelae*. Nine out of the ten ferrets, which were given a dose of 50 mg/kg MNNG orally, developed adenocarcinoma. This was the first experimental study using carcinogens combined with infection with a *Helicobacter* species. Although spontaneous gastric adenocarcinomas have been reported[43] in aged ferrets with *H mustelae* even in the absence of carcinogen exposure, an important additional problem is that the bacterium used was not *H pylori* but *H mustelae*. Fox *et al*[44]. also described the development of gastric adenocarcinoma, which was led from severe gastritis in C57BL/6 mice with *Helicobacter felis* inoculation. In their report, p53+/- mice showed significant low prevalence of fundic lymphoplasmacytic infiltration and submucosal lymphoid follicle formation than those in C57BL/6 mice. They indicated two distinct roles of p53, one of them displayed the gastric cancer risk. However, deletion of one *p53* allele results in a down-regulated Th1 response to *Helicobacter* infection, which may indirectly protect against the development of gastric cancer associated with chronic inflammation.

The differences between *H felis* in mice and *H pylori* in human beings are the lack of induction of neutrophil and cag pathogenicity island, which are recognized as main pathogens of *H pylori*. Kim *et al*[45]. reported that C57BL/6 mice infected with *H pylori* (SS1 strain) showed no evidence of gastric adenoma, dysplasia, and carcinoma during 80 wk of infection. They explained this result by the balance that exists between cell proliferation and apoptosis.

Transgenic hypergastrinemic (INS-GAS) mouse model have also been useful for the investigation of gastric carcinogenesis. Fox *et al*[46]. reported that male INS-GAS mice infected with *H pylori* developed atrophy, intestinal metaplasia, and dysplasia and adenocarcinoma. This murine model with *H pylori cagE* mutant showed the deletion of development of cancer. In contrast, none of the female mice with *H pylori* infection developed adenocarcinoma. However, IL-1 levels showed no significant difference between males and females. Fox *et al*. concluded that the INS-GAS model is effective for investigating discrete host-microbial interactions that culminate in gastric cancer within the context of biologic conditions induced by *H pylori*.

DEVELOPMENT OF MONGOLIAN GERBIL MODEL

Yokota *et al*[28]. developed the experimental Mongolian gerbil model with *H pylori* infection, in which only a mild inflammatory infiltration in the gastric mucosa was seen during two months of their observation. Hirayama *et al*[47]. described that ulcers and intestinal metaplasia were produced 6 mo after inoculation with *H pylori* in Mongolian gerbils.

In our laboratory, 5-wk-old male Mongolian gerbils weighing 30-40 g (Seiwa Experimental Animals Co. Ltd., Fukuoka, Japan) were used[48]. *H pylori* ATCC-43504 possessing the cagA gene and expressing vacuolating cytotoxin was used. A 4-d culture on blood agar at 37 ℃ under microaerophilic conditions was harvested and incubated in brucella broth (DIFCO Laboratories, Detroit,

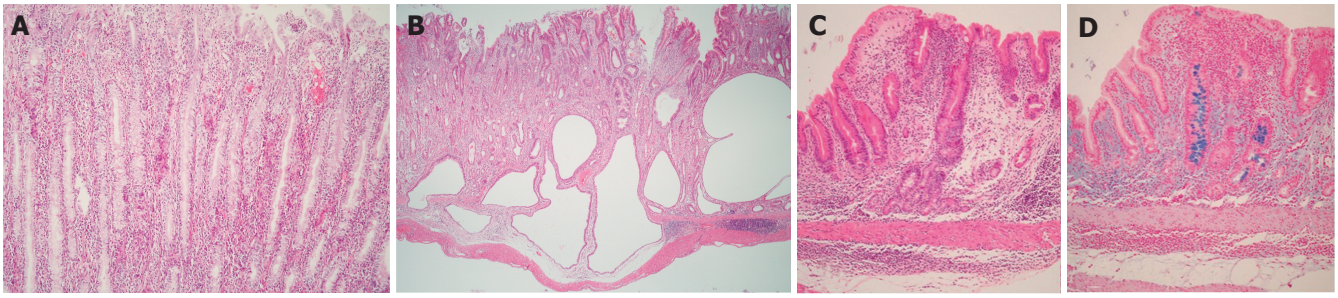

Figure 2 Microscopic views of the gastric body of Mongolian gerbils at 18 mo after *H pylori* inoculation. **A:** Severe infiltration of polymorphonuclear and mononuclear cells were seen in the lamina propria. (HE stain, x100); **B:** Some glands have extended into the submucosa but not into the proper muscularis layer. Severe infiltration of mononuclear cells in the submucosa (HE stain, x10); **C:** Intestinal metaplasia is seen scattering in gastric mucosa (HE stain, x10); **D:** Intestinal metaplasia (Alcian blue stain (pH 2.5); original magnification, x10).

MI, USA) with 10% horse serum for 24 h. Inoculum size was adjusted with sterile saline to produce the optical density of McFarland 4 at 540 nm. Mongolian gerbils were housed five per cage, starved for 24 h, and then fed with chow (Oriental Yeast Co., Tokyo, Japan) and water *ad libitum* beginning 12 h after *H pylori* inoculation. On the day of infection, the Mongolian gerbils were challenged orally with vehicle or 10^9 CFU *H pylori* in 1.0 mL of brucella broth with 10% horse serum. The spiral bacteria were observed in the mucus and gastric pits of all inoculated animals from 1 mo after inoculation throughout the whole observation period. However, nearly half of the animals had barely detectable *H pylori* in the stomach by bacterial culture. The bacterial counts from the stomachs of gerbils 1 and 6 mo after *H pylori* inoculation were 25 and 410 CFU/10 mg of gastric tissue, respectively[48]. These levels of colonized bacteria were nearly 1/10 to 1/100 than those of human being and monkey.

Mongolian gerbils with *H pylori* infection showed irregularly thickened gastric walls and spotty hemorrhages and erosions macroscopically, 1 year after inoculation. A severe infiltration of polymorphonuclear and mononuclear cells was seen in the lamina propria and mononuclear cells infiltration with lymphoid follicle in the submucosa, 1 mo after *H pylori* inoculation (Figure 2A). Erosion of the gastric mucosa appeared soon after inoculation, whereas gastric ulcers, gastritis cystica profunda (Figure 2B), and atrophy with goblet cell metaplasia (Figures 2C and D) occurred between 3 and 6 mo after inoculation[48,49]. Moreover, Suzuki *et al*[50]. reported that *H pylori* inoculation induced neutrophil followed by an increase in the level of lipid peroxidation and activated glutathione (antioxidant) turnover. These sequential changes of histological changes in gastric mucosa were quite similar to those observed in human beings. Therefore, Mongolian gerbil model may be useful to study the relationship between *H pylori* infection and gastric lesions, which include gastric malignancy.

GASTRIC CANCER AND MONGOLIAN GERBIL MODEL

Mongolian gerbils have also been induced by the development of gastric carcinoma with chemical carcinogen alone[51]. In addition, the results of several experimental studies have confirmed that administration of MNNG or MNU to Mongolian gerbils with chronic *H pylori* infection enhanced the development of different histopathological types of gastric carcinoma (Table 2)[31-33].

Sugiyama *et al*[31]. reported the development of carcinoma in the Mongolian gerbils evaluated at 40 wk after an experiment in which 7-wk-old animals were inoculated with *H pylori* (ATCC43504) and given 10 or 30 ppm MNU before or after inoculation. In this report, only the groups of the animals, which were administered with both *H pylori* and MNU, developed gastric cancers; more specifically, they developed different types of adenocarcinoma, such as well-differentiated, poorly differentiated, and signet ring cell carcinoma. These interesting experimental results support the results so far obtained in largescale epidemiological investigations[52].

The group inoculated with *H pylori* after being given MNU showed a distinctive initiation-promotion effect, whereas the group to which MNU was given after inoculation with *H pylori* appeared to demonstrate the simultaneous action of these two factors, with *H pylori* acting as a coinitiator. No gastric carcinoma was found within 40 wk of *H pylori* infection alone.

Tokieda *et al*[32]. conducted a study in which 5-wk-old Mongolian gerbils were inoculated with *H pylori* (ATCC43504) and orally given MNNG at 50 g/mL for 20 wk for comparison against animals administered with MNNG alone. At the 52nd wk after initiation, the group treated with MNNG and *H pylori* developed gastric carcinoma at a significantly higher frequency than the group treated with MNNG alone. In addition, cell proliferation was revealed to be markedly accelerated in those animals infected with *H pylori* with evaluation using a labeling index of 5-bromo-2'-deoxyuridine. This result suggests the possibility of explaining the link between *H pylori* infection and early events in gastric carcinogenesis. One of the interests in this study is that administration of MNNG reduced the infection rate of *H pylori* with the lapse of time, due to the likelihood of MNNG showing low-level (200 μg/mL) antibacterial activity against *H pylori*[32]. It is also of interest that *H pylori*-free animals did not develop gastric carcinoma even with

Table 2 Gastric carcinogenesis in *Helicobacter pylori*-infected Mongolian gerbils

MNNG administration. This result indicated a stronger carcinogenic role of *H pylori* infection. Although it has been reported by Sugiyama[31] that *H pylori* can persistently colonize the stomach of MNUtreated Mongolian gerbils, it is interesting that the two studies[32,33] report that MNNG administration eradicates *H pylori* infection, resulting in a reduction of its carcinogenic effects in the stomach. In *H pylori*-infected Mongolian gerbils with MNNG administration, duodenogastric reflux due to surgical procedure might attenuate the effect of *H pylori* on gastric tumorigenesis[53]. Because of our study, which indicated that bile reflux might lead to *H pylori* eradication[54], their results may probably depend on the *H pylori* eradication.

CARCINOGENICITY OF *H PYLORI* INFECTION ALONE

Although these studies showed marked increase of the chemical carcinogenic risk in the Mongolian gerbils, direct relationship between *H pylori* and gastric carcinogenesis was not indicated.

Two experimental studies attempted to confirm prior epidemiological studies that have demonstrated an association between *H pylori* infection and gastric carcinogenesis in human beings using Mongolian gerbils chronically infected with this bacterium (Table 3)[55,56]. Both studies confirmed gastric carcinogenesis resulting from *H pylori* infection alone, and were the first papers to fulfill Koch's postulates concerning *H pylori* infection and gastric carcinoma.

Watanabe *et al*[55]. used *H pylori* isolated from patients with gastric ulcer (TN2GF4), and Honda *et al*[56]. used ATCC43504 type strain, both of which were inoculated into 5-wk-old SPF Mongolian gerbils. The results showed that 37% (10 out of 27) of the animals in the former study developed well-differentiated adenocarcinoma at 62 wk after inoculation, whereas 40% (2 out of 5) of the animals in the latter study developed well-differentiated adenocarcinoma at 72 wk after inoculation (Figure 3). Both of these strains contained *cagA* and produced vacuolating cytotoxins. Sequential histopathological changes leading to carcinogenesis of the gastric mucosa were found to be common to the two studies, and very closely resembled the histopathological changes in human gastric mucosa caused by *H pylori* infection.

Hirayama *et al*[57]. reported that poorly differentiated adenocarcinoma and carcinoid were developed in

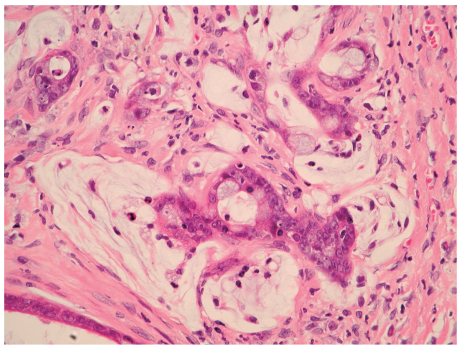

Figure 3 Microscopic views of the gastric mucosa of Mongolian gerbils at 18 mo after *H pylori* inoculation. Well-differentiated adenocarcinoma has extended into the muscular layer. Atypical glands and nuclei and abnormal mitosis are evident (HE stain, x40).

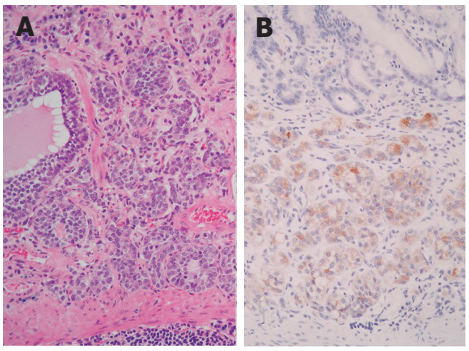

Figure 4 Gastric carcinoid in the stomach of a Mongolian gerbils colonized for 24 mo by *H pylori*. Microscopic view showing intramucosal carcinoid tumor (**A:** HE stain, x20; **B:** immunohistochemistry of chromogranin A, x20').

Mongolian gerbils model with *H pylori* (ATCC43504 type strain) infection alone. Zheng *et al*[58]. reported that Mongolian gerbils models, which were infected with *H pylori* (ATCC43504) and *H pylori* 161 (isolated from a Chinese patient with gastric adenocarcinoma) showed the development of well-differentiated adenocarcinoma (Table 3). Ogura *et al*[59]. reported the development of well-differentiated gastric cancer in wild type (TN2) and isogenic mutant of *vacA* (TN2Δ*vacA*) of Mongolian gerbil.

Mongolian gerbils' model also showed the development of gastric carcinoid[57,59,60]. In our laboratory, ECL cell tumors with marked atrophic gastritis and with hypergastrinemia were observed in the fundic gland area of infected Mongolian gerbils, 24 mo after inoculation (Figure 4); in contrast, adenocarcinoma developed in pyloric gland area. Histopathological findings of the entire observation period in Mongolian gerbils after *H pylori* inoculation are summarized in Table 4.

Ogura *et al*[59]. discussed the virulence factors of *H pylori* in Mongolian gerbils. Experimental gastric cancer derived in Mongolian gerbils with wild type of *H pylori* and *vacA* mutant infection, whereas *cagE* mutant induced far milder change of gastritis and induced no gastric cancer, which indicates the essential role of cagPAI in the gastric diseases with *H pylori* infection.

Table 4 Gastric carcinogenesis in *Helicobacter pylori*-infected Mongolian gerbils

PREVENTION OF GASTRIC CARCINOMA BY ERADICATION OF *H PYLORI*

Shimizu *et al*[61]. reported that the incidence of adenocarcinomas in MNU-administered Mongolian gerbils with *H pylori* infection (15 out of 23) was significantly higher than in MNU-administered Mongolian gerbils that underwent *H pylori* eradication (5 out of 24). Their results suggest that *H pylori* eradication may prevent gastric carcinogenesis, and Mongolian gerbil's models have also been useful to study the prevention of gastric carcinogenesis in human beings.

DIFFERENCES BETWEEN ANIMAL MODELS AND HUMAN BEINGS

Although the Japanese monkey model and Mongolian gerbil model showed the similar change of human stomach that was infected with *H pylori*, several features of animal models differ from those seen in human beings. In Japanese monkey model intestinal metaplasia was not seen during the whole observation period. Severe gastritis and lymphoid follicular hyperplasia in the submucosal layer and gastritis cystica profunda, which are seen in Mongolian gerbils, are not observed in human gastric mucosa.

Table 5 shows our tentative opinion on p53 and *H pylori* infection in animal model and human beings. Although no gastric carcinoma developed in Japanese monkey model, Mongolian gerbil model showed gastric carcinoma resulting from *H pylori* infection alone. In human and Japanese monkey, both p53 immunostaining[29,62-64] and point mutations[30,65] were observed in *H pylori* infection. In

Mongolian gerbil, the p53 immunostaining was detected in gastric cancer but not in atrophic gastritis; moreover, there were no p53 mutations in exons 5 to 8 in infected gastric mucosa[66].

Suzuki *et al*[67]. reported that Mongolian gerbil model showed significant attenuation of apoptosis and promotion of cell proliferation than those seen in mice model with *H pylori* inoculation. Crabtree *et al*[68]. also described the differences of mucosal cytokine response between Mongolian gerbils and mice, and gender differences in the magnitude of cytokine response to *H pylori*. The differences of features between the species suggested that the pathogens of gastric diseases does not associate only with *H pylori* and may reflect in part other host factors.

Sonic hedgehog (Shh) is an important endometrial morphogenetic signal during the development of the vertebrate gut. Shh controls gastrointestinal patterning in general and gastric gland formation in particular. Suzuki *et al*[69]. reported that the long-term colonization of *H pylori* led to attenuation of Shh expression. Loss of Shh expression correlated with the loss of parietal cells, disturbed maturation of the mucous neck cell-zymogenic cell lineage. van den Brink *et al*[70]. described the loss of Shh expression in the intestinal metaplasia of the human stomach. Loss of Shh expression not only in intestinal metaplasia, but also in the tissue of *H pylori*-induced fundic gland atrophy is important for considering the possible link to preneoplastic lesion formation[69].

QUITE A NEW CONCEPT OF GASTRIC CANCER ORIGIN

In 2004, Houghton *et al*[71]. reported the innovative idea of gastric cancer origin with the usage of *H. felis*/C57BL/6 mouse model. Previously, tissue stem cells have been recognized as the origin of carcinoma. However, their study showed that bone marrow-derived cells (BMDCs) might also represent a potential source of malignancy. Female C57BL/6 mice after undergoing lethal irradiation were transplanted with bone marrow from male C57BL/*6JGtrosa26* (ROSA26), which was labeled with X-galactosidase or green fluorescent protein. In this model, gastric mucosal apoptosis increased at 6- 8 wk after *H. felis* inoculation. After 52 wk of inoculation, beta-galactosidase (gal) and trefoil factor2 (TFF2) positive cells increased gradually, then 90% of the gastric mucosa at the squamocolumnar junction was replaced with cells derived from the donor marrow. One year after infection, intramucosal carcinoma or high-grade gastrointestinal intraepithelial neoplasia were seen in these mice. No evidence of BMDC engraftment was seen in *H. felis* uninfected mice. Authors indicated that BMDC originated the epithelial cancer and the necessity of *Helicobacter* infection in this process.

CONCLUSION

In various experimental models, nonhuman primate and rodent models showed the variable evidences, which clarified the association between *H pylori* infection and gastric cancer.

Experiments developed using Mongolian gerbils have demonstrated that *H pylori* infection is clearly responsible for gastric carcinogenesis, and provide important confirmation of the statements issued by IARC/WHO. It will be of critical importance to extrapolate the sequential histopathological changes found in the Mongolian gerbil to lesions in the human gastric mucosa, since this model is proven to provide important pointers for the study of the mechanism of gastric carcinogenesis as a result of *H pylori* infection. While Koch's postulates for *H pylori* and gastric carcinoma have now been fulfilled, an important question to be addressed is why the Mongolian gerbil is the only species in which carcinogenesis has been experimentally induced by infection with *H pylori*.

Abstract

AIM: To elucidate the effect of p27^{KIP1} on cell cycle and apoptosis regulation in gastric carcinoma cells.

METHODS: The whole length of p27^{KIP1} cDNA was transfected into human gastric cancer cell line SCG7901 by lipofectamine. Expression of p27^{KIP1} protein or mRNA was analyzed by Western blot and RNA dot blotting, respectively. Effect of p27^{KIP1} on cell growth was observed by MTT assay and anchorage-independent growth in soft agar. Tumorigenicity in nude mice was used to assess the *in vivo* biological effect of p27^{KIP1}. Flow cytometry, TUNEL, and electron microscopy were used to assess the effect of p27^{KIP1} on cell cycle and apoptosis.

RESULTS: Expression of p27^{KIP1} protein or mRNA increased evidently in SCG7901 cells transfected with p27^{KIP1}. The cell growth was reduced by 31% at 48 h after induction with zinc determined by cell viability assay. The alteration of cell malignant phenotype was evidently indicated by the loss of anchorage-independent growth ability in soft agar. The tumorigenicity in nude mice was reduced evidently (0.55±0.14 cm *vs* 1.36±0.13 cm, $P<0.01$). p27^{KIP1} overexpression caused cell arrest with 36% increase (from 33.7% to 69.3%, $P<0.01$) in G_1 population. Prolonged p27^{KIP1} expression induced apoptotic cell death reflected by pre-G1 peak in the histogram of FACS, which was also confirmed by TUNEL assay and electron microscopy.

CONCLUSION: p27^{KIP1} can prolong cell cycle in G1 phase and lead to apoptosis. p27^{KIP1} may be a good candidate for cancer gene therapy.

Key words: Cell cycle; Apoptosis; Gastric neoplasm; p27^{KIP1}

INTRODUCTION

The number of cells is regulated by a balance between proliferation, growth arrest and programmed cell death (apoptosis, PCD). Disorders of the cell cycle and apoptosis are closely related to the progression and aggressiveness of cancers[1]. p27^{KIP1}, a member of the Cip/Kip family of cyclin-dependent kinase inhibitors (CDKI), was first identified as a negative cell cycle regulator in transforming growth factor β-treated cells and in G_1 phase quiescent cells by cell contact inhibition[2,3]. p27^{KIP1} binds to a wide variety of cyclin/CDK complexes including CDK2 and CDK4[4], inhibits kinase activity[5] and blocks cell cycle[6-8]. The overexpression of p27^{KIP1} protein in mammalian cells induces G_1 arrest of the cell cycle and apoptosis[9,10]. Decreased p27^{KIP1}, which is positively correlated with a deceased rate of apoptosis, may be not only an indicator of tumor aggressiveness, but also an important prognostic marker in gastric carcinoma[11].

In this study, an inducible expression system was used to induce overexpression of p27^{KIP1} in human gastric cancer cells. Then whether transfection of SCG7901 with p27^{KIP1} gene could alter the cell and molecular biology as well as the spontaneous rate of apoptosis was studied.

MATERIALS AND METHODS

Cell culture

Human gastric cancer cell line SCG7901 was provided by the Department of Pathology, Fourth Military Medical University (Xi'an, China). SCG7901 cells were cultured in Eagle's medium containing phenol red supplemented with 50 mL/L fetal bovine serum (FBS) in a humidified atmosphere of 950 mL/L air and 50 mL/L CO_2 at 37℃. All the media were supplemented with 2 mmol/L L-glutamine, 100 mg/L penicillin and 100 kU/L streptomycin. Culture medium and supplements were obtained from Gibco BRL.

Plasmid construction and DNA transfection

pGEM T-Easy-KIP1 vector containing human full-length

cDNA of $p27^{KIP1}$ was used. Complementary DNA of $p27^{KIP1}$ cleaved from the pGEM T-Easy-KIP1 plasmid by EcoRI was subcloned into the inducible vector neo-control pMD-neo vector to generate pMD-KIP1 containing 0.6 kb $p27^{KIP1}$ cDNA and controlled expression of protein upon addition of 100 mmol/L zinc as an external inducer. Clonfectin (Clontech, USA) was used to transfect $p27^{KIP1}$ inducible expression vectors into SGC7901 cells. Logarithmically growing cells were transfected with 1 μg of plasmids and 2 μL of clonfectin reagent according to the manufacturer's instructions. For stable transfection, the transfected SGC7901 cells were selected in medium plus 0.5 g/L G418 (Life Technologies, USA) for 2 wk, then the G418 concentration was reduced to 0.2 g/L. Stable SGC7901 cell line transfected with pMD-KIP1 vector was treated by continuous exposure to 100 mmol/L $ZnSO_4$.

Western blot analysis of transgene expression

Monolayers of the cells were rinsed with PBS and lysed with SDS-PAGE loading buffer (50 mmol/L Tris-HCl pH 6.8, 100 mmol/L dithiothreitol, 2 g/L SDS). Mock and pMD-neo transfected cells served as controls. Samples were analyzed by SDS-PAGE and transferred into Hybond-C super membranes. The membranes were blocked with 50 mL/L skim-milk and 1 g/L Tween-20, then probed with primary antibody overnight according to the manufacturer's instructions, washed in PBS, 2g/L Tween-20 and then incubated with appropriate horseradish-peroxidase (HRP) conjugated second antibody. After being washed, the membranes were developed by DAB reagents according to the manufacturer's guide (Dako Co., USA). $p27^{KIP1}$ (Santa Cruz Biotechnology, USA) was detected after HRP-conjugated anti-rabbit IgG (Fc) was used. The level of β-actin was used as a control for equal loading of protein.

Total RNA extraction and RNA dot blotting

Total RNA was extracted from SGC7901 cells using TRIzol (Life Technologies, USA) following a standard acid-guanidium-phenolchloroform method. The digoxingenin-labeled specific DNA probe was obtained as follows. The plasmid containing $p27^{KIP1}$ cDNA was used as template, a pair of primers (-5 ℃-ggggtaccatgtcaaacgtgcgagt-3 ℃and -5 ℃-gctcaacgtttgacgtcttc-3 ℃) was used to amplify the sequence. The PCR system containing Dig-11-dUTP and four normal dNTPs and Taq polymerase were used. After a standard PCR procedure (94 ℃ to 30 s, 60 ℃ for 30 s, 72 ℃ for 1 min, 30 cycles), the PCR product was purified by 1% agarose electrophoresis and DNA extraction. The labeling efficiency was further determined by Dot blot of serially diluted plasmid. Finally, the digoxingenin-labeled DNA probe was used in the experiment. RNA Dot blot was performed according to the Dig system user's guide for filter hybridization (Boehringer Mannheim, Germany). Briefly, RNA sample was diluted in RNA dilution buffer (a mixture of DEPC-treated H_2O, 20×SSC, and formaldehyde at 5:3:2). The membrane was marked slightly with a pencil to identify each dilution before spotting. One microliter of the RNA sample was spotted onto a dry nylon membrane using a micropipettor. Then the RNA was fixed to the membrane by baking in an oven at 120 ℃ for 30 min. Hybridization and the following procedures were similar to *in situ* hybridization. Hybridization mixture contained 5×SSC, 500 g/L deionized formamide, 1 g/L sodium-lauroyl sarcosine, 0.2 g/L SDS, 20 g/L blocking reagent and a 25 ng/mL DNA probe. The level of GADPH mRNA was used as a control for equal loading of RNA.

MTT and colony assay

SGC7901/KIP1 and SGC7901/pMD cells (1×10^4) were seeded in 96-well plates and continuously exposed to 100 mmoL/L $ZnSO_4$. After treatment, 50 μL of 5 g/L 3-(4,4-dimethylthiazol-2-yl) 2,5-diphenyltetrazolium bromide (MTT) in PBS was added to each well, incubated for 4 h at 37 ℃ and the formed formazan crystals were dissolved in 50 μL of dimethyl sulfoxide. The absorbance was recorded at 490 nm on a microplate reader (BioRad). Cell proliferation was expressed as IC50 for cells. Soft agar was prepared with the 6 g/L bottom agar layer and the 4 g/L top agar layer. The number of cells plated for each clone was 2 000. Plates were incubated at 37 ℃ with 50 mL/L CO_2 for 2 wk and the colonies were counted and photographed under a phase contrast microscope (Nikon, Tokyo, Japan).

Tumorigenicity tests in nude mice

$p27^{KIP1}$-transfected SGC7901/KIP1 cells were injected into the right flank of a nude mouse at 2.5×10^6. pMD-neo-transfected SGC7901/pMD cells served as control. Each group had five nude mice. From the second day, each nude mouse received 100 mmol/L $ZnSO_4$ at a dose of 0.2 mL daily by subcutaneous injection for over 4 wk. The time of tumorigenicity and the tumor volume were measured.

Cell cycle analysis

SGC7901 cells including adherent cells (with trypsin-EDTA) and nonadherent cells were harvested. All cells were washed with PBS, resuspended and incubated in 700 mL/L ethanol for at least 12 h at 4 ℃ to permeabilize the plasma membrane. Cells were centrifuged at 1 000 r/min, resuspended in 100 mg/L RNase and 10 mg/L propidium iodide, incubated for 15 min at 25 ℃ in the dark. Single color fluorescent flow cytometry was performed with a FACScalibur flow cytometer (Becton Dickinson, USA). The histograms were analyzed with Multiplus Software Π.

Electron microscopy

SGC7901/pMD cells were gently washed with serum-free medium and fixed with 25 g/L glutaraldehyde in 0.1 mol/L sodium cacodylate buffer. These cells were scraped from the surface of the dishes and pelleted by spinning for 5 min at 10 000 *g*. The cells were osmicated with 10 g/L osmium tetroxide. The block was stained, dehydrated in graded ethanol, infiltrated with propylene oxide, embedded with EMBED overnight and cured in a 60 ℃ oven for 48 h. Silver sections were cut with an

Ultracut E microtome, collected on a formvar and carbon-coated grid, stained with uranyl acetate and Reynold's lead citrate, and viewed under a JEOL 100 CX electron microscope.

Apoptosis analyzed by TUNEL assay

SGC7901/KIP1 and SGC7901/pMD cells were harvested for TUNEL staining. The proportion of cells showing DNA fragmentation was measured by incorporation of fluorescein (FITC)-12-dUTP into DNA using terminal de oxynucleotidyltransferase (TdT). The kit was bought from Boehringer Mannheim (*In Situ Cell Death Detection*). Cells were fixed by 40 g/L paraformaldehyde in PBS overnight at 4 ℃. The samples were washed thrice with PBS and permeabilized by 2 g/L Triton X-100 in PBS for 15 min on ice. After being washed twice, cells were equilibrated at room temperature for 15-30 min in a equilibration buffer with 30 g/L BSA and 200 mL/L normal bovine serum in PBS at pH 7.4, then the slides were covered with the TUNEL mixture (calf thymus TdT, FITC-12-dUTP, and cobalt chloride in 1×reaction buffer) for 1-2 h at 37 ℃ in the dark. The tailing reaction was terminated by 2× standard saline citrate (SSC). The samples were washed thrice with PBS and analyzed by fluorescence microscopy. Routine HE staining was also conducted. Negative control was performed by omitting TdT. Quantitative analysis of apoptosis was represented by apoptotic index (AI) as described previously. AI referred to percentages from at least 1 000 counts apoptotic and non-apoptotic cells.

Statistical analysis

Fisher's exact test was performed. $P<0.05$ was considered statistically significant.

RESULTS

Inducible expression of p27^{KIP1} in SGC7901 cells

Western blot analysis demonstrated p27^{KIP1} expression 0, 4, 24, 48, and 72 h after the addition of $ZnSO_4$. Mock and pMD-neo vector-transfected cells as a control contained no detectable level of p27^{KIP1} in the presence of 100 mmol/L $ZnSO_4$. However, p27^{KIP1} expression was increased at 4 h and further increased to a steady level at 24 h after the addition of $ZnSO_4$ as determined by the Western blot analysis (Figure 1). In RNA dot blotting survey of the expression, p27^{KIP1} mRNA was very low in untransfected or noninduced SGC7901 cells. In contrast, mRNA for p27^{KIP1} was expressed at a high level 4 and 24 h after the addition of $ZnSO_4$ (Figure 2). This expression pattern was rather consistent with the expression of protein.

Inhibition of tumor cell growth by exogenous p27^{KIP1}

Exogenous p27^{KIP1} inhibited cell growth significantly. SGC7901 cell viability was determined by MTT assay (Figure 3). The cell viability rate decreased from 88% to 57% 48 h after p27^{KIP1} induction with zinc treatment ($P<0.01$). Another biological feature of malignant cells was anchorage-independent growth capability. The neo-

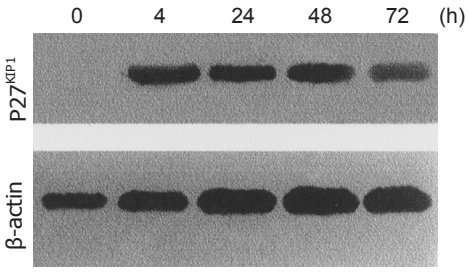

Figure 1 Induction of p27^{KIP1} expression by Western blotting analysis.

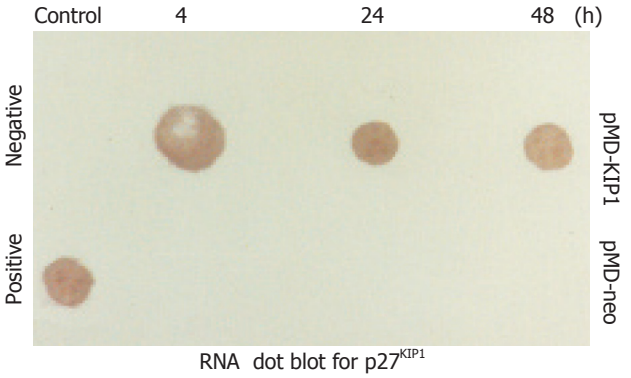

Figure 2 Expression of p27^{KIP1} in mRNA level by RNA dot blot analysis.

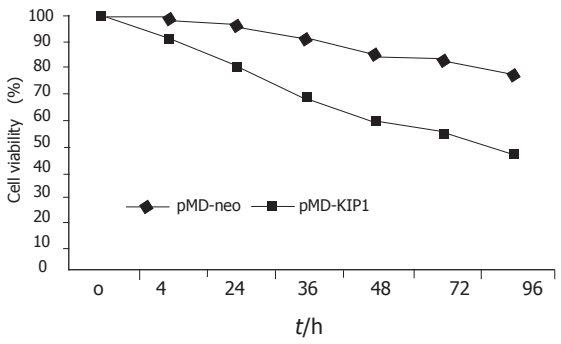

Figure 3 Growth course of SGC7901 cells.

control SGC7901/pMD and SGC7901 cells formed large colonies in each well after 2 wk, and the rate of colony formation was increased by 80% and 60%, respectively. SGC7901/KIP1 cells showed markedly lower ability to form colony with a rate of 30% ($P<0.01$). Moreover, tumors were generated in nude mice on the 7th d from SGC7901/pMD cells, but SGC7901/KIP1 cells generated tumor on the 12th d and grew slowly. The tumor diameter generated from SGC7901/KIP1 cells was smaller than that from SGC7901/pMD cells (0.55 ± 0.14 *vs* 1.36 ± 0.13 cm, $P<0.01$, Figure 4). These data indicated that the exogenous p27^{KIP1} had a cytostatic effect on cell growth.

Overexpression of p27^{KIP1} prolonged cell cycle in G$_1$ phase

p27^{KIP1} was identified as a negative cell cycle regulator

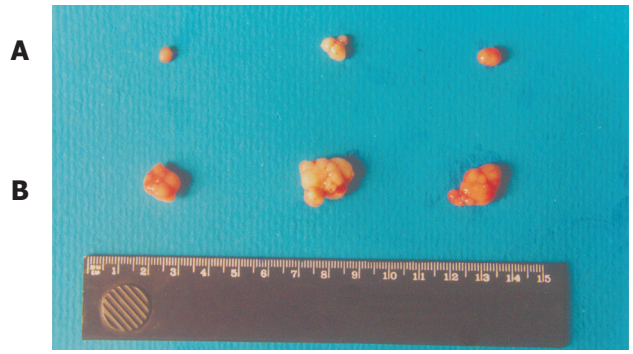

Figure 4 Tumorigenicity in nude mice. **A:** SGC7901/KIP1 group; **B:** SGC7901 group.

in transforming growth factor β-treated cells and in G_1 phase quiescent cells by cell contact inhibition. The overexpression of p27^{KIP1} protein in mammalian cells induced G_1 arrest of the cell cycle. In order to investigate whether p27^{KIP1} had the ability to induce G_1 arrest in SGC7901 cells, cell cycle analysis was performed on transfected SGC7901 cells. Flow cytometry analysis showed that overexpression of p27^{KIP1} increased remarkably the proportion of SGC7901 cells with G_1 phase DNA content increased from 33.7% to 69.3% ($P = 0.000$) and decreased with S phase DNA content at 48 h after induction (Figure 5). There was no significant change in the proportion of cells with G_2/M phase DNA content.

Overexpression of p27^{KIP1}-induced apoptosis in SGC7901 cells

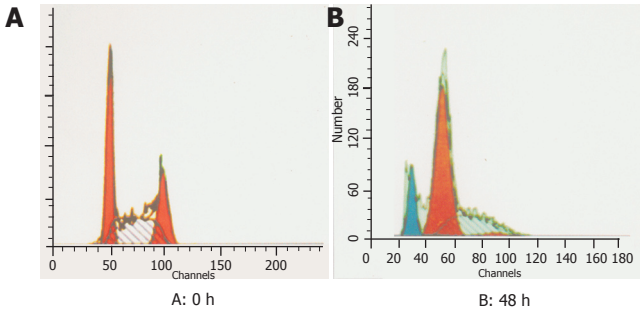

Figure 5 Flow cytometric analysis of SGC7901 cells at 0 h (**A**) and 48 h (**B**).

Morphological changes SGC7901/KIP1 cells-transfected p27^{KIP1} altered their morphology and induced DNA strand breaks in a manner consistent with apoptosis. The changes were indeed induced by apoptosis rather than necrosis, which was confirmed by electron microscopy. SGC7901/KIP1 cells showed compacted nuclear chromatin with fine granular masses marginated against the nuclear-enveloped and condensed cytoplasm, the nuclear outline was convoluted and the organelles were preserved (Figure 6).

TUNEL assay To determine whether overexpression of p27^{KIP1} was able to induce apoptosis in SGC7901 cells, TUNEL assay was performed. Compared to the pMD-neo-transfected SGC7901/pMD cells, p27^{KIP1}-overexpressed SGC7901/KIP1 cells showed obvious morphological changes. Some apoptotic cells appeared round and condensed cytoplasm as well as highly fragmented chromatin. TUNEL-positive cells were found with Kelly or green fluorescence in nucleoli. Cells without apoptosis observed by fluorescence microscopy had no fluorescence. Apoptotic index significantly increased in p27^{KIP1}-transfected SGC7901/KIP1 cells 24 and 48 h after being exposed to 100 mmol/L $ZnSO_4$ (3.0 *vs* 21.2, 3.6 *vs* 26.3, $P<0.05$).

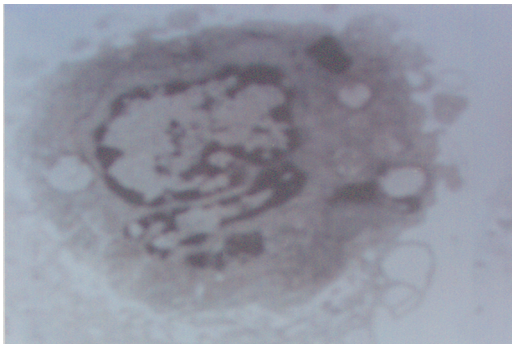

Figure 6 Ultrastructural changes associated with apoptosis in SGC7901/KIP1 cells (TEM×7 500).

Flow cytometry In order to determine the effect of p27^{KIP1} overexpression on apoptosis in SGC7901 cells, cells were exposed to 100 mmol/L $ZnSO_4$ for 48 h and apoptotic damage of DNA was detected according to the sub-G_1 peak on a flow cytometer. Overexpression of p27^{KIP1} showed significantly higher apoptotic peak than normal control as the sub-G_1 peak indicated. The apoptotic cells accounted for about 14.7% (Figure 5).

Taken together, p27^{KIP1} overexpression could inhibit proliferation of SGC7901 cells and subsequently induce apoptosis.

DISCUSSION

Gastric cancer is the second most common fatal malignancy in the world[12-14] and is still the leading cause of cancer-related deaths in China. The development of gastric cancer is a multi-factorial process[15]. A balance between proliferation and apoptosis of tumor cells is important for tumor growth. In gastric cancer, proliferative activity and apoptosis of cancer cells are associated with tumor growth[16]. Cyclins, cyclin-dependent kinase (CDK) and their inhibitors regulate cell growth, differentiation, survival and death. Cell cycle which progresses sequentially through G_1, DNA synthesis (S), G_2, and mitosis (M) phases, regulates DNA replication and chromosomal segregation into the daughter cells. Gene abnormalities and

aberrant expression of cell cycle regulators play a pivotal role in the pathogenesis of gastrointestinal tumors[17], of which CDKIs are major regulators.

$p27^{KIP1}$ is a member of the Cip/Kip family of CDKIs that regulate cell cycle progression, thus inhibiting various cycle-CDK complexes. Physiologically, $p27^{KIP1}$ is believed to primarily regulate progression of cells from late G_1 into S phase by interacting with cyclin E-CDK2 complexes[9]. $p27^{KIP1}$ has been implicated as a mediator of growth arrest due to TGF-β, cAMP and other extracellular factors. Moreover, elevated expression of $p27^{KIP1}$ protein leads to G_1 arrest in many cell types and promotes neuronal differentiation in mouse neuroblastoma cells, while inhibition of $p27^{KIP1}$ expression through the use of antisense technology prevents G_1 arrest and/or suppresses entry of fibroblasts into a state of quiescence in response to mitogen depletion.

Interestingly, in many types of tumors such as gastric[18,19], prostate[20,21] and breast carcinoma, the expression of $p27^{KIP1}$ gene is downregulated[22,23]. Loss of $p27^{KIP1}$ expression may result in tumor development and/or progression. However, this loss of expression does not appear from the result of gene mutations. It is believed that the aberrant expression of $p27^{KIP1}$ plays a pivotal role in the pathogenesis of carcinoma. Malignant human renal tumor cell transfection with $p27^{KIP1}$ gene leads to inhibition of proliferation and cell cycle arrest in G_1[24]. Ectopic overexpression of $p27^{KIP1}$ is associated with a striking decrease in aneuploid cells, loss of anchorage-independent growth in soft agar and failure to induce tumor development in a xenograft model[25]. In this report, we have also demonstrated that $p27^{KIP1}$ overexpression could inhibit proliferation of SGC7901 cells. The cell growth was reduced by 31% at 48 h, after the induction with zinc as determined by cell viability assay. The alteration of cell malignant phenotype was evidently indicated by the loss of anchorage-independent growth ability in soft agar. The tumorigenicity in nude mice was reduced evidently ($P<0.01$). $p27^{KIP1}$ overexpression increased cell arrest from 33.7% to 69.3% ($P<0.01$) in G_1 population.

Recent evidence demonstrated that high levels of $p27^{KIP1}$ protein induced by adenovirus vector leads to growth arrest as well as enhancement of apoptosis in several cell lines from different species and tissues of various origins[11,25]. Decreased $p27^{KIP1}$, which is positively correlated with a decreased rate of apoptosis, may be not only an indicator of tumor aggressiveness, but also an important prognostic marker in gastric carcinoma[16]. In this study, we have demonstrated that overexpression of $p27^{KIP1}$ not only prolonged cell cycle in G_1 phase of SGC7901 cells but also subsequently induced apoptosis as reflected by pre-G_1 peak in the histogram of FACS, TUNEL assay and electron microscopy. This is the first report in which a significant correlation between $p27^{KIP1}$ expression and cell cycle arrest and apoptosis has been demonstrated in SGC7901 cell line.

Mice lacking $p27^{KIP1}$ are abnormally large and display multiple organ hyperplasia indicative of tissue overgrowth[26,27]. Thus, it is possible that $p27^{KIP1}$ plays an important role in maintaining organ size through the induction of apoptosis. However, the mechanism of tumor growth suppression appears to include $p27^{KIP1}$ but also various other properties such as p53. p53 serves as a major G_1 checkpoint regulator through the induction of p21 but not of $p27^{KIP1}$ and p57, while it induces apoptosis. The p53-mediated CDK inhibitor p21 does not lead to significant apoptosis though both p21 and $p27^{KIP1}$ induce G_1 arrest through their potential abilities to inhibit CDK activity. These findings suggest that the inhibition of CDK activity may not be sufficient to induce apoptotic cell death. A possible explanation of these differences between $p27^{KIP1}$ and p53-mediated p21 function is that $p27^{KIP1}$ may have other functions in addition to its notable function as a CDKI. It can also be speculated that $p27^{KIP1}$, which has the potential to induce growth arrest and apoptosis, may play a more important role in tumor growth suppression than p53-mediated p21. Further understanding of the mechanism involved in this process can improve chemotherapeutic strategies aimed at achieving high level $p27^{KIP1}$ expression and gene therapy.

Abstract

AIM: To compare upper gastric endoscopic and histopathologic findings in older adults in the presence and absence of B12 deficiency.

METHODS: A prospective analysis of upper gastric endoscopic and gastric histopathologic findings from 30 newly identified B12-deficient patients (11 males, 19 females) and 16 controls with normal B12 status (6 males, 10 females) was performed. For all subjects, the indication for upper endoscopy and gastric biopsy were unrelated to B12 status. A single pathologist, blinded to B12 status, processed and interpreted the biopsy samples. Endoscopic and histopathologic findings were correlated with age, gender, hematocrit (Hct), MCV and B12 status.

RESULTS: The B12-deficient group had significantly lower mean serum B12 levels compared to the controls ($P<0.00005$) while their mean Hct, MCV and serum albumin levels were similar. Iron deficiency (ferritin-based) was present in 21% of B12-deficient patients and intrinsic factor antibodies were present in 29% (5/17) of B12-deficient patients. The endoscopic findings revealed significantly different rates of gastritis and atrophy between the B12-deficient and control groups ($P=0.017$). B12-deficient patients had significantly less superficial gastritis (62% *vs* 94%) and significantly more atrophic gastritis (28% *vs* 0%) as compared to the controls ($P=0.039$). Intestinal metaplasia was similar in both groups. *Helicobacter pylori* infection rates were similar in the B12-deficient patients and controls (40% *vs* 31%).

CONCLUSION: Significantly different endoscopic findings and types of gastritis could often be observed in the presence and absence of B12 deficiency. Atrophy, based on endoscopy, and atrophic gastritis, based on histopathology, suggest the presence of B12 deficiency. Gastric histopathology is not influenced by the age, gender, Hct or MCV of the patients.

Key words: Vitamin B12 deficiency; Gastric histopathology; Older adults

INTRODUCTION

Vitamin B12 deficiency is a common but under-recognized disorder with a prevalence ranging from 3% to 40% in the adult population[1-4]. In a previous study, we noted a prevalence of between 15% and 25% in the community and nursing home hospitalized older subjects[3]. B12 deficiency often goes undetected, with manifestations that range from asymptomatic to a wide spectrum of hematologic and/or neuropsychiatric features. For the purpose of this discussion, the term B12 will be used interchangeably with cobalamin.

B12 deficiency affects proliferating epithelium at all the sites[5]. Although the histopathological effects of B12 deficiency relating to the blood and nervous system are well described, histopathological changes in the stomach associated with cobalamin deficiency in older subjects have

received less emphasis in the literature. Presently, there exist some confusions whether gastric changes are a cause or an effect of deficiency[6]. It is worth stating that the stomach plays a major role both in the absorption of B12 and the pathogenesis of cobalamin deficiency[5,7]. Among the etiologies of cobalamin deficiency, pernicious anemia (PA), once believed to be the most common cause[6,9], actually accounts for only a small fraction of cases of B12 deficiency[2,3,8]. It is well recognized that PA, a type A gastritis, is characterized by fundic atrophic gastritis. There is a lack of knowledge about the examination of gastric endoscopic findings and histopathologic changes associated with vitamin B12 deficiency in older adults. We, therefore, have attempted to evaluate the endoscopic and histopathologic changes in older adults with newly diagnosed B12 deficiency and to compare the findings in adults of the same age group and normal B12 status.

MATERIALS AND METHODS

The study was performed by the staff from the divisions of geriatrics, gastroenterology, medicine, pathology and biomedical research at Our Lady of Mercy Medical Center, University Hospital of New York Medical College, Valhalla, NY, USA. A prospective analysis of upper gastric endoscopic and gastric histopathologic findings was performed on 30 adults who were above the age of 60 with newly diagnosed B12 deficiency. The subjects included men and women, ages ranging from 60 to 99 years. All patients required hospitalization for a cause other than B12 deficiency. The diagnosis of B12 deficiency was made following routine screening or during evaluation for hematological or neurological manifestations. A randomly selected group of 6 male and 10 female patients with normal B12 status, ages ranging from 63 to 93 years,served as controls. The male/female ratio in the B12-deficient group was 11/19, and 6/10 in the control group. Several indicators of nutritional status were assessed in the B12-deficient patients. We observed low folate status in 16%, low albumin status in 16% and low iron status (ferritin based) in 21% of the B12-deficient patients.

The primary indication for endoscopy was unrelated to cobalamin status and based on the usual indications for upper gastric endoscopy on both B12-deficient patients and controls. After obtaining informed consent, upper gastric endoscopy was performed and multiple endoscopic biopsies were obtained from several sites within the gastric fundus and antrum. Gastric biopsies were performed for reasons unrelated to cobalamin status and hence the sites examined and the number of biopsies taken varied between individuals. Endoscopic findings included a normal appearance of the stomach, atrophy and gastritis. Gastritis on endoscopy was defined as the presence of erosions or hemorrhage. Erosions were seen as breaks in the mucosa manifesting as multiple lesions with white bases that were commonly encircled by a halo of erythema. Atrophy on endoscopy was defined as the disappearance of gastric rugae and a thinning of the gastric mucosal folds with the prominence of the blood vessels seen through the thin mucosa (paper money appearance)[10]. Erosive gastritis and friable mucosa are suggestive findings of gastritis on endoscopy.

Gastric histopathology entailed the use of formalin-fixed and paraffin-embedded tissues, which were sectioned at five micrometer thickness, mounted on slides and stained with hematoxylin and eosin. All specimens (in both the B12-deficient group and controls) were reviewed by a single histopathologist who was unaware of the individual's B12 status. Biopsy findings were classified as normal (Figure 1A), inflammation (Figures 1B-D), atrophy and intestinal metaplasia (Figures 1B and C). Each specimen was also stained for the presence of *helicobacter*-like organisms using toluidine blue stain with Alcian yellow counterstain (Polyscientific, Bayshore, NY, USA) (Figure 1E). See Table 1 for definitions.

For the purpose of this study, B12 status was defined as normal, borderline and deficient as follows: normal >349 ng/L; borderline 100-349 ng/L; and deficient <100 ng/L. The reference range for cobalamin values in our laboratory is 157-1 059 ng/L. Endoscopic and histopathologic findings were correlated with age, gender, hematocrit

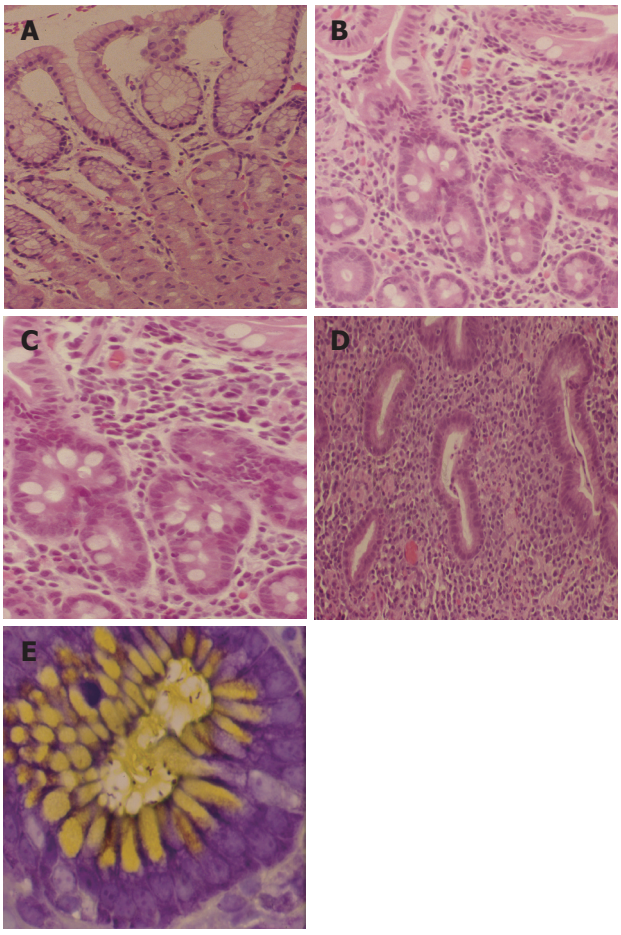

Figure 1 A: Normal histopathologic appearance of the gastric mucosa; **B:** Histopathology of the gastric mucosa, antral type, showing chronic inflammation with metaplasia (low power); **C:** Gastric mucosa, antral type (at higher power than in Figure 1B) showing chronic inflammation with intestinal metaplasia; **D:** Gastric biopsy showing presence of severe chronic active gastritis; **E:** Toluidine blue stain with alcian yellow counterstain of gastric mucosa revealing presence of *H pylori*.

Table 1 Histopathology: Definitions

- Chronic atrophic gastritis (CAG): more extensive inflammation accompanied by glandular atrophy. CAG further subdivided into mild, moderate and severe based on atrophy involving the upper one-third, upper two-thirds and full thickness of the mucosa respectively.
- Chronic superficial gastritis (CSG): inflammation limited to the foveolar region unaccompanied by glandular atrophy. (Figures 1B-1D).
- Gastric atrophy (GA): thinning of the mucosa with an absence of inflammatory changes.
- Hyperplasia: an increase in the number of mucosal epithelial cells.
- Metaplastic changes:
  Intestinal metaplasia characterized by goblet cells, brush border cells, Paneth cells and endocrine cells. (Figures 1B and 1C).
  Pyloric metaplasia of the fundus characterized by mucus secreting glands.

Table 3 Endoscopy findings

B12 deficient group (n=30) (%)		Control group (n=16) (%)	
Normal	11 (36.7)	Normal	5(31.3)
Gastritis	8 (26.7)	Gastritis	11(68.8)
Atrophy	8 (26.7)	Atrophy	0(0)
Polyps	1 (3.3)	Polyps	0(0)
Others [1]	2 (6.7)	Others	0(0)

[1] (includes 1 case of hiatal hernia and 1 case of candidiasis). Endoscopic findings between groups were compared using Fisher's exact test, (P=0.017).

Table 2 Baseline patient characteristics

Variable	B12 deficient (n = 30)	Controls (n = 16)	P-value
Age *(yr)*	78 ± 11	77 ± 8	0.9090 [1]
Gender *(M:F)*	11:19	6:10	1.0000 [2]
Serum B12 *(pg/L)*	183 ± 60	872 ± 459	<0.00005 [1]
Hematocrit *(%)*	34.9 ±4.8	33.4 ± 3.7	0.3010 [1]
MCV *(%)*	86.5 ± 7.6	87.4 ± 9.9	0.7321 [1]
Serum albumin *(g/dL)*	2.9 ± 0.5	2.9 ± 0.7	0.9692 [1]
H pylori infection *(+/-)*	12 / 18	5 / 11	1.000 [2]
Intrinsic factor Ab *(+/-)*	5/ 12	-	-

[1]Data presented as the means ± SD or actual numbers. Statistical comparisons used Student t-tests or χ^2-square analysis.

(Hct), MCV and B12 status. Additional tests, such as serum homocysteine and methylmalonic acid levels, which further delineate cobalamin status, were not performed in this study. Neither did we undertake to elucidate the etiology of B12 deficiency, barring tests for intrinsic factor antibodies in 23 patients in the B12-deficient group.

Statistical analysis

Statistical comparisons of sample means between patients and controls were performed using Student's t-tests while comparisons of proportions were carried out using Fisher' s exact test. Logistic regression analysis was used to examine the effect of aging, gender, and nutritional values on gastric histopathology.

RESULTS

Baseline characteristics of the study samples are shown in Table 2. The results of histopathological and endoscopic findings are shown in Tables 3-8. A statistically significant difference was observed for the endoscopic findings between the B12-deficient patients and controls (P=0.014). The prevalence of normal endoscopic appearance was similar in both groups. However, atrophy was noted only in patients with B12 deficiency, while gastritis was more common in patients with normal B12 status. Polyps, notably of the hyperplastic type, were more frequently detected in the presence of cobalamin deficiency (Table 3). We noted a statistically significant difference in the degree of gastritis between B12-deficient patients and controls (P=0.039). Atrophic gastritis was more common in individuals with B12 deficiency, while superficial gastritis was the most common finding in controls. The incidence of intestinal metaplasia (in the antrum) was similar in the individuals with or without B12 deficiency. None of the controls had features of atrophy on endoscopy or histopathology. In this study, age and gender had no influence on gastric histopathology. In addition, endoscopic findings and gastric histopathology were not related to Hct levels (Tables 4-7).

Our findings suggested that the rate of *H pylori* infection was similar in patients with B12 deficiency and controls (40% *vs* 31%; Table 8). Twenty-six percent of the B12-deficient patients had undiagnosed PA as demonstrated by the presence of intrinsic factor antibodies. Age appeared to have no effect on the presence or absence of intrinsic factor antibodies that is consistent with the literature. Parietal cell antibodies (not tested in our study), which are less specific, are known to increase with age[8]. The presence of intrinsic factor antibodies also was not related to *H pylori* infection (Table 8). Histopathological features also tended to overlap in both the groups.

DISCUSSION

Physiological changes accompanying the aging gut, in particular the stomach, may be difficult to differentiate from the disease[11]. Studies in older adults have suggested a high prevalence of subnormal cobalamin concentrations, and in some reports, an inverse relationship between age and serum cobalamin concentrations[12,13]. The most common etiology of vitamin B12 deficiency is food-cobalamin malabsorption resulting from gastric dysfunction. This entity is defined as the inability to absorb protein (or food) bound cobalamin, although the ability to absorb free cobalamin remains intact. Food cobalamin malabsorption may be a consequence of the use of acid-lowering agents, such as proton pump inhibitors (PPI) and histamine 2 receptor antagonists[2,14,15]. A small proportion of patients on continuous, long-term PPI therapy may manifest reduced cobalamin levels, however, a resultant distinct B12 deficiency is seldom reported[16]. Our earlier data suggested that the use of H2 antagonists and PPI

Table 4 Histopathology of the gastric fundic region

B12 deficient group (n = 27) (%)		Control group (n = 4) (%)	
Normal	3 (11.1)	Normal	0 (0)
Inflammation	16 (59.3)	Inflammation	4 (100)
Atrophy	8 (29.6)	Atrophy	0 (0)

Histopathology findings between groups were compared using Fisher's exact test, (P=0.541).

Table 5 Histopathology of the gastric antral region

B12 deficient group (n = 6) (%)		Control group (n = 12) (%)	
Normal	0 (0)	Normal	2 (14.3)
Inflammation	5 (83.3)	Inflammation	6 (42.9)
Hyperplasia	1 (16.7)	Hyperplasia	0 (0)
Intestinal metaplasia	0 (0)	Intestinal metaplasia	4 (28.6)

Histopathology findings between groups were compared using Fisher's exact test, (P=0.157).

Table 6 Gastritis types

B12 deficient group (n = 29) (%)		Control group (n = 16) (%)	
Normal	3 (10.3)	Normal	1 (6.3)
Superficial gastritis	18 (62.1)	Superficial gastritis	15 (93.7)
Atrophic gastritis	8 (27.6)	Atrophic gastritis	0 (0)

Gastritis types between groups were compared using Fisher's exact test, (P=0.039). The B12 deficient group is 29 in Table 6 *vs* 30 in Tables 7 and 8 because one biopsy sample could not be classified into a specific category.

Table 7 Metaplasia in B12 deficiency and controls

B12 deficient group (n = 30) (%)		Control group (n = 14) (%)	
No metaplasia	22 (73.3)	No metaplasia	10 (71.4)
Hyperplasia	1 (3.3)	Hyperplasia	0 (0)
Intestinal metaplasia	7 (23.3)	Intestinal metaplasia	4 (28.5)

Metaplasia between groups was compared using Fisher's exact test, (P=1.000).

Table 8 Frequency of *H pylori* infection

B12 deficient group (n = 30) (%)		Control group (n = 16) (%)	
H pylori positive	12 (40)	*H pylori* positive	5 (31.2)
H pylori negative	18 (60)	*H pylori* negative	11 (68.8)

Fisher's exact test determined that *H pylori* infection rates were similar in B12 deficient and control patients (P = 1.000) and that the presence of intrinsic factor antibodies was low and unrelated to *H.pylori* infection in the B12 deficient group (1/7 in *H pylori*+ *vs*. 0/10 in *H pylori*– patients, P = 0.338; data not presented).

over two years did not produce cobalamin deficiency[17]. As stated earlier, PA accounts only for a small number of cases of B12 deficiency. PA is characterized by an autoimmune gastric atrophy (GA) mediated by anti-intrinsic factor antibodies. Histomorphologically, PA is characterized by fundic atrophic gastritis (type A) leading to atrophy of the fundus and achlorhydria[18]. While the fundus and the body of the stomach contain acid-secreting gastric parietal cells and pepsinogen-secreting zymogenic cells, the antrum possesses gastrin-producing G cells. Chronic atrophic gastritis (CAG) is histopathologically classified into two types based on the presence or absence of antral involvement[8,19]. Strickland *et al*[19]. originally divided chronic nonspecific gastritis into type A (associated with PA) and type B (not associated with PA). Others have added type C (chemical gastritis, related to drug therapy or bile reflux)[20,21]. Though these concepts are still valid, the discovery of *H pylori* as an important cause of gastritis signifies that type B gastritis is now too broad a category and may not be as useful clinically. Hence, some authors suggest abandoning the alphabetic terminology[20]. Type A (autoimmune) gastritis involves the fundus and the body of the stomach and spares the antrum, whereas type B (non-autoimmune) gastritis involves the antrum as well as the fundus and body. Type A gastritis is associated with PA and the presence of auto-antibodies to gastric parietal cells and to intrinsic factor, achlorhydria, low serum pepsinogen 1 concentrations and high serum gastrin levels as a result of the lack of negative feedback inhibition by gastric acid and consequent hyperplasia of gastrin-producing cells. Type B gastritis, which is more common, is usually associated with *H pylori* infection, alcoholism and various medications, and is characterized by low serum gastrin concentrations because of the destruction of the gastrin-producing cells associated with antral gastritis[8,22]. Gastric biopsy specimens in PA demonstrate a mononuclear cellular infiltrate in the submucosa consisting of plasma cells, T cells and a large non-T cell population, extending into the lamina propria between the gastric glands[8,23]. The infiltrating plasma cells contain auto-antibodies to parietal cell antigen and to intrinsic factor[8,24]. Extension of the cellular infiltrate into the mucosa is accompanied by degenerative changes in parietal cells and zymogenic cells. With fully established lesions, there is a marked reduction in the number of gastric glands, parietal and zymogenic cells, with replacement by mucus containing cells[8]. More common than PA is a state, usually in the older patient, in which there is diffuse severe atrophic oxyntic gland gastritis with achlorhydria but the residual ability to absorb vitamin B12. To prove the existence of severe oxyntic gland gastritis, biopsy specimens are best taken from the midbody region on the greater curve since the mucosa on the lesser curve is thinner and can be falsely interpreted as atrophic. Severe oxyntic gland atrophy is commonly associated with only mild inflammatory cells infiltrate and a reduced prevalence of *H pylori*. The other features include varying amounts of metaplasia[10]. Hyperplastic or inflammatory polyps are the most common lesions found in endoscopic surveys in PA with a prevalence of 10-40%[10,25].

Characteristic gastric features, both gross and histopathologic, are not well described with B12 deficiency resulting from causes other than PA, particularly in older subjects. For this reason, we have attempted to relate gastric histopathology with B12 status in an attempt to examine whether gastric histopathology is a cause or an

effect of B12 deficiency. Furthermore, B12 deficiency can affect proliferating cells at all sites and so an association between B12 status and gastric histopathology would help in the development of strategies for screening and early diagnosis of B12 deficiency based on endoscopic and histopathologic findings.

Our study demonstrated that a normal endoscopic appearance was not correlated with B12 status but that endoscopic findings of atrophy and gastritis were significantly different between B12-deficient patients and controls (P = 0.017). Similar rates of normal and abnormal histopathologic findings were observed in older adults with and without B12 deficiency. Inflammation was the predominant histopathologic finding in older adults with and without B12 deficiency. Our findings suggested that histopathologic findings were variable and not correlated with B12 status, however, a statistically significant difference in the degree of gastritis was noted between the B12-deficient patients and controls (P=0.039). Atrophic gastritis was more common in the B12-deficient patients, while superficial gastritis was more common in the controls. It should also be noted that atrophy was not seen when B12 levels were normal. In these samples of older adults, neither increasing age nor gender influenced gastric histopathology result, while endoscopic findings and gastric histopathology bore no relationship to Hct. There is a strong evidence that *H pylori* infection is associated with cobalamin deficiency; this is true even with non-ulcer dyspepsia or the presence of minimal to no GA[26]. Whether this is merely an association or a cause and effect relationship is unclear. In an earlier study, two-thirds of the patients with atrophic gastritis of the body had *H pylori* infection[27]. Eradication of *H pylori* infection alone has been reported to correct B12 status and improve anemia in B12-deficient individuals[28]. Thus, the possible role of *H pylori* infection in cases of severe food cobalamin malabsorption suggests specific options to prevent and treat B12 deficiency when associated with *H pylori* infection[29].

We observed a 40% rate of *H pylori* infection in patients with cobalamin deficiency compared to a 31% rate in individuals with normal status. Though this finding was not statistically significant (Figure 1E), the comparative trend supported the belief that *H pylori* infection occurs more frequently in B12 deficiency and is consistent with recent studies that implicate *H pylori* as an etiological factor for B12 deficiency[28]. The data may not be uniform in all countries as concluded in a Japanese study that noted higher rates of both *H pylori* infection and atrophic gastritis in Japan where PA is uncommon[30]. The presence of intrinsic factor antibodies were not correlated with the presence or absence of *H pylori* in the present study. Moreover, intrinsic factor antibodies were present in 29% (5/17) of cobalamin-deficient patients, suggesting a higher prevalence of PA than the previously reported prevalence of less than 5% in B12 deficiency patients[31]. Also, age had no effect on the presence or absence of intrinsic factor.

We recognized that this study had some limitations. The total number of subjects was not large, and not every individual had biopsies from the gastric fundus, a site recognized for histopathologic changes in B12 deficiency[18]. In control subjects, although a small number of biopsies were obtained from the fundus, the reality was that a number of biopsies contained inadequate tissue for meaningful interpretation. In addition, intrinsic factor antibodies and ferro-kinetics were not obtained in all the patients. Iron deficiency is known to be associated with gastric histopathological changes and 4 of 19 patients tested with ferro-kinetics were noted to have iron deficiency as demonstrated by the ferritin assay. We also did not have precise data on the specifics of treatment for *H pylori* infection prior to endoscopy. Our aim was to evaluate endoscopic and histopathologic findings in B12 deficiency and controls irrespective of etiology and to attempt to decipher the changes related to cobalamin deficiency. This study made no attempt to delineate the etiology of B12 deficiency in our subjects. As stated, the indication for endoscopy was other than for an evaluation of B12 status. Thus, it is also possible that the primary disease process necessitating the endoscopy may have affected the gastric mucosa and influenced the histopathologic findings. Finally, the extent of injury from medications, bile reflux or infection also could not be assessed.

In conclusion, abnormal gastric endoscopic findings appear to be correlated with B12 levels, with GA being the predominant finding in cobalamin deficiency and gastritis being the common finding when B12 levels are normal. Normal en doscopic findings are also observed in B12-deficient as well as in control subjects. Histopathology results are variable, with a predominance of inflammation that lacks any correlation with B12 deficiency. However, gastritis type does correlate with B12 status in that atrophic gastritis is more prevalent in B12 deficiency and superficial gastritis is more common when B12 status is normal. GA is absent on both endoscopy and histopathology, when B12 levels are normal. Our findings are consistent with literature in that *H pylori* infection is associated with cobalamin deficiency, implicating *H pylori* as an etiological factor for B12 deficiency.

Abstract

AIM: To investigate the anti-ischemic properties of perfluorochemical emulsion "perftoran" in mesenteric region.

METHODS: Experiments were conducted on 146 nonlinear white male rats weighing 200-350 g. Partial critical intestinal ischemia was induced by thorough atraumatic strangulation of 5-6 cm jejunal loop with its mesentery for 90 min. Global critical intestinal ischemia was made by atraumatic occlusion of the cranial mesenteric artery (CMA) for 90 min also. Perftoran (PF, 0.8-1.0 mL per 100 g) in experimental groups or 0.9% sodium chloride in control groups was injected at 75 min of ischemic period. Mean systemic arterial blood pressure (BP_M) registration, intravital microscopy and morphological examination of ischemic intestine and its mesentery were performed in both groups.

RESULTS: During 90 min of reperfusion, BP_M progressively decreased to 27.3±7.4% after PF administration *vs* 38.6±8.0% in the control group of rats with partial intestinal ischemia (NS) and to 50.3±6.9% *vs* 53.1±5.8% in rats after global ischemia (NS). During the reperfusion period, full restoration of microcirculation was never registered; parts with restored blood flow had leukocyte and erythrocyte stasis and intra-vascular clotting, a typical "non-reflow" phenomenon. The reduction of mesenteric 50-400 μm feeding artery diameter was significantly less in the PF group than in the control group (24±5.5% *vs* 45.2±3.6%, $P<0.05$) 5 min after partial intestinal ischemia. This decrease progressed but differences between groups minimized at the 90th min of reperfusion (41.5±4.2% and 50.3±2.8%, respectively). In reperfusion of rat's intestine, a significant mucosal alteration was registered. Villous height decreased 2.5-3 times and the quantity of crypts decreased more than twice. In the group of rats administered PF, intestinal mucosal layer was protected from irreversible post-ischemic derangement during reperfusion. Saved cryptal epithelial cells were the source of regeneration of the epithelium, which began to cover renewing intestinal villi after 24 h of blood flow restoration. View of morphological alterations was more heterogeneous in CMA groups.

CONCLUSION: Systemic administration of perftoran promotes earlier and more complete structural regeneration during reperfusion in rats after partial and global critical intestinal ischemia.

INTRODUCTION

Prophylaxis and treatment of ischemia-reperfusion injuries in common and especially in mesenteric circulation are the most actual problems of modern-day surgery, intensive care medicine and pathology, and still require improved understanding of the pathophysiology and mechanisms of the development of these disorders[1,2]. Pathophysiological derangement, which occurs after restoration of a blood flow known as the reperfusion syndrome, continues to be responsible for the very high mortality rate in the fields of surgery associated with acute mesenteric occlusion or

intestinal strangulation[3,4]. There is no generally accepted opinion about the critical terms of intestinal ischemia. During this time, the answer to this question has not only theoretical but also important practical significance. For example, this problem is one of the main aspects in the field of intestinal transplantation[5,6].

There has been extraordinary progress in the treatment of ischemia-reperfusion injuries over the past two decades. Though advances have been made in the management of acute vascular occlusion, the optimal treatment of a reperfusion injury is still not defined. Perfluorocarbon emulsion (PFCE) is among the medicines administered in different cases of ischemia-reperfusion injuries. Investigations in this field are one of the most priority branches of scientific researches in the world. Designation and intensive investigation of the effects of PFCE in different fields of biology and medicine have been conducted by a number of Russian scientists since 1979 under the general direction of the Institute of Biological Physics of the Acad. Sci. USSR. Perftoran (OAO NPF "Perftoran", Puschino Russia) is a well-known PFCE containing 20% of perfluorodecalin and perfluo romethylcyclohexylpiperidin stabilized by proxanol-168. The diameter of an average particle is about 0.07 μm. Local (intraluminal or intraperitoneal) administration of PFCE on intestinal ischemia-reperfusion injury has been extensively elucidated[7-13].

MATERIALS AND METHODS

Procedures

All animal procedures were performed in accordance with the recommendations for the proper use and care of laboratory animals. Experiments were performed on 146 white nonlinear adult male pathogen-free rats weighing 200-350 g. Before the surgery, they were anesthetized with pentobarbital sodium (CPF, Tallinn, Estonia) (5-7 mg per 100 g, i m). Except for chronic experiments, tracheostomy cannula was inserted and animals were supported by time-cycled, volume-limited ventilation with room air by mechanical respirator 4601-1 Advanced (Technical and Scientific Equipment, GmbH, Germany) at the frequency of 70 breaths/min and the tidal volume of 5 mL/kg.

Animal models

The rats were then randomized into two groups depending on the type of chosen critical intestinal ischemia. Each group was divided into two subgroups. In the subgroup A, perftoran was used as a protective remedy before reperfusion. In the subgroup B, the same volume of 0.9% sodium chloride was injected as a control.

In group 1 (n = 110), animals were exposed to a critical segmentary (local) tourniquet ischemia of the intestine. This model corresponded to incarcerated hernia or different types of bowel strangulation such as commissural ileus, volvulus, formation of knots and others. After a midline abdominal incision was made, intestinal ischemia was produced by atraumatic strangulation of the jejunal loop (5-6 cm in length) and its mesentery (15-30 cm distal after duodeno-jejunal flexion) with thick tourniquet until visual absence of regional artery pulsation for 90 min. In subgroup 1A (n = 48), perftoran (1 mL per 100 g) was injected slowly intra-arterially (i a) at 75 min of ischemic period. In subgroup IB (control group, n = 62), 0.9% sodium chloride solution was injected i.a. at the same time and volume.

In group 2 (n = 36), rats were exposed to a critical global (total) ischemia of the intestine. This model corresponded to acu 2A (n = 22), PF (1 mL per 100 g, 5-6% of circulating blood volume) was injected i a at 75 min of ischemic period. In subgroup 2B (control group, n = 14), 0.9% sodium chloride solution was injected i.a. at the same time and volume.

External hemoexfusion volume was thoroughly counted during the experiments and 0.95% sodium chloride (2:1) was injected i.a. in order to fill up the blood loss and maintain the volume of circulating plasma. In chronic experiments (n =17), gut contents were replaced in the abdominal cavity, the incision was closed with suture technique and animals were returned to the prone position.

Blood pressure registration

Caudal or femoral arteries were prepared and cannulated by polyethylene (PE)-10 or PE-50 catheters (Becton Dickinson, USA) after i.a. heparin administration (30 ME per 100 g). During the experiments, mean systemic arterial blood pressure (BPM) was monitored by pressure transducers of Bentley Trantec and Statham P231D (Cobe Laboratories, Inc., USA) or MPU-05-290-0-III (San-EI, Japan) connected to the polygraph Schwarzer (Picker International GmBH, Munchen, Germany) or the automatic recorder 142-8 (San-EI, Japan).

Intravital microscopical examination

After a midline abdominal incision was made, the chosen segment of the proximal jejunum with mesentery was extracted on a transparent table of the microscope and covered by a transparent film to prevent tissue withering. Rectal temperature of the animal and intestinal loop was kept at 36.5 ℃. Rat's mesenteric microcirculatory bed was observed under a through-passage light bio-microscope MBI-15 (LOMO, Russia) supplied with photo-camera Zenit-ET (Zenit, Russia), an original device for registration of micro-vessel diameters by the splitting image method[14]. An analogous signal with amplitude proportional to the external vessel diameter was registered simultaneously with BPM line on the automatic recorder 142-8. Diameters of the mesenteric micro-vessels were registered before ischemia and during 90 min of reperfusion.

Morphological examination

Tissue samples were harvested from ischemic zone in experiments with tourniquet intestinal loop strangulation. In experiments with mesenteric occlusion, a very heterogeneous view of the injured intestine was registered. Morphological examination of the different segments of the intestinal wall was performed. Morphological samples were harvested just before the end of 1.5 ischemic period

and after 1.5 and 24 h of reperfusion.

Tissue samples of the intestinal wall were prepared as rings, fixed in 10% neutral buffered formalin and embedded in paraffin. Four-to six-micrometer-thick sections were stained with hematoxylin and eosin and examined under light microscope. PAS-reaction was also conducted. Morphological examination was performed on 243 sections of the rat's intestine by the "blind" method. The numerical six-step scale proposed in 1970 by Chiu *et al*[15]. was used for qualitative evaluation of the degree of the mucosal layer alterations.

Statistical analysis

Data were analyzed with "Microsoft Excel 97 SR-2" statistical software. All values were expressed as mean±SD. Paired and unpaired *t*-criteria were used to test the differences within and between groups, respectively. $P<0.05$ was considered statistically significant.

RESULTS

Microcirculatory disorders

Tourniquet application on the intestinal loop (group I, $n = 42$) led to complete blood flow interruption in the mesenteric bed and intestinal wall. Erythrocyte diapedesis around the mesenteric micro-vessels increased with terms of ischemia. Capillary network structure underwent significant alterations. One minute after tourniquet removal, blood flow was registered visually as a rule, only in the large mesenteric vessels and their branches directly before the intestinal wall, the so-called "feeding" arteries and veins with a diameter from 100 to 400 μm (Figure 1). In smaller vessels, full restoration of microcirculation was never registered; parts with restored blood flow had leukocyte and erythrocyte stasis and intra-vascular clotting, a typical "no-reflow" phenomenon. Hemorrhages occupied considerable areas of intestinal mesentery. During the reperfusion period, decreased blood flow velocity, increased number of leukocytes with activated aggregation and leukocyte-endothelial wall interactions were also registered in the micro-vessels.

During the initial phase of global intestinal ischemia (group 2, $n = 9$) in some large mesenteric arteries, no total stasis but slow blood flow was registered in contrast with total mesenteric occlusion. Probably, total mesenteric occlusion activated the collateral circulation of ischemic intestine in the first few minutes. After 15-20 min of ischemia, full stasis came in the mesenteric bed. After the removal of occluder from CMA, blood flow was restored in large arteries and veins which divides mesentery on transparent "windows" and in branches near the intestinal wall, the "feeding" vessels. In smaller blood vessels of mesentery, the "no-reflow" phenomenon progressed within 90 min of reperfusion.

In general, reperfusion injuries of mesenteric microcirculation did not change either after partial tourniquet ischemia or CMA occlusion, but impairments were more heterogeneous in rats of group 2.

Blood pressure dynamics

Systemic BP_M level during 90 min of partial and global intestinal ischemia and reperfusion is shown in Figure 2A. BP_M level did not change during the ischemic period but abrupt decrease was significant at 5 min of reperfusion (about 40% in cases with CMA occlusion). This systemic BP_M level decrease continued till the end of the observation period (90 min of reperfusion).

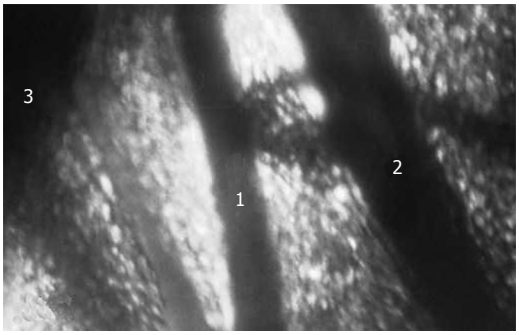

Figure 1 View of the "feeding" artery in rat's intestinal mesentery in light microscope. **1:** "feeding" vein; **2:** "feeding" arteries; **3:** mesenteric edge (wall) of intestine.

Effects of perftoran

Administration of PF in subgroups 1A and 2A (partial and global intestinal ischemia) had no impact on the general picture of microcirculatory alterations in the intestinal mesentery during reperfusion. As in the control group, the systemic BP_M level progressively decreased in the post-ischemic period (Figure 2B). As shown in Figures 2A and B, changes in the BP_M level during reperfusion had no differences after the administration of PF before the end of the ischemic period and in control rats. There were no significant differences between subgroups 1A and B or between subgroups 2A and B.

Though there were no post-ischemic significant changes in microcirculation of rat's intestinal mesenteric bed, intestinal blood supply was restored. During this time, blood flow restoration was not complete because the diameters of the "feeding" arteries in reperfusion period were significantly smaller. In eight rats of the subgroup 1A injected with PF before the end of ischemia, diameter of 19 "feeding" arteries at 5 min of reperfusion became smaller. At the same time, in six rats of subgroup 1B (15 arteries) this value differed ($P<0.05$, Figure 3). During this time, the diameter of mesenteric "feeding" arteries continued to decrease, but differences between groups became less visible after 90 min of reperfusion. In nine rats of subgroup 2A injected with PF before CMA occluding, micro-clamp removing vascular reaction was heterogeneous. The diameter of 15 "feeding" arteries at 5 min of reperfusion was decreased by 10% in comparison with the initial one. In contrast, this value in 10 arteries was increased by 23%. The increase of some feeding artery diameters in post-ischemic period was typically exact for global model of rat's intestinal ischemia.

Morphological examination

Morphological examination of the intestinal wall sections

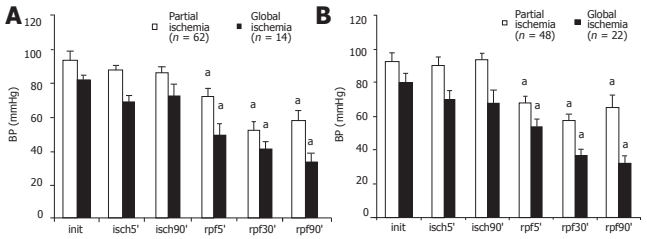

Figure 2 Systemic BP_M at 90 min of partial and global intestinal ischemia and during reperfusion after 0.9% sodium chloride injection (**A**) and perftoran administration (**B**). BP_M level decreased more significantly in groups after CMA occlusion. [a]*P*<0.05 *vs* initial values in each group.

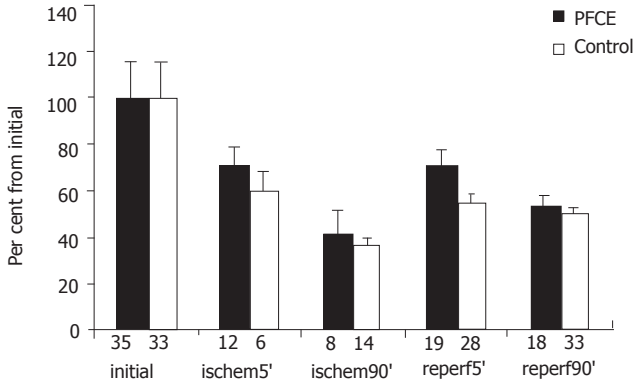

Figure 3 Diameter of "feeding" arteries at 90 min of partial intestinal ischemia and during reperfusion. The recovery of the diameter to initial value during reperfusion was more significant in the group administered PF in comparison with control group. harvested in group I (partial tourniquet ischemia) only revealed moderate alterations of mucosal layer such as slight apical swelling of intestinal villi with "lifting" of apical epithelium in the ischemic period. But within 90 min after tourniquet removal, degree of intestinal wall alteration progressively increased in comparison to the ischemic period. Therefore, impairment of crypts at 90 min of reperfusion was registered in rats of subgroup IB, spacious parts of intestinal luminal surface were completely denuded with marked villous architecture destruction (Figure 4A). At the same time, in rats of subgroup IA (administered PF) the intestinal wall structural safety was higher in the reperfusion period than in control rats (Figure 4B). Necrobiotic processes and structural changes in rats of subgroup IB progressed with the appearance of focal transmural necroses in the ischemic intestinal wall within 24 h after the end of ischemia (Figure 4C). In rats of subgroup IA (administered PF), alteration was not so significant and even reparative processes such as restoration of villous architecture and epithelial layer regeneration were also marked (Figures 4D and 5). Morphometric analysis data of intestinal wall sections in group I are presented in Table 1.

Morphological examination of intestinal tissue in group II (occlusion of CMA) revealed a number of characteristic

peculiarities. As in a partial intestinal ischemia, moderate changes in the mucosa appeared only at the end of the ischemic period. Then, damage of mucosal and other layers of the intestinal wall progressively increased during 90 min of reperfusion. Destruction of superficial mucosal layer, erythrocyte diapedes, massive hemorrhages, and leukocyte infiltration of the intestinal wall and mesentery occurred in subgroups 2A and B. In general, view was more heterogeneous than in the intestine of group I rats. Moreover, a lot of rats died after 90 min of CMA occlusion in early reperfusion period because of intoxication and progressing circulatory failure. Results of intestinal wall section morphometric analysis in group II are presented in Table 2.

DISCUSSION

The problem of post-ischemic or reperfusion impairments of organ blood flow restoration arises acutely after pharmacological and surgical intervention. Therapeutic measures have been concentrated on a critical threshold, minimization of cell metabolism and degree of tissue microcirculation reperfusion injuries[16-20]. If significant success is achieved in ischemic disorders, the problem of

reperfusion injury prophylaxis is far from its final solution and requires not only ways of correction but thorough investigation of its mechanisms. Investigation of the natural phenomena and main mechanisms of reperfusion injuries at "critical" terms of partial and global intestinal ischemia in rats was conducted in the current work.

The tourniquet partial intestinal ischemia model was chosen in the present work for more homogenous pathomorphological receipts. This model reproduces such disorders as incarcerated hernia and other types of bowel strangulation in clinical practice. The second model occluding CMA corresponds to global intestinal ischemia in consequence of arteriomesenteric thrombosis or embolism.

After significant and irreversible structural and functional changes occurred, the "critical term" (point-of-no-return) was about 90 min for tourniquet segmentary intestinal ischemia in rats. The distinct tendency to stable systemic BP_M level during ischemic period and its abrupt decrease in early reperfusion period were observed. This BP_M level falling was naturally more significant in experiments with CMA occlusion.

Anti-ischemic effect of PF was evaluated in intestinal wall sections from rats that received 0.9% sodium chloride solution. Morphometric analysis was used for quantitative evaluation of rats' intestinal wall alteration degree. A number of morphometric indexes such as the average villous height, number of crypts, epithelial layer safety, and degree of mucosal alteration were analyzed as previously described[15].

The destructive activity increased significantly during reperfusion of ischemic intestine. Mucosa was the most sensitive layer of the intestinal wall. Maximal degree in rat's ischemic intestine was noted at 1.5 h of reperfusion. At the same time, the reperfusion injury strength was significantly smaller in rats that received PF than in controls. In subgroup IA (PF), an explicit regenerative tendency was noted, while destructive process progressed in control rats. In general, luminal surface was covered by low non-mature cubic epithelium, suggesting that crypt's safety is a definitive factor in the viability of ischemic intestine.

It was reported that PFCE has multifunctional properties and is effective in preventing ischemic and reperfusion disorders[21-23]. At the same time, PFCE

administration is extremely limited and its mechanisms are poorly understood.

Differences in the intestinal morphologic structure of rats administered PF and control showed the protective role of PF in the reperfusion period. Though no significant destructive changes were found in mesenteric micro-vascular bed, intestinal circulation was restored during reperfusion period. Nevertheless, blood flow restoration during reperfusion was not complete because of "feeding" artery diameter and systemic BP_M were significantly smaller than before. At 5 min of reperfusion, feeding artery diameter was decreased by 45% in average compared to the control rats. At the same time, feeding artery diameter was decreased by 24% in rats after PF administration, while BP_M level was decreased in both groups (42%), suggesting that there are more feeding arteries after the "critical" ischemia in rats administered PF.

In the analysis of mechanisms of PF protective action on intestinal mucosa, polyfunctional properties of PFCE were taken into account. Therefore, some of them were protected from destruction and mucosal layer regeneration was maintained. Rheological and nitric oxide (NO) transporting properties of PF may take part in this phenomenon.

It is well known that powerful vasodilator NO can protect rat intestine against reperfusion injury[24]. Results of another investigation witness PFCE penetration from blood into endothelial cells of micro-vessels[25], suggesting that PFCE interacts directly with NO in tissues. PF in intestinal microvascular bed may play a role as a NO depot-regulator and protect intestinal wall tissues reperfusion against injury.

PF and NO interactions can be applied to vascular bed of the ischemic intestine. PF may support vasodilatatory potential of mesenteric feeding arteries as a NO depot-regulator during intestinal reperfusion.

In the present study, ischemia-reperfusion systemic and local pathological functional and structural changes were reproduced on experimental models of tourniquet segmentary intestinal loop strangulation and CMA occlusion in rats. "Critical" term (point-of-no-return) for normal thermic tourniquet segmentary intestinal ischemia in rats was about 90 min. Reperfusion could disregulate the systemic blood pressure support system and lead to its abrupt progressive decrease in the early reperfusion period.

In conclusion, the main pathophysiological reperfusion injury of rat's intestine is the significant mucosal alteration. The degree of intestinal changes is proportional to the duration of ischemia. Systemic administration of perftoran before the reperfusion promotes earlier and more complete structural regeneration in rats with critical partial intestinal ischemia.

Abstract

AIM: To investigate the effects of arginine (Arg)-enriched diets before sepsis and/or Arg-containing total parenteral nutrition (TPN) after sepsis or both on cytokine mRNA expression levels in splenocytes of rats with gut-derived sepsis.

METHODS: Rats were assigned to four experimental groups. Groups 1 and 2 were fed with a semipurified diet, while groups 3 and 4 had part of the casein replaced by Arg which provided 2% of the total calories. After the rats were fed with these diets for 10 d, sepsis was induced by cecal ligation and puncture (CLP), at the same time an internal jugular vein was cannulated. All rats were maintained on TPN for 3 d. Groups 1 and 3 were infused with conventional TPN, while groups 2 and 4 were supplemented with Arg which provided 2% of the total calories in the TPN solution. All rats were killed 3 d after CLP to examine their splenocyte subpopulation distribution and cytokine expression levels.

RESULTS: Plasma interleukin (IL)-2, IL-4, tumor necrosis factor-α (TNF-α) and interferon (IFN-γ) were not detectable 3 d after CLP. There were no differences in the distributions of CD45Ra+, CD3+, CD4+, and CD8+ cells in whole blood and splenocytes among the four groups. The splenocyte IL-2 mRNA expression in the Arg-supplemented groups was significantly higher than that in group 1. IL-4 mRNA expression in groups 3 and 4 was significantly higher than that in groups 1 and 2. The mRNA expression of IL-10 and IFN-γ was significantly higher in group 4 than in the other three groups. There was no difference in TNF-α mRNA expression among the four groups.

CONCLUSION: The influence of Arg on the whole blood and splenic lymphocyte subpopulation distribution is not obvious. However, Arg administration, especially before and after CLP, significantly enhances the mRNA expression levels of Th1 and Th2 cytokines in the spleen of rats with gut-derived sepsis.

INTRODUCTION

Sepsis is a major cause of death in critically ill patients. Under a condition of sepsis, different endogenous mediators are oversecreted, which may result in an imbalance of the metabolic pathway[1,2]. These metabolic abnormalities that occur during sepsis mainly result from the secretion of cytokines[3]. Cytokines belong to a superfamily of low molecular weight glycoproteins that act as important regulatory proteins, and play a key role in inflammatory responses either directly or by their ability to induce the synthesis of cellular adhesion molecules or other cytokines in numerous cell types[4-6]. Cytokines have beneficial properties in initiating immune responses and maintaining homeostasis in critically ill patients. However, exaggerated or prolonged secretion of cytokines may be detrimental for the host[4-6]. Modulation of cytokines is very important for patients under metabolic stress.

Arginine (Arg) is a semi-essential amino acid that possesses numerous useful physiologic properties[7]. Accumulating experimental and clinical evidence has suggested that Arg reduces protein catabolism and enhances immune function in severely injured animal models and critically ill patients[8–12]. Although a meta-analysis by Heyland *et al*[13]. suggested that immune-enhancing diets rich in Arg may be harmful in unstable critically ill patients, immunonutrition with Arg positively modulates postsurgical immunosuppressive and inflammatory responses[14]. Arg is considered to be an

essential amino acid for patients with catabolic diseases[7,15]. Previous reports by our laboratory showed that preventive use of a Arg-supplemented enteral diet or Arg administered both before and after cecal ligation and puncture (CLP) enhances peritoneal macrophage phagocytic activity and bacterial clearance[16]. Also, total lymphocyte yields in Peyer's patches and intestinal immunoglobin (Ig) A secretion are improved after Arg administration both before and after CLP[17]. In order to understand the protective mechanisms of Arg, the cytokine mRNA expression and protein secretion in septic hosts need to be investigated. However, cytokine protein detection is usually limited, due to lack of sensitive commercial ELISA kits and the short half-life of most cytokines in plasma. Wu *et al*[18]. have investigated the relation between cytokine mRNA expression and organ damage after sepsis. Cui *et al*[19]. reported that an Arg-supplemented diet decreases the expression of inflammatory cytokines in burn rats. As we know, there is no study investigating the effects of Arg on Th1 and Th2 cytokine mRNA expressions of splenocytes in septic rats. Therefore, the aim of this investigation was to study the effect of Arg-supplemented diets before sepsis and Arg-enriched total parenteral nutrition (TPN) after sepsis or both on plasma cytokine levels and splenic cytokine mRNA expression in gut-derived sepsis. Also, the lymphocyte subpopulations of whole blood and splenocytes were analyzed to understand the effects of Arg on the phenotype of lymphocytes in a septic condition.

MATERIALS AND METHODS

Animals

Male Wistar rats weighing 200-230 g were housed in stainless steel cages in a temperature- and humidity-controlled room with a 12:12 h light-dark cycle. Animals were allowed free access to standard rat chow for 3 d prior to the experiment. All procedures conducted in this study were approved by the Taipei Medical University Animal Care Committee.

Surgical procedure and grouping

All rats were divided into four groups. Groups 1 and 2 were fed a semipurified diet. Rats in groups 3 and 4 were fed an identical diet except that part of the casein was replaced by Arg, which provided 2% of the total energy intake (Table 1). After the rats were fed the experimental diets for 10 d, sepsis was induced by CLP according to the method of Wichterman *et al*[20]. Briefly, the rats were anesthetized with intraperitoneal pentobarbital (50 mg/kg), and the abdomen was opened through a midline incision. The cecum was isolated, and a 3-0 silk ligature was placed around it, ligating the cecum just below the ileocecal valve. The cecum was then punctured twice with an 18-gauge needle and placed back into the abdomen. The abdominal wound was closed in two layers.

Immediately after CLP, all rats underwent placement of a catheter for TPN infusion. A silicon catheter (Dow Corning, Midland, MI, USA) was inserted into the right internal jugular vein. The distal end of the catheter was tunneled subcutaneously to the back of the neck, and exited through a coiled spring which was attached to a swivel, allowing free mobility of animals inside individual metabolic cages. TPN at 2 mL/h was administered on the first day. Full-strength TPN (56-64 mL/d, according to body weight) was given thereafter for 3 d. The infusion speed was controlled by a Terufusion pump (Model STC-503, Terumo, Tokyo, Japan). The TPN solution without fat was prepared in a laminar flow hood. Sterilized fat emulsions were added to the TPN solution daily just before use. The TPN solution was infused for the entire day at room temperature. No enteral nutrition was administered during the period of TPN. Groups 1 and 3 were infused with conventional TPN. Groups 2 and 4 were supplemented with Arg, which replaced 10% of the total amino acids, and provided 2% of the total energy of the TPN solution. TPN provided 280 kcal/kg body weight, and the energy (kcal):nitrogen (g) ratio was 119:1. The calorie density was almost 1 kcal/mL. The TPN solutions were isonitrogenous and identical in nutrient composition except for the difference in the amino acid content (Table 2). There were four groups in this study: group 1, no Arg supplementation before or after CLP (–/–); group 2, a semipurified diet given before and Arg-enriched TPN after CLP (–/+); group 3, an Arg-supplemented diet before and conventional TPN after CLP (+/–); and group 4, Arg supplementation both before and after CLP (+/+). There were 10 rats in each group.

Table 1 Composition of the semipurified diet (g/kg)

Ingredients	Arg-supplemented	Non-supplemented
Casein	180	220
Arg	20	–
Total nitrogen	35.2	35.2
Corn starch	677	657

[1]From Chinese Pharmaceuticals, Taipei, Taiwan. Contents per deciliter: 1 250 mg Leu, 560 mg Ile, 1 240 mg Lys acetate, 350 mg Met, 935 mg Phe, 650mg Thr, 130 mg Trp, 450 mg Val, 620 mg Ala, 790 mg Arg, 380 mg Asp, 100 mg Cys, 650 mg Glu, 600 mg His, 330 mg Pro, 220 mg Ser, 35 mg Tyr, and 1 570 mg aminoacetic acid (Gly). [2]From Yu-Liang Pharmaceuticals, Taoyuan, Taiwan. Contents per milliliter: 20 mg ascorbic acid, 660 IU vitamin A, 40 IU ergocalciferol, 0.6 mg thiamine HCl, 0.72 mg riboflavin, 8 mg niacinamide, 0.8 mg pyridoxine HCl, 3 mg D-panthenol, 2 mg dl-a-tocopheryl acetate, 12 μg biotin, 80 μg folic acid, and 1 μg cyanocobalamin.

respectively. There were no differences in the survival rates among the groups as described previously[16]. A middle abdominal incision was made, and the spleen was aseptically removed and teased on a stainless mesh immersed in chilled RPMI-1640 (Gibco, BRL, Grand Island, NY, USA). After filtration through a sterile nylon mesh, cell suspensions were washed thrice in HBSS and resuspended in RPMI-1640. Flow cytometry was used to determine the proportions of CD45Ra, CD3, CD4, and CD8 from the whole blood or splenocytes. One hundred microliters of heparinized whole blood or 10^5 splenocytes suspended in 100 μL HBSS were stained with fluorescein-conjugated mouse anti-rat CD3 (Serotec, Oxford, UK) and phycoerythrin-conjugated mouse anti-rat CD45Ra (Serotec) to distinguish T cells from B cells, respectively. Fluorescein-conjugated mouse anti-rat CD8 and phycoerythrin-conjugated mouse anti-rat CD4 (Serotec) were used to identify T helper cells and cytotoxic T lymphocyte cells, respectively. After staining for 15 min, 1 mL red blood cell (RBC) lysing buffer (Serotec) was added to lyse the RBCs and to fix the stained lymphocytes. Fluorescence data were collected on 5×10^4 viable cells and analyzed by flow cytometry (Coulter, Miami, FL, USA).

Plasma cytokine immunoassay

Plasma interleukin (IL)-2, IL-4, IL-10, interferon (IFN-γ), and tumor necrosis factor (TNF-α) concentrations were determined by commercially available enzyme-linked immunosorbent assay (ELISA) kits (Amersham Pharmacia Biotech, Buckinghamshire, UK).

Primers of cytokines

The primers of IL-2, IL-4, IL-10, TNF-α, and IFN-γ, and the housekeeping gene (18S rRNA) of rats were purchased from PE Applied Biosystems (Foster City, CA, USA).

Real-time reverse-transcription polymerase chain reaction (RT-PCR) method

Total RNA from rat spleen was isolated using the TRIzol reagent according to the manufacturer's protocol. RNA was reverse-transcribed using the Reverse Transcript system (Frementas, Vilnins, Lithuania). Briefly, 20 μL water containing 2 μg RNA was mixed with 1 μL oligo (dT) primer (0.5 μg/μL) and incubated for 5 min at 70 ℃. To the mixture, 22 μL $MgCl_2$ (25 mmol/L), 10 μL 10× RT-buffer, 20 μL dNTP (10 mmol/L), 2 μL RNase inhibitor, and 2.5 μL MultiScribe-RT (50 U/μL) were added and incubated at 25 ℃ for 10 min, then at 42 ℃ for 30 min. The reaction was stopped by heating the samples for 5 min to 95 ℃. cDNA was used for the real-time PCR assay performed with an ABI 7700 Sequence Detection System (PE Applied Biosystems) according to the supplied guidelines. The PCR reaction for IL-2, IL-4, IL-10, IFN-γ and TNF-α was carried out using a TaqMan PCR kit (PE Applied Biosystems).

Statistical analysis

Data were expressed as mean±SD. Differences among the groups were analyzed by ANOVA using Duncan's test. $P<0.05$ was considered statistically significant.

RESULTS

There were no differences in initial body weights and body weights after feeding the experimental diets for 10 d and after TPN administration for 3 d (data not shown). In this study, we were unable to detect plasma IL-2, IL-4, TNF-α and IFN-γ 3 d after CLP. Plasma IL-10 levels could be detected, but there was no difference in IL-10 levels among the groups (data not shown).

No differences in the distribution of CD45Ra+, CD3+, CD4+, and CD8+ cells in blood and splenocytes were observed among the four groups (Figures 1A and 1B). The expression of IL-2 mRNA in splenocytes was significantly higher in the Arg-supplemented groups (groups 2, 3, and 4) than in group 1 (–/–) (Figure 2A). The mRNA expressions of IFN-γ and IL-10 in group 4 (+/+) were significantly higher than in the other three groups (Figures 2B and 2D). IL-4 mRNA expression in groups 3 and 4 was higher than that in groups 1 and 2 (Figure 2C). There were no differences in splenocyte TNF-α mRNA expression among the four groups (Figure 2E).

DISCUSSION

In this study, 2% of total energy was supplied in the diet by Arg. This amount of Arg has been proved to enhance immune functions in rodents with gut-derived sepsis[21]. We administered TPN for 3 d after CLP, because the severity of infection and mortality are the highest at this time point in an established septic animal model[20]. In this

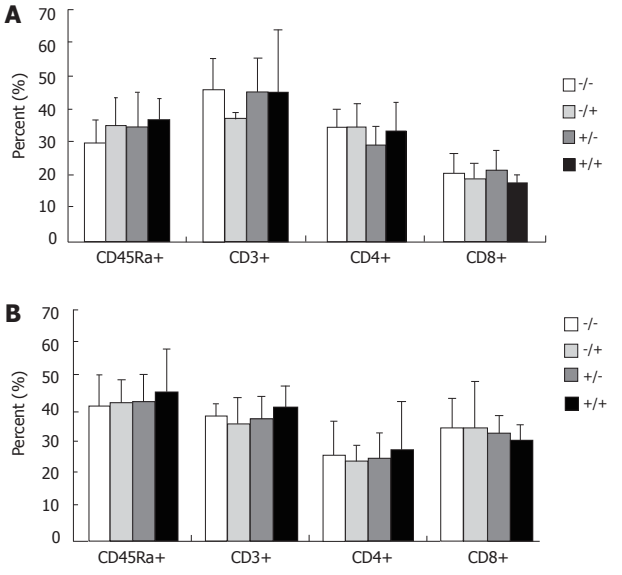

Figure 1 Distribution of CD45Ra+, CD3+, CD4+, and CD8+ lymphocytes in whole blood (**A**) and splenocytes (**B**) among the four groups 3 d after CLP (*n* = 10 in each group).

study, we did not include a sham-operation control (TPN without CLP) group; therefore, this study was not able to assess whether Arg supplementation could restore immune functions comparable to the control rats.

Circulating cytokine levels are usually used as a marker of injury or infection[3]. In order to understand the possible effects of Arg on the systemic cytokine expression in sepsis, IL-2, IL-4, IL-10, IFN-γ, and a pro-inflammatory cytokine TNF-α were measured. IL-2 and IFN-γ were produced by Th1 lymphocytes. Th1 cytokines enhance cell-mediated immunity. A predominant Th1 effect results in activation, growth, and differentiation of T and B lymphocytes as well as macrophages. Th2 cytokines, including IL-4 and IL-10, enhance humoral immunity. A predominant Th2 effect results in the activation of B lymphocytes, upregulation of antibody production, and mucosal immunity[22]. The effects of Th1 or Th2 lymphocytes were counter-regulatory.

In this study, we were unable to detect plasma IL-2, IL-4, TNF-α, and IFN-γ 3 d after CLP. Previous reports by our laboratory showed that IL-1β, IL-2, and IFN-γ were undetectable 24 h after CLP[23,24]. Cruickshank *et al*[25]. also reported that plasma IL-1, TNF, and IFN-γ are rarely detected in the plasma of injured patients. The inability to measure circulating cytokines may be due to a lack of highly sensitive assay kits and late assay times, or due to the fact that the quantities of cytokines do not enter the

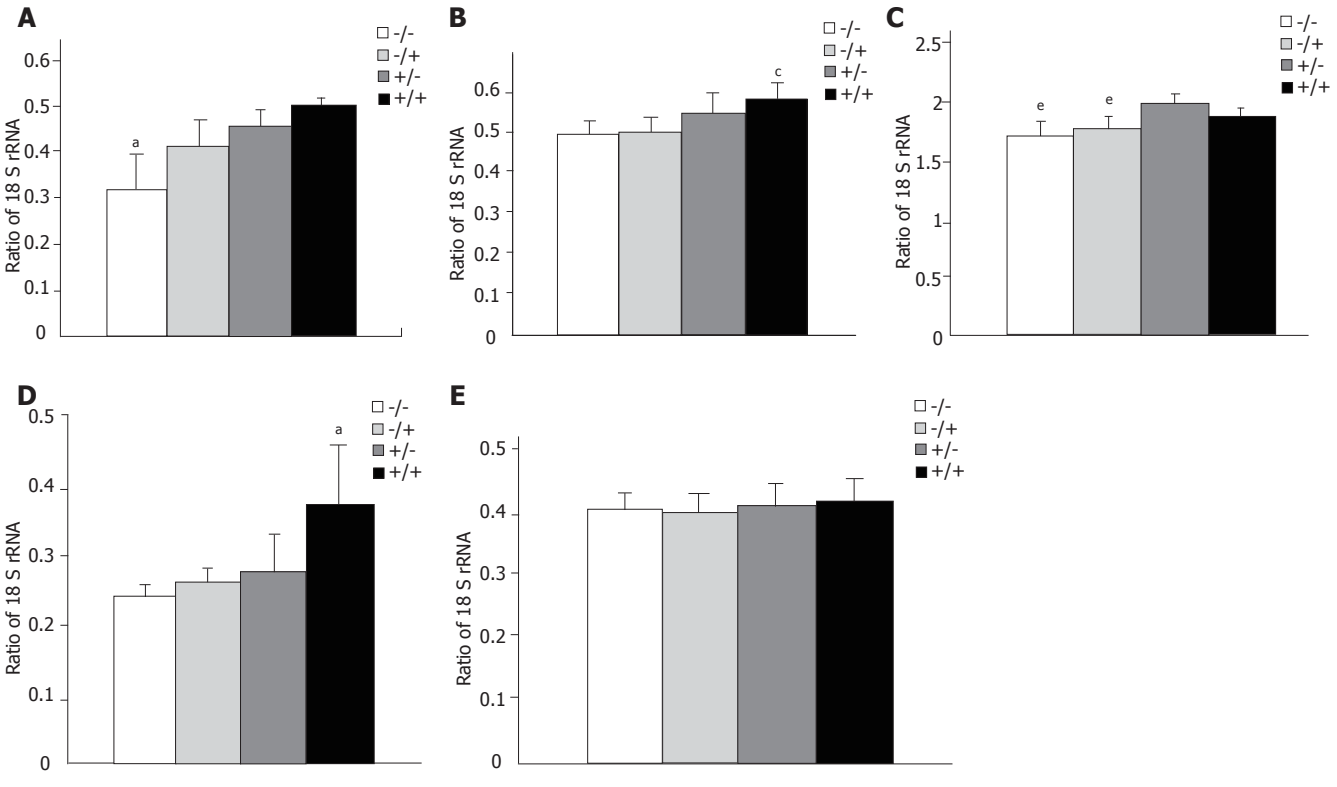

Figure 2 Expression of interleukin (IL)-2 (**A**), interferon (IFN-γ) (**B**), IL-4 (**C**), IL-10 (**D**) and tumor necrosis factor (TNF-**α**) (**E**) messenger RNA in the spleen as determined by real-time reverse-transcription polymerase chain reaction (*n* = 10 in each group). [a]*P*<0.05 *vs* other groups; [c]*P*<0.05 *vs* group 1 (–/–) and group 2 (–/+); [e]*P*<0.05 *vs* group 3 (+/–) and group 4 (+/+).

systemic circulation, even though the levels of cytokines in the tissues have increased[4]. Therefore, we used real-time RT-PCR to quantify splenic cytokine mRNA expression, this is a highly sensitive and reproducible tool to investigate the cytokine profiles at the mRNA level[26,27]. Our findings showed that Arg administration enhanced both Th1 (IL-2, IFN-γ) and Th2 (IL-4, IL-10) cytokine mRNA expression, and Arg given both before and after had a synergistic effect on enhancing cytokine mRNA expression in a septic condition. These results are consistent with our previous report that Arg supplementation promotes intestinal IgA secretion and enhances peritoneal macrophage phagocytic activity in septic rats[16,17]. Although Th1 type cytokines promote the differentiation of cytotoxic T cells, these cytokines usually respond to viral infection and intracellular pathogens. The secretion of IFN-γ may activate macrophages, promote microbicidal activity and stimulate expression of the secretory component for intestinal sIgA by epithelial cells[28]. IL-4 and IL-10 are anti-inflammatory cytokines released by Th2 cells. Furthermore, IL-10 induces the synthesis and secretion of sIgA[22,29,30].

In this study, Arg seemed to have no effect on splenocyte TNF-α mRNA expression. This result is inconsistent with a report by Cui *et al*[19]. who showed that dietary Arg supplementation decreases the mRNA expression of inflammatory cytokines in the spleen after thermal injury. Since the insults of scald burns and gut-derived sepsis differ, the inflammatory cytokine response may vary. Burn injury results in generalized inflammation in organs remote from the region of thermal injury due to activated neutrophil and reactive oxygen metabolites[31,32], whereas CLP causes peritoneal infection with mixed intestinal bacterial flora, which may result in a direct damage to the tissue and organs by circulating bacterial toxins.

In order to understand the effect of Arg on the distribution of lymphocyte subpopulations, the total B lymphocytes (CD45Ra+), total T cells (CD3+), helper T cells (CD4+), and cytotoxic T cells (CD8+) within the blood and splenocytes were evaluated. The results showed that there were no differences in the ratio of B cell and T cell subpopulations among the groups. This finding may indicate that the differences in cytokine mRNA expression after Arg supplementation do not influence the distribution of systemic and splenic lymphocyte subpopulations. Although the effects of Th1 and Th2 lymphocytes are counter-regulatory, cytokine mRNA expression and protein secretion may be regulated by different mechanisms in various tissues and organs, and the final performance of the immune response to specific tissues or organs may vary. Whether there are intracellular factors which regulate the post-transcriptional expression of these cytokines requires further investigation.

In conclusion, the influence of Arg supplementation on the distribution of whole blood and splenic lymphocyte subpopulations is not obvious. However, Arg supplementation, especially before and after CLP, significantly enhances the splenic mRNA expression of Th1 and Th2 cytokines in rats with gut-derived sepsis.

Abstract

AIM: To study the secretory expression of human hepatocyte growth factor (hdHGF) gene in *Pichia pastoris*.

METHODS: The full-length gene of human cDNA encoding the deleted variant of hdHGF was cloned by RT-PCR and overlapping-fragment PCR technique using mRNA of human placenta as a template. The cloned hdHGF cDNA was inserted into the *Escherichia coli-yeast* shuttle vector of pPIC9. The constructed plasmid, pPIC9-hdHGF, was transformed into the GS115 cells of the methylotrophic yeast, *P pastoris,* using a chemical method. The Mut$^+$ transformants were screened to obtain high-expression strains by the test and analysis of expressed products of shake-flask culture. A secretory form of rhdHGF was made with the aid of the leader peptide sequence of *Saccharomyces cerevisiae* α-factor.

RESULTS: The expressed products, which showed a band of molecular mass of about 80 ku, were observed on 15% SDS-PAGE and identified by Western blotting and N-terminal amino acid sequencing. In the high cell density culture of 5 L fermentor by fed-batch culture protocol, the cell biomass was reached at approximately 135 g (DCW)/L. The productivity of secreted total supernant protein concentration attained a high-level expression of more than 8.0 g/L and the ratio of rhdHGF band area was about 12.3% of the total band area scanned by SDS-PAGE analysis, which estimated that the product of rhdHGF was 500-900 mg/L.

CONCLUSION: The *P pastoris* system represents an attractive tool of generating large quantities of hdHGF for both research and industrial purposes.

INTRODUCTION

Hepatocyte growth factor (HGF) was identified initially as a mitogen for hepatocytes, called as scatter factor (SF) and fibroblast-derived tumor cytotoxic factor (F-TCF) as well as fibroblast-derived growth factor called plasminogen-like growth factor (PLGF)[1-3]. Nakamura *et al*[16]. reported that HGF could be purified from the serum of partially hepatectomized rats. Subsequently, HGF has been purified from rat platelets and its subunit structure is determined. The purification of human HGF from human plasma is described by Godowski *et al*[5].

The gene locus of human HGF is assigned to chromosome 7q21.1. The genomic gene consists of 18 exons and 17 introns, and spans about 70 kb. The whole length form of human hepatocyte growth factor (preproHGF) consists of 727 amino acids and the mature form of hHGF is composed of 674 amino acids, corresponding to the major form purified from human serum[5]. HGF is a disulfide-linked heterodimer derived by proteolytic cleavage of the human pro-hormone between amino acids R494 and V495. This cleavage process generates a molecule composed of an alpha-subunit of 440 amino acids (MW 69 ku) and a beta-subunit of 234 amino acids (MW 34 ku). The nucleotide sequence of hHGF cDNA reveals that both the alpha-and the beta-chains are contained in a single open reading frame coding for a pre-pro precursor protein. In the predicted primary structure of mature hHGF, an interchain S-S bridge is formed between Cys 487 of the alpha-chain and Cys 604 in the beta-chain. The N-terminus of the alpha-chain is preceded by 54 amino acids, starting with a methionine

group. This segment includes a characteristic hydrophobic leader (signal) sequence of 31 residues and the prosequence. The alpha-chain starts at amino acid (aa) 55 and contains four Kringle domains. The Kringle 1 domain extends from about aa 128 to about aa 206, the Kringle 2 domain is between about aa 211 and about aa 288, the Kringle 3 domain extends from about aa 303 to about aa 383, the Kringle 4 domain extends from about aa 391 to about aa 464 of the alpha-chain. It will be understood that the definition of the various Kringle domains is based on their homology with Kringle-like domains of other proteins (prothrombin, plasminogen). Therefore, the above limits are only approximate. Until now, the function of these Kringles has not been determined. The beta-chain of hHGF shows high homology to the catalytic domain of serine proteases (38% homology to the plasminogen serine protease domain). However, two of the three residues, which form the catalytic triad of serine proteases, are not conserved in hHGF. Therefore, despite its serine protease-like domain, hHGF appears to have no proteolytic activity and the precise role of the beta-chain remains unknown. HGF contains four putative glycosylation sites, which are located at positions 294 and 402 of the alpha-chain and at positions 566 and 653 of the beta-chain. Wild-type human HGF gene *in vivo* exists in the polymorphism. It has been observed that human HGF has a few natural variants. For example, hdHGF-encoded HGF molecule lacking five amino acids in the Kringle 1 domain (FLPSS) is fully functional[6-8].

HGF biological activity refers to any mitogenic, motogenic or morphogenic activities exhibited by wild-type human HGF or hdHGF, which have a broad spectrum of mitogenic cell specificity that can promote the proliferation of hepatocytes, endothelial cells, fibroblasts, melanocytes, and epithelial cells etc.[1,4], inhibit the growth of some tumor cell lines such as $HepG_2$, B6/F1, and KB from tumorigenic target cell lines[9]. Recent studies displayed that hdHGF can exert many important biological effects mediated via their specific tyrosine kinase receptor, C-met. Even to the extent, hdHGF has more significant biological effects on promoting the regeneration of hepatocytes and kidney epithelial cells compared to wild-type human HGF, suggesting that hdHGF has the therapeutic effect *in vivo* on liver injury[2].

Recently, methylotrophic yeast *Pichia pastoris* has become a dominant tool in molecular biology for the production of recombinant proteins. *P pastoris* is known for its high-level expression of heterologous proteins and its tightly regulated alcohol oxidase 1 (AOX1) gene promoter[10]. *P pastoris* can be easily grown to high cell densities using defined minimal media and is able to introduce eukaryotic post-translational modifications[11,12]. The techniques for molecular genetic manipulation are similar to those well established for *Saccharomyces cerevisiae*. At present, *P pastoris* as an efficient protein expression system can be fermented routinely in large scale to meet the industrial demands of interest proteins[13-15]. In the present report, we have described the recombinant production of hdHGF in *P pastoris* and its characterization.

MATERIALS AND METHODS

Strain, vector, reagents, and enzymes

P pastoris host strain GS115 (His^+Mut^+) and secretion expression vector pPIC9 were purchased from Invitrogen (San Diego, CA, USA). *E coli* DH5α was used for routine plasmid amplification and the cloned vector of pUC19 was maintained in our laboratory. Superscript™ II RNase H⁻Reverse transcriptase was purchased from GibcoBRL. Human placenta mRNA was obtained from Clontech Co. Expand™ High Fidelity PCR System was purchased from Boehringer Mannheim Co. Yeast nitrogen base, D-biotin, yeast extract and tryptone were obtained from Sangon (Shanghai, China). *EcoRI*, *NotI, SalI, XbaI, SphI,* T4 DNA ligase, and *Taq* DNA polymerase were obtained from TaKaRa Biotechnology (Dalian, China). Anti-hHGF antibody was purchased from Santa Cruz Biotechnology Co.

Molecular cloning of hdHGF

The whole length gene of human cDNA encoding the deleted variant of hdHGF was amplified by RT-PCR and overlapping fragments were amplified by PCR technique using mRNA of human placenta as the template. Three pairs of PCR primers for amplified hdHGF fragments were designed as follows.

In primer M1, single bottom line stands for SphI and two lines for SalI. Oblique boldface capital letters (included 8 codons) represent the frequently used codons in the highly expressed *P pastoris* genes. In primer M2, single bottom line stands for *XbaI* and two lines for *NotI*. Its complementary chain encodes the sequence for *TACAAGGTTCCACAGTCTTAA* (included 6 codons) and the oblique boldface capital letters represent the bias of codons in the highly expressed *P pastoris* genes. Therefore, the codons encoding N-and C-terminal amino acids of the deleted variant of hdHGF were amplified by RT-PCR and overlapping-fragment PCR technique, using mRNA of human placenta as the template, which has the advantage to acquire high-level expression of foreign genes in *P pastoris*.

A forward primer(P1: 5'TTCTTTCACCCAGGCATCTC3') and a reverse primer (P2: 5'CTATGTTTGTTCGTGTTGG AATCC3') as well as another forward primer (P3: 5'GTGG GACAAAGAACATGGAAGACTTAC3') and its reverse primer (P4: 5'GCTTCAGACACACTTACTT CAGCTA3') were designed to synthesize the two cDNA fragments based on the hdHGF sequence reported by Nakamura *et al*[16], namely one fragment (F1, about 1.6 kb) was amplified using a pair of primers P1 and P2 and the other fragment (F2, approximately 1.0 kb) was amplified using a pair of primers P3 and P4. Overlapping-fragment amplification using F1 and F2 fragments as templates was performed by routine PCR procedure using a pair of primers M1 and M2 (Figure 3). The cDNA product obtained from RT-PCR was modified by introducing *SphI* and *SalI* sites at the 5'end and *XbaI* and *NotI* sites as well as a TAA stop codon at the 3'end. Thirty-five cycles of PCR were performed: denaturation at 94 ℃ for 60 s, annealing at 55 ℃ for 60 s,

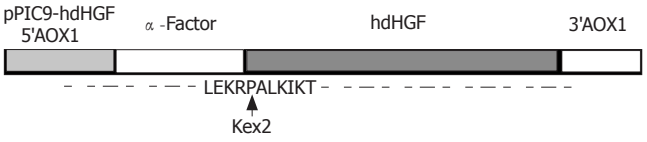

Figure 1 Schematic representation of hdHGF expression cassettes used. Arrowhead indicates the cleavage site of Kex2 protease.

extension at 72 ℃ for 90 s, and then a further extension at 72 ℃ for 10 min. The PCR procedures were carried out according to the standard procedures published earlier[17].

Construction of expression plasmid

The PCR products were digested with *SphI* and *XbaI*, and cloned into the same enzyme digested vector pUC19. The recombinant vectors were transformed into *E coli* DH5 α . The recombinant transformants were acquired via the blue-white colony screening in the agar medium containing X-gal and characterized using restriction endonucleases *SphI* and *XbaI*. The gene sequence analysis of the recombinant pUC-hdHGF was carried out by Sanger's dideoxynucleotide DNA sequencing. The verified hdHGF cDNA fragment with *SalI* and *NotI* was cloned into the site of expression vector pPIC9 digested with *XhoI* and *NotI* enzymes. The recombinant plasmids were transformed into *E coli* strains of JM109. Screening and selection of expression plasmid clones containing hdHGF cDNA fragments through the identification with restriction endonucleases *Bam*HI and *NotI*, resulted in the plasmid pPIC9-hdHGF containing hdHGF gene under the control of AOX1 promoter and in-frame with α -factor signal sequence (Figure 1).

Yeast transformation

Plasmids used for transformation were linearized with *SalI*. The *SalI*-linearized pPIC9-hdHGF or parent pPIC9 was transformed into *his4* competent *P pastoris* GS115 cells by a chemical method. After the growth on minimal dextrose medium (MD) plates at 30 ℃ for 3 d, several colonies containing the linearized pPIC9-hdHGF fragment were selected for PCR confirmation by colony PCR, which was designed to amplify the 200-bp special sequence of pPIC9-hdHGF using a pair of primers, namely P5 (sense, 5'GTGGGACAAGAACATGGAAGA CTTA3') and P6 (antisense, 5'CTATGTTTGTTCGTGTTGGAATCC3').

Expression of hdHGF by recombinant Pichia in shake flask

Ten colonies were used to inoculate 10 mL buffered minimal glycerol-complex medium (BMGY) in a 50 mL shake flask, respectively. After being shook at 250 r/min for 2 d at 30 ℃, the cells were pelleted and resuspended in a 2 mL buffered minimal methanol-complex medium (BMMY). Following the additional 2 d of induction at 30 ℃, the samples of expressed hdHGF in culture supernatants were determined and hdHGF in culture supernatants was also analyzed by SDS-PAGE.

Fed-batch cultivation of P pastoris in a 5-L bioreactor

The clones exhibiting the highest level expression of hdHGF were selected for fed-batch fermentations which were carried out in a 5-L working volume bioreactor using a BIOFLO 3000 (New Brunswick Scientific) interfaced with AFS-Biocommand Bioprocessing software version 2.6 (New Brunswick Scientific) for data acquisition and supervisory control.

Seed culture for the bioreactor was started from the fresh glycerol stock and inoculated directly into 500-mL shake flasks (50-mL working volume) containing a minimum glycerol medium (1.34% YNB, 1% glycerol, and 1.61 μmol/L biotin). After 24 h of growth, seed culture was inoculated with 1% inoculum. After 16-20 h of growth, seed culture was used to inoculate the bioreactor. Ten percentage of the inoculum was used for the inoculation of a 5-L bioreactor containing 2.-L medium of high-cell density fermentation, comprising of 10× basal salts (42 mL/L 85% H_3PO_4, 1.8 g/L $CaSO_4{\cdot}2H_2O$, 28.6 g/L K_2SO_4, 50 g/L glycerol, 23.4 g/L $MgSO_4{\cdot}7H_2O$, 6.5 g/L KOH, and 4.35 mL/L 10·PTM_1 salts, 6.0 g/L $CuSO_4 \cdot 5H_2O$, 0.08 g/L KI, 3.0 g/L $MnSO_4{\cdot}H_2O$, 200 g/L $ZnCl_2$, 0.02 g/L HBO_4, 65 g/L $FeSO_4{\cdot}7H_2O$, 0.2 g/L $Na_2MoO_4{\cdot}2H_2O$, 0.5 g/L $CoCl_2$, 0.2 g/L biotin, and 5 mL/L H_2SO_4, buffered to pH 5.5 using 2 mol/L NH_4OH). Dissolved oxygen was maintained at over 20% air saturation at 30 ℃ and aeration was maintained at 2 vvm. pH was maintained at 5.5 and fermentation was carried out in two phases. Growth phase consisted of a glycerol batch phase and cells were grown batch-wise until glycerol in the medium was utilized. To achieve a high cell density, the glycerol (50% glycerol, 4.3 mL/L PTM_1, feeding rate: 18 mL/h·L) fed-batch phase was initiated and lasted for 6-10 h. Production phase consisted of a methanol fed-batch phase when cells were induced by methanol (100% methanol plus 12 mL/L PTM_1 salts). The methanol feed rate was gradually increased over a period of 6 h-6 mL/h and the fermentation continued for an additional 46-92 h. Expressed hdHGF in culture supernatants was analyzed by SDS-PAGE and the concentration of secreted total supernant proteins was also determined at different intervals of induction phase using the standard curve analysis of human serum albumin (HSA).

Western blotting of rhdHGF

The purified recombinant hdHGF was run in 15% Tris-tricine electrophoresis[20] and then transferred onto a polyvinylidene difluoride (PVDF) membrane and probed with rabbit anti-hdHGF antibody as described previously[19].

RESULTS

Molecular cloning of hdHGF fragments

Based on the hdHGF sequence reported by Nakamura *et al*[16], we designed three pairs of PCR primers for amplified hdHGF fragments. A forward primer P1 and a reverse primer P2 and another forward primer P3 and

its reverse primer P4 were designed to synthesize the two fragments. The two fragments of hdHGF PCR products about 1 570 (F1) and 970 bp (F2), respectively, were also clearly seen in 1% agarose gel electrophoresis stained with 5 mg/mL ethidium bromide amplified with P1-P2 and P3-P4 primer pairs (Figure 2A). Overlapping-fragment PCR amplification using F1 and F2 fragments as templates was performed by routine PCR procedure using a pair of primers M1 and M2 and the PCR product of full-length gene of hdHGF was revealed (Figure 2B).

Construction of the expression plasmid

A cDNA encoding the mature form of hdHGF was used in these experiments. This cDNA consisted of 2.1 kb (Figure 2B) with an open-reading frame encoding a 669 amino acid peptide. The DNA fragment encoding the mature hdHGF was digested with *XhoI* and *NotI* from pUC19 vector and cloned into the same enzyme digested vector pPIC9 downstream of the alcohol oxidase I (AOXI) promoter (Figures 1 and 3). The resultant

construct harbored a single open reading frame encoding a 85 amino acid translation product consisting of the α-factor secretion leader peptide (Figures 1 and 3). Prior to the secretion of the peptide into the culture medium, the signal peptide should be cleaved off by the *KEX2* gene products at the site (Glu-Lys-Arg-X) (Figure 1). The integrity of the recombinant plasmid was confirmed by direct DNA sequencing. Enzyme identification of the recombinant plasmids of pPIC9-hdHGF digested by *BamHI* and *NotI* is shown in Figure 4. This constructed vector was linearized with *SalI* and transformed into the competent cells of *P pastoris* GS115. The transformants were selected on MD plates and confirmed by colony PCR. Forty-one colonies presenting strong amplification

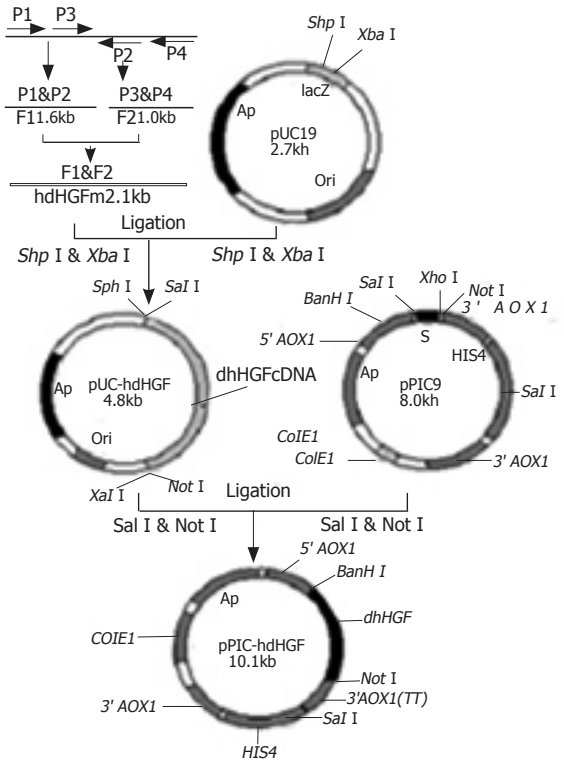

Figure 3 Cloning of hdHGF cDNA and construction of expression vectors pUC-hdHGF and pPIC9-hdHGF.

products were used for small-scale expression trials and the amount of the recombinant peptide was determined by SDS-PAGE.

Expression of recombinant hdHGF in shake flask

We investigated the expression of recombinant hdHGF by both Mut^s and Mut^+ (GS115) strains in shake flasks. Since SDS-PAGE analysis revealed that the hdHGF level expressed by Mut^s strain was much higher than that of Mut^+ (data not shown), Mut^s was chosen for the expression of th e growth factor. In addition, Mut^s phenotype was selected over the Mut^+ phenotype because

of the latter's higher oxygen requirement that could result in oxygen-deficient conditions within the bioreactor. Fifty transformants (Mut^s) were used for the expression studies in shake flask experiments and secretion of the recombinant hdHGF into the culture medium was determined by SDS-PAGE analysis. The expression experiments were performed to screen out four high-level expression strains of hdHGF, which were named as HG209, HG211, HG305, and HG309 (Figure 5).

Expression of recombinant hdHGF in fermenter cultures

The selected clones with the highest expression level were chosen for fed-batch cultivation. A time-course study of

secretion of hdHGF revealed a gradual accumulation of recombinant cytokines. The effect of induction pH on the production of recombinant cytokines was investigated. *P pastoris* is known to grow over a wide pH range from 3 to 7, with a minimal effect of pH on the growth rate. However, pH could significantly affect the productivity of secreted recombinant proteins in the fermentation broth. To find out the optimal pH for the expression of recombinant hdHGF, we conducted experiments with pH between 3.5 and 6.5 during the fed-batch production phase. The highest yield of recombinant hdHGF was observed at pH 5.5 (Figure 6).

Protein expression was initiated by changing carbon source from glycerol to methanol. At first, we attempted to express hdHGF in baffled shake flasks and obtained about 50 mg/L of hdHGF secreted into the medium after 72-h induction. For more systematic production of hdHGF, we expressed the protein using fermenter cultures. Figure 6 shows the secretion level of hdHGF using 5 L fermenter. Upon depletion of glycerol, the dry cell weight reached 45.6 g/L. A glycerol fed-batch phase was performed for an additional 6-12 h and the cell biomass reached at

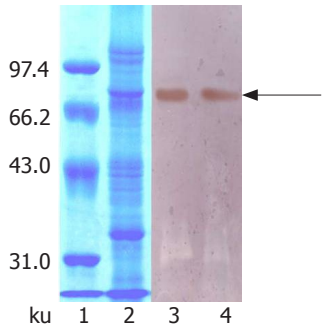

Figure 6 Fifteen percentage SDS-PAGE and Western blotting analysis of the 5-L fed-batch high cell density fermentation of GH209. Lane 1: LMW marker; lane 2: 10% SDS-PAGE result; lanes 3 and 4: Western blotting result. The arrowhead shows bands of the interesting protein.

approximately 135 g (DCW)/L. Induction of hdHGF was initiated by the addition of 100% methanol containing 12 mL of PTM1 trace salts/L. Sample analysis at different intervals was also performed to show the increasing amounts of recombinant hdHGF presented in the culture medium with increasing induction time until 96 h. Dissolved oxygen (DO) was monitored by DO sensor and the oxygen transfer rate 1 min after turning off the carbon source feed. Dissolved oxygen was maintained between 20% and 30% air saturation in the two-phase fermentation. The secreted total supernant protein concentration in the induction phase was traced and observed to attain the high-level expression of more than 8.0 g/L after 84-96 h of induction cultivation, which was determined using the standard curve analysis of human serum albumin (HSA). The scanning result showed that the secreted rhdHGF protein band (in lane 3 of Figure 6) achieved about 12.3% of the total supernatant proteins. By comparison with the standard protein markers, the estimated product of rhdHGF was 500-900 mg/L. The maximum secretion yield was approximately 980 mg/L (Figure 6). Upon induction by methanol, four clones secreted a specific 80-ku protein with the same size as the standard HGF. The productivity varied among the four high-level expression strains of hdHGF.

These clones indicated that the highest product of rhdHGF was named HG209 (GS115/pPIC9-hdHGF) and selected for further analysis. Western blotting analysis showed that the 80-ku protein band from HG209 (GS115/pPIC9-hdHGF) reacted specifically with the rabbit anti-hHGF antiserum (Figure 6). The N-terminal sequence of the recombinant hdHGF was determined to be PALKI, which was identical to the N-terminal sequence of native hdHGF (Figure 1).

DISCUSSION

hdHGF is a large complex protein comprising of 669 amino acids. It is the most potent multifunctional cytokine on the regeneration of hepatocytes and kidney epithelial cells compared to wild-type human HGF[20]. It can promote cell division, migration, and differentiation.

Its receptor is the product of oncogene c-met. Besides being a nutritional factor of liver and kidney, hdHGF also promotes angiogenesis for peripheral artery disease and myocardial ischemia[20] and can affect synthesis of extracellular matrix and matrix metalloproteinases and tissue inhibitor of metalloproteinases in autosomal dominant polycystic kidney disease cyst-lining epithelial cells[21].

Since the concentration of native HGF in plasma is very low, purification of HGF from plasma is very difficult. It was reported that HGF is expressed in foreign gene expression systems such as mammalian cells, CHO cells[22,23], insect cells[24], and gene therapy[25]. Dang *et al*[26] and Li *et al*[27]. reported that the HGF gene is expressed in *E coli* and *P pastoris*. However, the expression of recombinant-deleted variants of human hepatocyte growth factor (hdHGF) has not been reported in yeast expression system. Therefore, in this investigation, we used the methylotrophic yeast *P pastoris* as the host for the high-level expression and secretion of recombinant hdHGF. Recombinant hdHGF was successfully secreted by *P pastoris* and the productivity of secreted total supernatant protein concentration attained high-level expression of more than 8.0 g/L and the ratio of rhdHGF band area was about 12.3% of the total band area scanned by SDS-PAGE analysis, which estimated the product of rhdHGF to be 500-900 mg/L. It had an approximately fivefold increase in productivity compared to that of HGF expressed in *P pastoris*[27]. Western blot analysis showed that the 80-ku protein band of GS115 (pPIC9-hdHGF) reacted specifically with the rabbit anti-hHGF antibody. N-terminal sequencing revealed that recombinant rhdHGF had the correct N-terminal amino acid sequence. These results suggest that the optimization of bias codons of *P pastoris* encoding N-and C-terminal amino acids of hdHGF via PCR-mediated codon replacement can acquire high-level expression of foreign genes in *P pastoris*. Nakamura *et al*[16]. reported that native hdHGF is composed of an alpha-subunit of 440 amino acids (MW 69 ku) and a beta-subunit of 234 amino acids (MW 34 ku). However, we found that the recombinant hdHGF produced by *P pastoris* was translated as a single-chain polypeptide comprising of 669aa, which was not cut by the proteolytic cleavage of the human pro-hormone between amino acids R494 and V495 in host cells of *P pastoris*.

In conclusion, though further characterization, bioassay, and optimization of the expression and cultivation of recombinant hdHGF by *P pastoris* are required, this expression system of hdHGF is expected to be a powerful tool in the industrial production of this foreign protein.

Abstract

AIM: To transfect mutant C-kit cDNA at codon 579 into human embryonic kidney cell line to observe its role in the pathogenesis of gastrointestinal stromal tumor (GIST).

METHODS: Eukaryotic expression vectors of pcDNA3-Kit-NW and pcDNA3-Kit-W were constructed. Then pcDNA3-Kit-NW and pcDNA3-Kit-W plasmids were transfected into human embryonic kidney cell line by Lipofectamine. The resistant clone was screened by G418 filtration and identified by sequencing, Western blotting, and immunocytochemical staining. Human embryonic kidney cells were divided into three groups including pcDNA3-Kit-NW, pcDNA3-Kit-W, and vector control groups. Absorbency value with a wavelength of 574 nm was detected by MTT analysis. Mice were injected with three groups of cells. Volume, mass, and histological examinations of the tumors in different groups were measured and compared.

RESULTS: The C-kit gene and mutant C-kit gene were successfully cloned into the eukaryotic expression vector pcDNA3. pcDNA3-Kit-NW and pcDNA3-Kit-W were successfully transfected into human embryonic kidney cell line and showed stable expression in this cell line. Cell proliferating activity had significant differences between pcDNA3-Kit-NW and pcDNA3, pcDNA3-Kit-NW and pcDNA3-Kit-W ($P<0.05$), respectively. Tumors were only observed in nude mice implanted with cells transfected with pcDNA3-Kit-NW.

CONCLUSION: Mutation of C-kit gene increases the proliferation activity of human cells and plays an important role in the malignant transformation of GIST.

Key words: Gastrointestinal stromal tumors; Protooncogene C-kit; Gene mutation; Malignant transformation

INTRODUCTION

Gastrointestinal stromal tumor (GIST) is a designation for a major subset of mesenchymal tumors of the gastrointestinal tract. Their line of differentiation or cell of origin and clinical behavior are a persistent source of controversy[1-5]. Recently, specific mutations between transmembrane and tyrosine kinase domains in exon 11 at codon 550-560 of C-kit have been found in GISTs, which can lead to ligand-independent activation of the tyrosine kinase of C-kit and have a tumor promoting effect *in vitro*[4,6-10]. We studied the C-kit mutation type of exon 11 by PCR-SSCP and DNA sequencing in a series of Chinese GIST[11]. The results showed that C-kit mutations existed among GISTs. Compared to the reports in the published data, an insertion of 12 bp at codon 579 lies outside the hot spot area[12]. In order to fully characterize the activation of the insert mutation at codon 579 of C-kit gene, we constructed an expression vector containing mutant C-kit and evaluated its effect on implanted tumor in nude mice.

MATERIALS AND METHODS

Main reagents

Fetal bovine serum was produced by Hyclone and 96-well plates by Costa. Dimethyl sulfoxide (DMSO), ethylened iaminetetraacetic acid (EDTA), 3-(4,5-dimethy1-thiazol-2-yl), 2,5-diphenyl tetrazolium bromide (MTT), *N*-2-hydroxyethyl piperazine-*N*'-2-ethanesulfonic acid (HEPES) and trypsin were the products of Sigma. Rabbit polyclonal antibody against C-kit was obtained from DAKO. Envision two-step and DAB test kits were obtained from Beijing Zhongshan Biotechnology Inc.

Human embryonic kidney cell line

Human embryonic kidney cell (HEKC) line was established in our laboratory and prepared after long-term generation.

Construction of plasmids

Eukaryotic expression vector of pcDNA3 (Invitrogen, USA), plasmid pMD18-T-KIT-NW containing full-length of C-kit gene (C-kit cDNA was conducted in our laboratory) and plasmid pMD18-T-Kit-NW containing mutant-type C-kit cDNA with insertion of 12 bp at codon 579 (mutant C-kit cDNA was conducted in our laboratory) were digested by restriction enzymes *Xba*I *and Hind*III. The digested vector and plasmid cDNA fragment were ligated. Recombinant clones were identified by *Xba*I *and Hind*III double digestion. Positive clones named pcDNA3-Kit-W and pcDNA3-Kit-NW were further confirmed by sequencing.

Transfection of recombinant plasmid into HEKCs and grouping

Cultured HEKCs were divided into three groups, which were transfected with pcDNA3 vector, recombinant pcDNA3-Kit-W, and recombinant pcDNA3-Kit-NW, respectively. Transfection was performed according to the instructions of Lipofectamine TM2000 reagent kit (Gibco). Cells were cultured in RPMI 1640 medium containing 200 mL/L fetal calf serum and 350 mg/L G418. Resistant clones could be detected 2 wk later.

Cell culture

HEKCs were inoculated in RPMI 1640 with 100 g/L fetal bovine serum and incubated at 37 ℃ in an incubator containing 50 mL/L CO_2 to measure the logarithmic growth phase. After the treatment with digestive fluid, HEKCs were suspended by adding D-Hank's fluid, deposited by centrifugation at 190 r/min for 5 min and then counted. Using RPMI 1640 containing 100 g/L fetal bovine serum, HEKCs were adjusted to a density of 5×10^4/mL and added to a 24-well plate containing flying sheets, 0.2 mL/well. Flying sheets were taken out respectively at 24, 48, and 72 h, fixed with cold acetone for 10 min, dried and preserved at -60 ℃.

Cell fixation and immunocytochemical staining

Preserved cell flying sheets were immersed in PBS for 5 min, blocked with 10 mL/L H_2O_2 for 10 min, washed thrice with PBS (5 min each time) and then incubated with 10% goat serum for 30 min. C-kit antibody was diluted at a concentration of 1:50 and added as the first antibodies, staying 1 h at 37 ℃. After being washed thrice with PBS (5 min each time), horseradish peroxidase-conjugated goat anti-rabbit secondary antibody was added, staying 30 min at 37 ℃, washed thrice with PBS (5 min each time) and stained with DAB. Counterstaining with hematoxylin was performed before the final analysis. The first antibody was replaced with fetal bovine serum as a negative control.

Western blot analysis

Cell lysates were prepared in extraction buffer containing 50 mmol/L Tris-HCl (pH 7.4), 150 mmol/L NaCl, 10 g/L Triton-100, 1 g/L SDS, 1 mmol/L EDTA, 1 mmol/L AEBSF, 20 g/mL aprotinin, and 20 g/mL leupeptin. After centrifugation at 12 000 *g* for 10 min at 4 ℃, the supernatant was collected. Equal amounts of total protein (10 g) from each sample were loaded and separated by 120 g/L SDS-polyacrylamide gel electrophoresis and then transferred to Hybond-P polyvinylidene difluoride (PVDF) membrane (Amersham Pharmacia Biotech, Piscataway, NJ, USA). After being blocked with 50 g/L nonfat dry milk in PBS (pH 7.4) with 1 g/L Tween-20, membranes were probed with a rabbit anti-C-kit polyclonal antibody (1:500 dilution) followed by subsequent incubation with horseradish peroxidase-conjugated goat anti-rabbit secondary antibody (1:1 000 dilution).

MTT assay

HEKCs with a density of approximately 2.5×10^5/mL were seeded into each well of the 96-well plate (0.2 mL/well). Each group contained 12 wells. After 4 d of incubation at 37 ℃ in an incubator containing 50 mL/L CO_2, 50 mL of MTT (50 mg MTT) was added and the culture was continued for 4 h at 37 ℃. After the fluid at the top was removed, 150 mL DMSO was added to each well. After being concussed and dissolved, absorbency value with a wavelength of 574 nm was detected by enzyme-labeled instrument (BioRad 2250, Japan).

Animal experiment

Nine Balb/c male mice aged 4-6 wk (body mass 18-20 g) were purchased from Experimental Animal Center of Second Military Medical University, Shanghai and randomly divided into three groups, three mice in each group. The mice in vector-treated control group were injected with HEKCs transfected with pcDNA3 vector, the mice in Kit-W group received an injection of HEKCs transfected with recombinant pcDNA3-Kit-W, the mice in Kit-NW group received an injection of HEKCs transfected with recombinant pcDNA3-Kit-NW. After the cancer cells were cultured into the stage of logarithmic growth phase, they were digested with trypsin to make cancer cell suspension of 2.5×10^7/L. Then, 0.2 mL of each suspension was subcutaneously injected into the right back of the nude mice.

Tumor volume measurement

The survival of nude mice was observed every day. After tumor cell injection, the nude mice were killed after 6 wk. The surrounding fatty tissues were dissected and the tumors were weighed. Tumors were fixed in 10% buffered formalin and processed in paraffin wax. Five-micrometer thick sections were stained with hematoxylin and eosin.

Statistical analysis

Data were treated with SPSS for LSD and one-way ANOVA test. $P<0.05$ was considered statistically significant.

RESULTS

Identification of recombinant plasmids pcDNA3-Kit-W and pcDNA3-Kit-NW

After digestion by *Xba*I *and Hind*III, bands at 3 kD could be detected for positive clones (Figure 1), suggesting

that Kit-W and Kit-NW fragments were inserted into the pcDNA3 vector, named as recombinant plasmids pcDNA3-Kit-W and pcDNA3-Kit-NW, respectively.

pcDNA3-Kit-W and pcDNA3-Kit-NW DNA were prepared for sequencing. The sequence obtained was the same as the reported sequence of C-kit cDNA and mutant

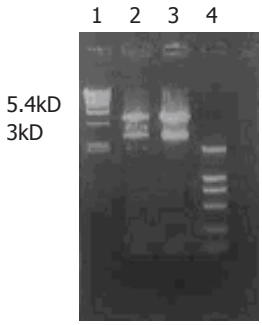

Figure 1 Restriction enzyme digestion of recombinant plasmids pcDNA3-Kit-W and pcDNA3-Kit-NW at *Xba*I and *Hind*III. Lane 1: DNA/*EcoR*I+*Hind*III marker; lane 2: pcDNA3-Kit-W clone; lane 3: pcDNA3-Kit-NW clone; lane 4: DL-2000 marker.

C-kit cDNA, indicating that the C-kit gene and mutant C-kit gene were successfully cloned into the eukaryotic expression vector pcDNA3.

Screening of C-kit gene-transfected cells

No significant differences were observed between the morphological characteristics of transfected cells and normal HEKCs.

Expression of C-kit protein

Supernatants of cultured cells in three groups were collected and analyzed by immunocytochemistry. The cells transfected with pcDNA3-Kit-W and pcDNA3-Kit-NW were positively stained for C-kit protein (Figure 2). However, the cells in vector control group were negatively stained for C-kit. In accordance with the findings on immunocytochemical staining, a band in a molecular mass of 145 ku was detected with rabbit anti-C-kit antibody from the cells transfected with pcDNA3-Kit-W and pcDNA3-Kit-NW, but no bands were detected in the vector control group. There was no significant difference in the protein level of C-kit between pcDNA3-Kit-W and pcDNA3-Kit-NW groups (Figure 3).

MTT assay

Absorbance values of the three groups were 0.1340±2.353×10^{-3}, 0.1830±3.888×10^{-3}, and 0.1274±3.537×10^{-3}, respectively. LSD analysis and one-way ANOVA analysis with SPSS10.0 software were used to compare the difference of absorbance in each group at 574 nm. Statistical analysis indicated that significant differences were detected between pcDNA3-Kit-NW and pcDNA3, pcDNA3-Kit-NW and pcDNA3-Kit-W ($P<0.05$), respectively. The results implied that the cell proliferating activity in pcDNA3-Kit-NW group was higher than that in control group.

Figure 3 Western blotting of pcDNA3-Kit-W, pcDNA3-Kit-NW, and pcDNA3 on HEKC line. Lanes 1-3: pcDNA3-Kit-NW; lanes 4-6: pcDNA3-Kit-W; lanes 7 and 8: pcDNA3.

Tumor growth in nude mice

Tumors were observed in the nude mice 3 wk after being implanted with cells transfected with pcDNA3-Kit-NW (Figure 4). Mice had no visible tumor after cell injection in pcDNA3-Kit-W transfection group and vector control group after 6 wk. Tumor volumes in pcDNA3-Kit-NW transfection group were approximately similar and no significant difference was observed between the three tumors ($t = 13.07$ $P>0.05$). Many areas of hemorrhage and necrosis were present, residual tumor cells were frequently found to have giant, bizarre-shaped pyknotic nucleoli, or prominent pathologic mitosis in the tumors (Figure 5).

DISCUSSION

GIST is the most common mesenchymal tumor in human gastrointestinal tract and is enigmatic in terms of its differentiation or cell origin and clinical behavior. In recent years, C-kit protein expression and activated gene mutation have been found in GIST[13-17]. C-kit encodes a growth factor receptor with ligand-dependent tyrosine kinase activity[18,19]. Kit ligand-stem cell factor (SCF) is the only known ligand of the Kit receptor[20]. SCF binding to the receptor mediates receptor dimerization, activation of kinase activity, and autophosphorylation. Subsequently, Kit activates several signaling cascades, leading to cell proliferation, cell survival, and other cellular responses. Kit and SCF are encoded at the white spotting (W) and steel (Sl) loci in mice, respectively[20-22]. Mutation at the murine W and Sl loci generates deficiencies in several major cell systems during embryogenesis and in postnatal animals. In hematopoiesis Kit receptor signaling is critical in the stem cell hierarchy, erythropoiesis, mast cell development and

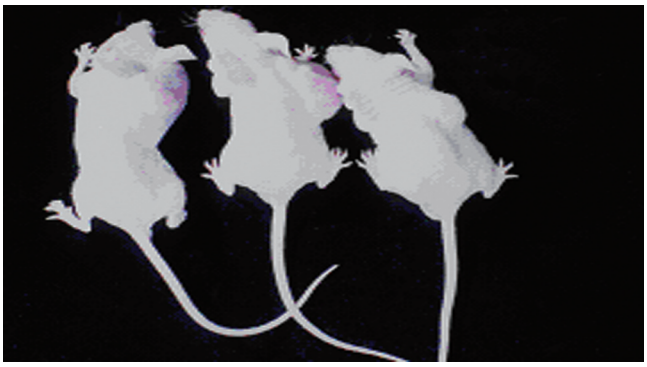

Figure 4 Tumor growth in nude mice 6 wk after being implanted with cells transfected with pcDNA3-Kit-NW.

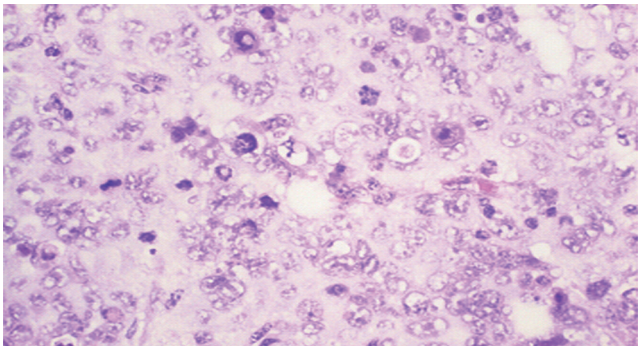

Figure 5 Giant, bizarre-shaped pyknotic nucleoli, or prominent pathologic mitosis in tumor (HE ×200).

function, megakaryopoiesis, and lymphopoiesis[23-26].

GISTs most often harbor mutations at exon 11 codon 550-560 of C-kit cDNA, while the mutations in human mastocytosis predominantly involve the activation loop of the Kit kinase[27,28]. The C-kit mutations in this domain can lead to spontaneous ligand-independent activation of the tyrosine kinase of C-kit and was called "gain-of-function mutation". Development of GIST is highly associated with Kit-activating mutations, suggesting that the activated Kit receptor plays a critical role in tumor development[29]. In addition, gene mutation has shown a good correlation with biologic behavior in such tumors. For instance, it can provide valuable adjunctive prognostic information. In agreement with this notion, familial cases of GIST have been reported with Kit-activating mutations in the germ line[30]. We have found a mutation at codon 579 in malignant GIST, which lies outside the hot spot area[12]. In order to fully characterize the activation of the insert mutation at codon 579 of C-kit gene, we studied the expression of mutant C-kit gene in human embryonic kidney cell line and its effect on implanted carcinoma in the nude mice.

In the present study, we constructed a target fragment containing mutant-type C-kit cDNA with insertion of 12 bp at codon 579 and full-length of C-kit gene. The target gene fragment of 5.4 kD in length was cloned into *Xba*I *and Hind*III restriction sites of eukaryotic expression vector pcDNA3. Restriction digestion and sequence analysis for positive clones indicated that the two recombinant eukaryotic expression vectors containing the gene were successfully constructed. These recombinant vectors were then transfected into HEKCs and screened by G418. The result of direct sequencing showed that the recombinant plasmids were stably integrated into the cells. Immunocytochemical staining revealed that HEKCs transfected with pcDNA3-Kit-W and pcDNA3-Kit-NW were stained positively for C-kit, indicating that C-kit protein is expressed in transfected HEKCs. Furthermore, a protein (145 kD) was detected by Western blotting and there was no significant difference in the expression level of C-kit protein between transfected pcDNA3-Kit-W and pcDNA3-Kit-NW HEKCs, indicating that the insert mutation at codon 579 of C-kit gene has no effect on protein expression of HEKCs.

In vitro characterization of the Kit V558 mutation in BaF/3 cells indicates that the Kit V558 mutation promotes cell proliferation and abolishes the growth factor dependence of BaF/3 cells[30]. Sommer *et al*[31]. showed that young bone marrow-derived mast cell cultures are refractory to growth factor deprivation-induced apoptosis. However, these cultures do not promote cell cycle progression. There is evidence that short kit protein product is more active than long Kit protein product. Therefore, it may be possible that the long-Kit variant is expressed predominantly in the young mutant bone marrow-derived mast cells, while the older cultures express the short-Kit variant, which may explain the progression from partial to complete growth factor independently of these cultures. Our results showed that the insert mutation at codon 579 of C-kit gene promoted HEKC proliferation. In addition, no significant differences between the morphological characteristics of transfected cells and normal HEKCs were observed, suggesting that mutant C-kit has no effect on the morphology of HEKCs.

In this experiment, HEKCs transfected with recombinant pcDNA3-Kit-NW and pcDNA3 vector were subcutaneously implanted into the nude mice. The implanted tumors appeared later in the pcDNA3-Kit-NW transfection group. Mice had no visible tumor after cell injection in pcDNA3-Kit-W transfection group and vector control group after 6 wk. These results suggest that the insert mutation at codon 579 of C-kit gene can significantly induce the growth of tumors and constitutive Kit signaling is critical and sufficient for the induction of neoplasia in the mice.

Abstract

AIM: To examine the relationships between γ-glutamyl-transferase (GGT), alanine-aminotransferase (ALT), aspartate-aminotransferase (AST) and various metabolic parameters, C-reactive protein (CRP) and an oxidative stress marker (nitrotyrosine, NT) in subjects without any metabolic abnormalities from a population-based sample.

METHODS: Two hundred and five subjects with normal body mass index (BMI), glucose tolerance, and without any metabolic abnormality were studied out of 1 339 subjects, without known liver diseases, alcohol abuse or use of hepatotoxic drugs, who are representative of the 45-64 aged population of Asti (north-western Italy).

RESULTS: In all patients metabolic parameters and hs-CRP levels linearly increase from the lowest to the highest ALT and GGT tertiles, while in subjects without metabolic abnormalities, there is a significant association between fasting glucose, uric acid, waist circumference, hs-CRP, triglyceride values, and GGT levels. In these subjects, male sex, higher hs-CRP and glucose levels are associated with GGT levels in a multiple regression model, after adjustments for multiple confounders. In the same model, median NT levels are significantly associated with the increasing GGT tertile (β = 1.06; 95%CI 0.67-1.45), but not with the AST and ALT tertiles. In a multiple regression model, after adjusting for age, sex, BMI, waist, smoking, and alcohol consumption, both NT (β = 0.05; 95%CI 0.02-0.08) and hs-CRP levels (β = 0.09; 95%CI 0.03-0.15) are significantly associated with fasting glycemia.

CONCLUSION: GGT, an easy, universally standardized and available measurement, could represent an early marker of sub-clinical inflammation and oxidative stress in otherwise healthy individuals. Prospective studies are needed to establish if GGT could predict future diabetes in these subjects.

Key words: Alanine aminotransferase; Aspartate aminotransferase; Body mass index; C-reactive protein; γ-Glutamyl transferase; Metabolic syndrome; Nitrotyrosine

INTRODUCTION

Increased levels of the liver enzymes, γ-glutamyl transferase (GGT), alanine aminotransferase (ALT) and aspartate aminotransferase (AST) have been found to be associated with diabetes, cardiovascular risk factors and components of the insulin resistance syndrome, even within normal reference intervals[1-12]. In many prospective studies, strong relationships between GGT or ALT concentrations and incident diabetes have also been observed in non-drinkers, in individuals with normal levels of liver enzymes, independently of classical cardiovascular risk factors[2-10]. However, a strong interaction between body mass index (BMI) and GGT has been described, suggesting that this enzyme acts as an intervening factor in the association between obesity and diabetes[1,4,5,7,9]. Some authors have speculated that visceral fat could play a role in the association of GGT with metabolic abnormalities, or that this enzyme could be considered as a reliable marker of visceral fat[1,2,13]. Furthermore, GGT and ALT might be interpreted as markers of hepatic steatosis,

a condition well known to be associated with insulin resistance, type 2 diabetes and the metabolic syndrome[14,15]. Thus, the associations recently found between the levels of liver enzymes and insulin resistance might be mediated by a fatty liver, which is accompanied by higher GGT and aminotransferase concentrations.

Increasing data are available about the associations between GGT levels and markers of oxidative stress (directly with F2-isoprostanes, an oxidative damage product of arachidonic acid; inversely with serum and dietary antioxidant vitamins), suggesting that the strong associations between cardiovascular risk factors might be explained by some oxidative mechanism[4,16-18]. Indeed, oxidative processes are key components of chronic inflammation, acting on multiple pathways and amplifying inflammatory reactions[19]. Recent reports have found associations between elevated liver enzymes and several inflammatory parameters[3,4,9,10,20,21].

However, previous studies have always included a group of overweight, or obese subjects, or did not take into account the deposition of body fat; thus adiposity might be a confounding factor. Two recent papers suggested that a non-alcoholic fatty liver could be considered as an early predictor of metabolic disorders also in non-obese non-diabetic Asiatic cohorts; however, in these studies, the control group included individuals with other components of the metabolic syndrome and Asians have a higher proportion of visceral fat and a lower lean body mass than white subjects with the same BMI[22,23]. It seems thus interesting to evaluate the associations between the liver enzyme levels and metabolic and inflammatory parameters in a cohort of Caucasian subjects without any metabolic abnormalities, which could potentially influence this association.

Therefore, the aims of the present study are to examine the relationships between liver enzyme concentrations and various metabolic parameters, a marker of inflammation (C-reactive protein, CRP) and a marker of oxidative stress (nitrotyrosine, NT) in subjects without any metabolic abnormalities from a population-based cohort of middle-aged individuals, recognizing that the cross-sectional design of the study does not definitively establish causal or temporal relationships, and should be considered hypothesis-generating only.

MATERIALS AND METHODS

All the patients aged between 45 and 64 years under the practice of six family physicians from the province of Asti (north-western Italy), whose patients are representative of the local health districts, were enrolled for a metabolic screening. Of these 1 877 subjects, 1 658 (88.3%) accepted to be interviewed on personal habits, and to be tested for several clinical and laboratory measurements, giving written consent, while 219 refused. The resident population of corresponding age, in the same area, and missing patients show the same percentage of males, level of education, known diabetes, and subjects living in a rural area than participating patients.

All procedures were in accordance with the Declaration of Helsinki.

Subjects with >30 g/d alcohol consumption, with known liver or gastrointestinal diseases, as recorded by the family physicians, with liver enzyme concentrations higher than three times the upper limit of the sex-related reference range, or on corticosteroids, methotrexate, amiodarone, tamoxifen or other hepatotoxic drugs were excluded. Estrogen users (both on contraceptive medications or estrogen replacement therapy) were included, all being on low-dose estrogen drugs.

One thousand and three hundred and thirty-nine subjects (80.8%) were evaluated.

In the morning, a fasting venous blood sample was drawn to measure glucose, total and HDL-cholesterol, uric acid, triglyceride, insulin, liver enzymes, and hs-CRP levels.

Weight and height were measured after an overnight fast. Overweight and obese subjects were those with BMI respectively, $\geqslant$25, <30, and $\geqslant$30 kg/m^2. Waist circumference was measured with a plastic tape meter at the level of the umbilicus. Systolic and diastolic blood pressures were measured twice with a standard mercury sphygmomanometer in a sitting position, after at least 10 min of rest. Values reported are the mean of the two determinations. A resting electrocardiogram (ECG) was performed in all the subjects, and interpreted according to the Minnesota Code criteria. If fasting serum glucose value was $\geqslant$6.1 mmol/L, a second fasting glucose determination was then performed. Diabetes and impaired fasting glucose (IFG) were diagnosed according to published recommendations[24].

The metabolic syndrome (MS) was defined as the presence of at least three of the following five criteria: fasting serum glucose $\geqslant$6.1 mmol/L; arterial blood pressure $\geqslant$130/85 mmHg; plasma triglycerides $\geqslant$1.69 mmol/L; HDL-cholesterol <1.29 mmol/L (females) and <1.04 mmol/L (males); waist >88 cm (females) and >102 cm (males), in line with the National Cholesterol Education Program (Adult Treatment Panel III) (NCEP-ATP III) criteria[25].

Insulin resistance was calculated from the homeostasis model assessment (HOMA-IR), according to published algorithm[26].

Vascular disease was assessed on the basis of the Rose questionnaire, ECG evidence of ischemic heart disease, and history of documented events, recorded by the family physician (angina, previous myocardial infarction, coronary artery by-pass graft or other invasive procedures to treat coronary artery disease, transient ischemic attacks, strokes, gangrene, amputation, vascular surgery, intermittent claudication, absence of foot pulses, and abnormal brachial and posterior tibial blood pressure using Doppler techniques).

Former or present smokers were defined as ever smokers. Alcohol intake was assessed by multiplying the mean daily consumption for each beverage by the ethanol content, to give grams of alcohol/d (one can/bottle/glass of beer = 13 g, one glass of wine = 12 g, one standard drink of spirit = 14 g).

Later, we identified 205 subjects with normal BMI (<25 kg/m^2) and without any component of the MS. To avoid considering as normoglycemic individuals who could be classified as hyperglycemic after the stimulatory test, these subjects were submitted to the 75 g oral glucose tolerance test (OGTT), performed and interpreted in accordance to the guidelines[24]. All of the subjects showed normal glucose tolerance at the OGTT. NT levels were measured in all these subjects.

Serum glucose was measured by the glucose oxidase method (HITACHI 911 Analyzer, Sentinel Ch., Milan, Italy), and serum insulin by immunoradiometric assay (Radim SpA, Pomezia, Italy; intra-assay CV: 1.6-2.2%, inter-assay CV: 6.1-6.5%). Plasma triglycerides and HDL-cholesterol were measured by enzymatic colorimetric assay (HITACHI 911 Analyzer), the latter after precipitation of LDL and VLDL fractions using heparin-$MnCl_2$ solution (Mn^{2+} concentration: 0.092 mol/L) and centrifugation at 4 °C.

AST was evaluated by a kinetic determination. Malate dehydrogenase catalyzes the reaction of oxalacetic acid with β-NADH2 by forming lactic acid and β-NAD (HITACHI 911 Analyzer). ALT was evaluated by a kinetic determination. Lactate dehydrogenase catalyzes the reaction of pyruvic acid with β-NADH2 by forming lactic acid and β-NAD (HITACHI 911 Analyzer). GGT was evaluated by an enzymatic colorimetric method (HITACHI 911 Analyzer).

Uric acid was evaluated by an enzymatic colorimetric method with uricase (HITACHI 911 Analyzer). Serum hs-CRP levels were determined via a high-sensitivity latex agglutination method on the HITACHI 911 Analyzer. The kit had a minimum detection of less than 0.05 mg/L and a measurable concentration range of up to 160 mg/L. The intra-assay and inter-assay CVs were respectively 0.8-1.3% and 1.0-1.5%. Plasma NT values were determined by an ELISA kit (HyCult Biotechnology b.v., sold in Italy by Pantec, Turin; inter-assay and intra-assay CV respectively: 7 ±4% and 5±2%). All samples were run in blind.

Statistical analysis

Since the distribution of GGT, hs-CRP, insulin, HOMA, triglyceride, and NT values were highly skewed, the levels of these variables were log-transformed, in order to obtain a normal distribution. In all the analyses, the log-transformed values of these variables were used. For an easy interpretation, median (and range) of not transformed values are reported.

Linear (unadjusted) and multiple regression analyses were performed to evaluate the associations between liver enzyme levels with metabolic, inflammatory, and oxidative parameters, after adjustments for multiple confounders.

RESULTS

BMI, waist, blood pressure, fasting glucose, and insulin, HOMA-IR, triglyceride, low HDL-cholesterol, uric acid, and hs-CRP levels, percentages of males and prevalence of the metabolic syndrome increase from the lowest to the highest tertiles of ALT and GGT, and their values are significantly associated with these enzyme levels (Table 1). This trend is less evident within AST tertiles.

In subjects with normal BMI and without any component of the MS, there is a significant association of percentage of males, waist circumference, glucose, uric acid, hs-CRP, and triglyceride values with increasing GGT levels (Table 2). Waist, uric acid levels and percentages of males are significantly associated with ALT levels, while there is no significant association with AST values.

Table 3 describes the associations between the levels of each liver enzyme and age, gender, BMI, waist circumference, alcohol consumption, smoking habits, hs-CRP, HOMA-IR, and triglyceride uric acid levels (and hypertension in all the cohort) in a multiple regression model, after introducing all these as independent variables into the model. In all patients: waist levels are significantly associated with AST levels; male sex, waist, and higher levels of HOMA-IR, triglycerides, uric acid with ALT levels; male sex, alcohol and higher levels of hs-CRP, triglycerides, uric acid with GGT values.

In the subgroup of subjects with normal BMI, without any component of the MS, male sex and higher hs-CRP levels are associated with GGT levels, while no significant association is evident for the other liver enzymes. Fasting glucose is significantly associated with GGT levels in the same model, after adjusting for all previous variables, but insulin instead of HOMA-IR levels (β = 0.23; 95%CI 0.07-0.39); fasting glucose is not significantly associated with AST or ALT values.

In the subgroup of normal BMI subjects, the median NT levels are significantly associated with the increasing GGT tertile (β = 1.07; 95%CI 0.70-1.44), but not with the AST and ALT tertiles in a simple regression (Figure 1). After adjustments for age, sex, BMI, waist, smoking, and alcohol consumption, this association remains significant (β = 1.06; 95%CI 0.67-1.45).

Median NT levels are significantly correlated with: fasting glucose (β = 1.00; 95%CI 0.45-1.55) and waist circumference (β = 0.04; 95%CI 0.002-0.08). In a multiple regression model, after adjustments for age, sex, BMI, waist, smoking, and alcohol consumption, both NT (β = 0.05; 95%CI 0.02-0.08) and hs-CRP levels (β = 0.09; 95%CI 0.03-0.15) are significantly associated with fasting glycemia.

Correlations are similar also in non-drinkers, and after adjusting for AST or ALT levels (data not shown). Data do not change after excluding the subjects with CRP>10 (respectively n = 48 in the entire cohort and n = 2 in the subgroup of normal BMI), those with cardiovascular diseases (respectively n = 50 and n = 3) or those subjects on estrogen therapy (respectively n = 73 and n = 12).

DISCUSSION

Prospective studies have described that high levels of ALT and GGT[2-10] are associated with subsequent development of diabetes, while the association between AST levels and metabolic abnormalities is weaker and often attenuated or

Median (range) is reported for not-normally distributed variables; their log-transformed values and log-GGT values are used in the analyses.

abolished after adjustment for adiposity[2-6,8-10].

Accordingly, we have found in all our patients a worse metabolic pattern in subjects within the highest ALT and GGT tertiles than those within the highest AST tertile. Increased ALT and GGT levels are associated with hepatic insulin resistance and a subsequent decline in hepatic insulin sensitivity[1-5] and GGT seems implicated in oxidative stress[4,16-18].

Excess deposition of fat in the liver, the non-alcoholic fatty liver disease, shows strong cross-sectional associations with obesity, insulin resistance and type 2 diabetes[14,15] and is associated with liver enzyme elevation.

Median (range) is reported for not-normally distributed variables; their log-transformed values and log-GGT values are used in the analyses.

Thus, the relationships previously found might reflect associations between ALT or GGT levels and obesity or insulin resistance. Accordingly, authors have found that the associations between GGT levels and diabetes or blood pressure have been attenuated on adjustment for known risk factors for diabetes or for plasma insulin levels and have speculated that visceral fat could play a role in the association of GGT with type 2 diabetes[2,4,27].

The subgroup of subjects free from abnormal glucose, lipid, pressure values and with normal BMI and waist circumference avoids these possible interference from confounding factors. Within this group, increased GGT levels are significantly associated with hs-CRP and fasting glucose values, after multiple adjustments.

Multiple regression analyses with adjustments for all the variables listed.

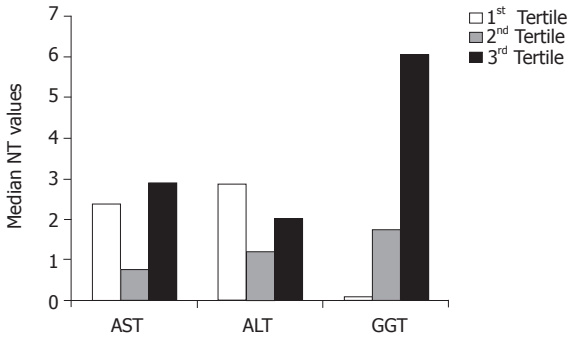

Figure 1 Median NT values for tertile of liver enzyme levels in subjects with normal BMI and without any component of the metabolic syndrome. At simple and multiple regression analyses NT values are associated with increasing GGT tertiles (P<0.001), but not with ALT or AST tertiles.

There is a progressive and significant increment of NT levels with increasing GGT tertile, not evident within the tertiles of the other liver enzymes that were tested (Figure 1). Furthermore, NT levels are significantly associated to fasting glucose values.

NT, generated from the oxidation of tyrosine, has been considered as a measure of oxidative injury from peroxynitrite (deriving from the reaction of nitric oxide with superoxide anion radicals), and reported to be elevated in diabetes, a condition associated with oxidative stress[28,29].

It could be speculated that the association between GGT levels and fasting glucose, not confounded by other metabolic abnormalities in the subgroup of "metabolically" healthy individuals, could be due to the adverse oxidative pattern of these subjects, suggested by the sharp increase of NT levels in the individuals within the highest GGT tertile.

In line with this, previous studies have reported a primary role for GGT in metabolizing extracellular reduced glutathione, a cellular antioxidant, allowing for precursor amino acids to be reutilized for the intracellular synthesis of glutathione[4,5,18]. Furthermore, dietary and serum antioxidants inversely predicted future GGT levels, while these latter are associated to F2-isoprostanes, a marker of oxidative damage[4,16-18]. It has been speculated that elevated GGT levels might be a defensive response to oxidative stress or, otherwise a marker of oxidative stress, being involved directly in the generation of reactive oxygen species, especially in the presence of iron or other transition metals, inducing lipid peroxidation in

human biological membranes[17,18,30,31]. Whether GGT is a causative factor for oxidative stress or a marker is currently unknown.

Aminotransferases were not associated with NT levels (Figure 1), in agreement with studies that showed lower associations between ALT levels and antioxidant vitamins and micronutrients, at least in individuals with normal BMI or fat distribution[18,32].

Thus, in subjects without other metabolic abnormalities, serum GGT might represent a marker of oxidative stress, and justify the associations found with higher fasting glucose values in these healthy individuals.

We cannot exclude the possibility that abnormal GGT values reflect fatty liver deposition, predating the development of subsequent diabetes; furthermore, hepatic ultrasonography or more invasive instrumental methods have not been performed in our subjects. Otherwise, they could be considered as "metabolically obese, normal weight" individuals, in consideration of their higher, though within the normal range, waist values[33]. Indeed our subjects with elevated GGT levels do not show higher insulin levels or insulin resistance (Table 2) and fatty liver has been associated with hyperinsulinemia and insulin resistance[14,15], and associations remain significant, after adjustments for waist circumference and BMI. Accordingly, abnormal liver enzymes have been found in a proportion of normal BMI individuals without fatty liver by ultrasound[34].

Furthermore, the correlations found are independent by adjustment for aminotransferase levels, which are better indicators of hepatocellular statuses and these latter are not associated with glycemia in the subgroup of normal BMI individuals.

Finally, increased GGT levels are conventionally considered as a marker of alcoholic abuse; however, only moderate drinkers have been included in the study, adjustments for alcohol intake have been performed, and correlations do not change after including only non-drinkers.

Another possible mechanism implicated is chronic inflammation: hs-CRP, an acute-phase reactant of hepatic origin and a sensitive marker for systemic inflammation, predicts the occurrence of diabetes, the metabolic syndrome and atherosclerotic diseases in healthy subjects[35]. Previous studies have found associations between GGT and CRP or other inflammatory parameters, suggesting that this enzyme represents the expression of sub-clinical inflammation, and has a role in cellular stress[3,4,9,10,20,21]. In our healthy cohort, hs-CRP levels are significantly associated either with highest GGT values or with fasting glucose. Oxidative processes might have an implication in chronic inflammation[19]; it has been hypothesized that elevation in GGT might occur before an elevation in CRP, and the related oxidative stress would give rise to a subsequent inflammatory response[21].

Again, aminotransferases are not associated with hs-CRP in normal BMI individuals, in line with previous reports, which did not find such an association[6,8,21].

Another explanation might be related to the liver response to pro-inflammatory cytokine tumor necrosis factor-α, giving fatty hepatic changes, or to the inflammatory processes accompanying non-alcoholic fatty liver and contributing to the systemic inflammation observed in these subjects, frequently affected by the MS[20,36]. However, the lack of a significant association between hs-CRP and ALT (a better marker for liver fat accumulation) levels in our normal BMI individuals is against this pathogenetic hypothesis at least in this subgroup. Accordingly, other authors demonstrated that CRP and aminotransferases predicted diabetes independent of each other, with similar magnitude associations[8].

Since the majority of healthy subjects within the highest GGT tertile show enzyme levels within targets of normality (89%), it could be suggested that variations within the normal ranges of GGT are associated with a worse oxidative or inflammatory pattern.

A single measurement of glucose, insulin, hs-CRP or liver enzyme levels represents a limitation of the present study, although common to most epidemiological studies. However, random errors due to the fluctuations of laboratory measurements usually lead to a reduced estimate of the associated strength. Serum oxidative markers could not directly reflect hepatocellular levels, and the existence of oxidative stress depends on the relative balance of reactive oxygen species and all the microenvironment antioxidant defenses, that could not be evaluated in such an observational study.

Whether elevated GGT levels should be added to the cluster of cardiovascular risk factors that form the metabolic syndrome and link insulin resistance to cardiovascular disease, as supported by literature[37,38] or if elevated GGT levels represent a marker of oxidative stress or inflammation could not be established by a cross-sectional study. Nevertheless, the hypothesis that elevated GGT levels may represent an early, easy, and inexpensive marker for a higher subsequent metabolic risk in apparently healthy subjects seems intriguing and worthy of future investigation.

In conclusion, in adult healthy subjects without any measurable metabolic abnormality, those with the highest GGT levels present with either higher fasting glucose values (even within the range of normality) and evidence of some oxidative stress or inflammation; aminotransferase levels do not show these correlations. The follow-up of these individuals would determine if GGT values might be considered as an early predictor of subsequent diabetes occurrence.

Abstract

AIM: To assess the value of long-chain ω-3 fatty acids (FAs) supplementation in addition to amino-salicylic-acid (5-ASA) in pediatric patients with Crohn's disease (CD).

METHODS: Thirty-eight patients (20 males and 18 females, mean age 10.13 years, range 5-16 years) with CD in remission were randomized into two groups and treated for 12 mo. Group I (18 patients) received 5-ASA (50 mg/kg/d)+ω-3 FAs as triglycerides in gastro-resistant capsules, 3 g/d (eicosapentanoic acid, EPA, 400 mg/g, docosahexaenoic acid, DHA, 200 mg/g). Group II (20 patients) received 5-ASA (50 mg/kg/d)+olive oil placebo capsules. Patients were evaluated for fatty acid incorporation in red blood cell membranes by gas chromatography at baseline 6 and 12 mo after the treatment.

RESULTS: The number of patients who relapsed at 1 year was significantly lower in group I than in group II ($P<0.001$). Patients in group I had a significant increase in the incorporation of EPA and DHA ($P<0.001$) and a decrease in the presence of arachidonic acids.

CONCLUSION: Enteric-coated ω-3 FAs in addition to treatment with 5-ASA are effective in maintaining remission of pediatric CD.

INTRODUCTION

The etiology and pathogenesis of CD are still unknown[1]. First-line therapy is still based on the combinations of glucocorticoids and amino-salicylic acid (5-ASA) derivatives. Knowledge of inflammatory mechanisms and the high incidence of side effects with steroids have induced researchers to look for valid alternatives, especially in maintaining remission secondary to steroid treatment[2]. The rationale for the use of ω-3 FAs in uncomplicated CD is that metabolites of the arachidonic acid (AA), which are considered as primarily responsible for inflammatory process and intestinal inflammation in CD, are produced from fatty acids[3]. Administration of EPA and DHA, the predominant fatty acids in fish oil, causes competition with AA for the utilization of 5-lipoxygenase enzyme cascade, thus inhibiting the production of inflammatory metabolites such as LTB4[4].

Data in literature on the use of ω-3 fatty acids are controversial. Belluzzi *et al*[5]. claimed that ω-3 FAs seem prudent to promote a diet rich in fish oil in patients with CD, while Lorenz-Meyer *et al*[6]. did not demonstrate any effect of ω-3 FA supplementation on the remission of CD in adults.

Since the use of fish oil has not yet been intensively studied in children with CD, we carried out a placebo-controlled clinical trial in children with CD by administering either ω-3 fatty acid or olive oil capsules used as a placebo in addition to 5-ASA.

MATERIALS AND METHODS

A double-blind, randomized study was carried out in 38 patients with CD (20 males and 18 females, mean age 10.13 years, range 5-16 years) recruited from eight Italian Pediatric Gastroenterology Centers. All of them had a definite diagnosis of CD based on accepted endoscopic and histological criteria if available (27 patients)[7].

Inclusion criteria were pediatric Crohn's disease activity index (PCDAI) score <20 for at least 2 mo obtained by an 8-wk course of corticosteroid treatment (1 mg/kg/d), no extraintestinal involvement of the disease, no previous intestinal resection (apart from appendectomy), no previous immunosuppressant treatment and a wash-out

period of at least 3 mo from corticosteroids.

All patients were non-smokers. After enrollment, patients were randomized into two groups according to the intestinal localization of the disease (Table 1) and treated for 12 mo as follows. Eighteen patients (9 males and 9 females) in group 1 were treated with time-dependant 5-ASA (50 mg/kg/d)+ω-3 FAs as triglycerides in gastro-resistant capsules, 3 g/d (TRIOLIP - SOFAR, Italy). Each capsule contained 400 mg/g EPA and 200 mg/g DHA. Eighteen patients (11 males and 9 females) in group 2 were treated with time-dependant 5-ASA (50 mg/kg/d)+olive oil placebo capsules. Patients who had a relapse were excluded from the study.

Clinical evaluations and several laboratory tests [assessment of blood cell count, erythrocyte sedimentation rate (ESR), C-reactive protein (PCR) and electrophoresis] were carried out at enrollment (T0) and after 6 (T1) and then 12 (T2) months of treatment. Fatty acids in the red blood cell membranes were also evaluated with gas chromatography on capillar column (SP 2340 Supelco). Analysis temperature was set at 160 ℃ and 210 ℃ with a gradient of 8 ℃/min, while the gas carrier (He) flow was 2 mL/min. The percentage (% mol) of each single fatty acid was compared to an external standard.

Statistical analysis

Data were analyzed by the statistical program 7.0 for Windows. The significance of the differences between averages and proportions was calculated by bivariate analysis (χ^2 square). $P<0.005$ was considered statistically significant.

Table 1 Characteristics of patients at the beginning of the study

	Group 1 (5-ASA+ω-3)	Group 2 (5-ASA+placebo)
Number of patients	18	20
Mean age (yr)	9.33	10.85
Sex (M/F)	9/9	11/9
Disease localization		
Ileal	10	7
Ileo-colic	6	8
Colic	2	5

RESULTS

Relapse (PCDAI score >20) after 1 year occurred in 11 patients (61%) of group 1 and 19 patients (95%) of group 2 (Figure 1A) with a statistically significant difference ($P = 0.0016$). However, no relapse occurred after 6 mo of follow-up in patients of group 1 who received capsules of EPA and DHA. The disease relapse occurred 8 mo after the treatment in group 1 and 1 mo in group 2 (Figure1B) with a statistically significant difference ($P<0.001$). Patients in group 2 and those with ileo-colonic localization presented a greater number of relapses (Figure 1C)

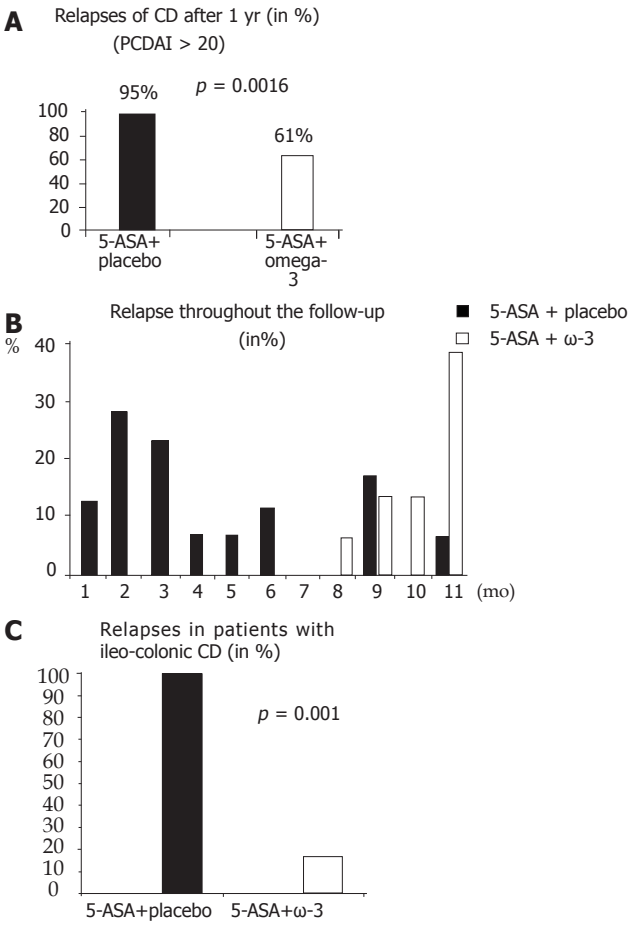

Figure 1 Relapses of CD after 1 yr (**A**), throughout the follow-up (**B**) and in those with ileo-colonic CD (**C**) (%).Characteristics of patients at the beginning of the study

compared to those under treatment (group 1) who had the same initial localization of the disease ($P = 0.001$). Compliance to the assumption of the capsules was optimal in all the patients and no side effects were reported in patients of either group.

All subjects in group 1 showed a significant increase in the range of incorporation of EPA (%/mol): 1.1±1, 2.48±1.83, 2.07±0.5 ($P<0.005$) and DHA (% mol): 1.81±0.68, 2.55±0.97, 3.54±0.85 ($P<0.001$) and a decrease in the presence of AA (% mol): 6.17±2.63, 5.5±2.33, 5.56±2.05 between T0 and T2.

DISCUSSION

Since no definite treatment for CD is available and the precise mechanism which triggers and maintains the intestinal inflammation is not yet well known, the aim of the treatment is to induce and maintain clinical remission[8]. There are several therapeutic options for the treatment of CD. Mild-to-moderate disease has been managed with nutritional support, 5-ASA and antibiotics[9], while the mainstay therapy for severe or complicated disease includes steroids, immunosuppressants and biological therapy[10].

Drugs most commonly used in the treatment of

inflammatory bowel disease (IBD) act by interfering with the AA metabolic pathway. Glucocorticoids prevent the formation of free AA through the inhibition of the activity of phospholipases A2 and C on the membrane phospholipids, while mesalazine acts with its N-acetyl-5-ASA metabolite through the inhibition of 5-lipoxygenase in the colonic mucosa. However, both drugs have not proved to be effective in maintaining the remission of CD[11] and many relapses of the disease can occur[12]. Biological agents introduced in recent years seem to be effective in inducing remission of active disease resistant to standard treatment but not in maintaining the remission[13].

The most prolonged remission has been obtained with 6-mercaptopurine and its pro-drug azathioprine[14]. Their efficacy in maintaining remission is widely accepted, but toxicity and possible side-effects have been reported[15]. Another therapeutic option to maintain CD remission is represented by w-FAs. In 1986, Lee *et al*[16]. reported that fatty acids contained in fish oil can limit the AA pathway. Kim[17] reported that patients with active CD have increased levels of LTB4 in the colic mucosa associated with the severity of the disease. The anti-inflammatory effect of fish oil has been tested on animals (rats with induced colitis) and ω-3 FAs are observed to determine other biochemical effects such as reduction of mucosal and circulating levels of the main powerful pro-inflammatory cytokines (IL-1, TNF-α) and reduction of synthesis of the platelet activating factor (PAF), which has a strong pro-inflammatory activity. In addition, it has even been demonstrated that it acts as a free radical scavenger[18]. Fish oil reduces the inflammatory process competing with the AA. In fact, EPA, a polinsaturi fatty acid of 20 carbon atoms produced by the metabolism of α-linoleic acids, is different from the AA only for the presence of various double bonds in position-17. It is a good substratum for 5-lipoxygenase and competes with the AA for the utilization of this enzyme together with its corresponding DHA. The incorporation of EPA and DHA into the erythrocyte membranes is necessary to stimulate a competitive action on the AA. This effect involves a reduced LTB4 production and synthesis of a new leukotriene, LTB5, which has no inflammatory effects[19]. In 1990 Mc Call *et al*[20]. and Salomon *et al*[21]. carried out the preliminary clinical studies, showing that administration of fish oil in patients with IBD causes a significant reduction of the disease activity score (CDAI score). Hawthorne *et al*[22]. have verified how fish oil supplementation in patients with IBD in the active phase significantly reduces steroid consumption and results in a longer clinical remission. Confirmation of the usefulness of EPA in IBD is demonstrated by the significant decrease in the production of LTB4[23]. Since there are no adequate formulations of fish oil which could be used as a drug without side-effects, its widespread use in the treatment of IBD is limited. Belluzzi *et al*[5]. showed that capsules of EPA and DHA, a free fatty acid mixture, are well tolerated and can be used to treat patients for long periods instead of administering pure fish oil. Other reports are controversial, showing contrasting results in maintaining the remission of CD[24,25].

All these experiences reported in literature are referred to adult CD, but ω-3 FAs have not yet been evaluated in children with CD. Our study is the first placebo-controlled clinical trial in pediatric CD and has achieved several interesting results though the number of patients enrolled was less. In fact, the addition of enteric-coated capsules to a conventional therapy with 5-ASA in pediatric CD delayed the relapse of the disease even if it could not prevent it. This association seems that the addition of enteric-coated capsules is more effective than 5-ASA alone probably due to the synergistic effect of the drugs used. 5-ASA can inhibit some key factors of the inflammatory cascade (cyclooxygenase, thromboxane-synthetase and PAF-synthetase) as well as production of interleukin 1 and free radicals[26-28] and has an intrinsic anti-oxidant activity[29]. Furthermore, ω-3 FAs inhibit PAF-synthetase and thromboxane-synthetase acts as a free radical scavenger decreasing mucosal and circulating levels of some powerful pro-inflammatory cytokines (such as IL-1 and TNF-α)[18]. In light of these biochemical characteristics, it is clear that the association of these two anti-inflammatory compounds may strengthen their single anti-inflammatory role and explain the better results obtained with 5-ASA alone in maintaining the remission of pediatric CD. 5-ASA/ω-3 FAs seem to play the same role in pediatric CD as the balsalazide/VSL#3 in the treatment of adult ulcerative colitis. 5-ASA plus a probiotic mixture can obtain significantly better results than balsalazide alone or mesalazine alone in maintaining remission of mild-to-moderate ulcerative colitis due to the synergistic effect of the two powerful anti-inflammatory compounds[30].

In conclusion, supplementation of ω-3 fatty acids to a standard treatment with 5-ASA is a good choice for maintaining remission of pediatric CD.

ACKNOWLEDGMENTS

Abstract

AIM: To prospectively assess the impact of time of endoscopy and endoscopist's experience on the outcome of non-variceal acute upper gastrointestinal (GI) bleeding patients in a large teaching hospital.

METHODS: All patients admitted for non-variceal acute upper GI bleeding for over a 2-year period were potentially eligible for this study. They were managed by a team of seven endoscopists on 24-h call whose experience was categorized into two levels (high and low) according to the number of endoscopic hemostatic procedures undertaken before the study. Endoscopic treatment was standardized according to Forrest classification of lesions as well as the subsequent medical therapy. Time of endoscopy was subdivided into two time periods: routine (8 a.m.-5 p.m.) and on-call (5 p.m.-8 a.m.). For each category of experience and time periods rebleeding rate, transfusion requirement, need for surgery, length of hospital stay and mortality we compared. Multivariate analysis was used to discriminate the impact of different variables on the outcomes that were considered.

RESULTS: Study population consisted of 272 patients (mean age 67.3 years) with endoscopic stigmata of hemorrhage. The patients were equally distributed among the endoscopists, whereas only 19% of procedures were done out of working hours. Rockall score and Forrest classification at admission did not differ between time periods and degree of experience. Univariate analysis showed that higher endoscopist's experience was associated with significant reduction in rebleeding rate (14% *vs* 37%), transfusion requirements (1.8±0.6 *vs* 3.0±1.7 units) as well as surgery (4% *vs* 10%), but not associated with the length of hospital stay nor mortality. By contrast, outcomes did not significantly differ between the two time periods of endoscopy. On multivariate analysis, endoscopist's experience was independently associated with rebleeding rate and transfusion requirements. Odds ratios for low experienced endoscopist were 4.47 for rebleeding and 6.90 for need of transfusion after the endoscopy.

CONCLUSION: Endoscopist's experience is an important independent prognostic factor for non-variceal acute upper GI bleeding. Urgent endoscopy should be undertaken preferentially by a skilled endoscopist as less expert staff tends to underestimate some risk lesions with a negative influence on hemostasis.

Key words: Non-variceal acute GI bleeding; Time of endoscopy; Surgeon's experience; Endoscopic hemostasis

INTRODUCTION

Acute upper gastrointestinal bleeding (AUGB) is the most common emergency managed by gastroenterologists, with an incidence ranging from approximately 50 to 150 per 100 000 per year in the Western population[1,2]. The treatment of this condition has made important progress since the introduction of emergency endoscopy and endoscopic techniques for hemostasis along with

the application of specific post-endoscopic protocols, significantly decreases rebleeding and the need for surgery[3-7], whereas mortality rates associated with AUGB still range as 5-15%[8,9].

Several clinical and endoscopic score systems have been proposed to risk-stratify patients with AUGB in order to predict outcome and several factors such as age, shock and tachycardia at presentation, the presence of severe medical comorbidity and the lesion's appearance at endoscopy have been shown to be associated with adverse prognosis[10 -13]. In particular, Forrest's classification of endoscopic findings closely associated with peptic ulcer disease but sometimes seen with other causes of AUGB is associated with specific recurrent bleeding rates and is commonly used to assess the need for endoscopic therapy[14].

As far as the effectiveness of various endoscopic therapies for AUGB is concerned, a recent review indicates that differences in terms of hemostatic results using the same treatment modality, exist between research studies and clinical practice as well as among various randomized clinical trials and are probably related to surgeon-dependent factors[15]. Surprisingly, the experience of surgeons in achieving endoscopic hemostasis has not yet been examined, whereas the time of endoscopy has received so far little attention as a possible variable influencing the outcome of AUGB[16-19].

We therefore undertook a 2-year survey in order to assess prospectively the impact of surgeon's experience and time of endoscopy on the outcome of acute non-variceal upper gastrointestinal (GI) bleeding patients in a large tertiary referral center of western Milan.

MATERIALS AND METHODS

Patients

Two hundred and seventy-two (mean age 67.3 years) patients who presented with AUGB to L. Sacco University Hospital, Milan, between June 2001 and July 2003 were included in this study. L. Sacco Hospital is a large teaching hospital located in western Milan with a catchment area of nearly 250.000 inhabitants and provides 24 h emergency endoscopy for two district neighboring hospitals serving an additional population of approximately 200 000 inhabitants.

The treatment protocol for patients with AUGB did not change during the study period and could be summarized in short as follows. All patients who arrived or were referred from a district hospital to the Accident and Emergency Department of our hospital with clinical manifestations of AUGB were managed according to a three-stage scheme: stage I: initial clinical and laboratory evaluation in the Emergency Department including placement of a double-bore nasogastric tube; stage II: hemodynamic stabilization including infusion of crystalloid fluids to maintain adequate blood pressure; stage III: urgent endoscopy within 12 h from presentation in patients who had at least one of the following presenting features: hematemesis with red blood or coffee grounds, passage of melena and a hematocrit below the normal range with a nasogastric aspirate demonstrating red blood or coffee ground material. Recommendations regarding admission to the various hospital departments were made to the attending physicians by the endoscopist mainly based on the assessment of clinical and endoscopic criteria.

We used the Forrest's classification[14] for endoscopic grading of bleeding lesions as follows: class 1A: active ulcer bleeding presenting as arterial spurting or pulsatile bleeding from the ulcer base; class 1B: milder forms present as continuous oozing either from a visible vessel or from underneath an adherent clot; class 2A: in the absence of active bleeding, the stigmata of recent hemorrhage including a non-bleeding visible vessel seen as a red or whitish-gray elevated lesion at the base of the ulcer; class 2B: an adherent clot covering the base of an ulcer; class 2C: a flat pigmented spot or a black membrane covering the ulcer base; class 3: a clean ulcer bottom (i.e, without vessel nor clot).

Patients with endoscopic stigmata of recent hemorrhage, regardless of whether they received endoscopic hemostasis or not were usually admitted to the surgical or gastroenterological ward. The allocation choice was mainly based on the presence of additional medical comorbidity (such as diabetes mellitus, renal failure, etc.) and available space at the different services. Patients with hemodynamic instability after the endoscopic procedure were usually admitted to the intensive care unit (ICU).

Study population

All patients aged 16-95 years undergoing urgent endoscopy (within 12 h after admission) for non-variceal AUBG and those who presented endoscopic stigmata of recent hemorrhage were potentially eligible for this study. Patients were excluded if they had variceal bleeding (both from esophagus and stomach), those who bled from an evident digestive tumor and other non-ulcer lesions such as Dieulafoy's lesions and Mallory-Weiss tears. In particular, Mallory-Weiss tears could not enrolled be since they have a low risk of recurrent bleeding[20]. Dieulafoy's lesions were excluded since we preferred to treat these lesionsby mechanical methods (such as banding or clipping) or APC rather than by epinephrine injection plus heat probe as in this study. Even patients with clearly malignant ulcers at endoscopy (i.e, patients with large flat, plaque-like, ulcerated tumors) were excluded due to the difficulty of standardizing the endoscopic hemostatic maneuvers under these circumstances. Finally, patients with ASA grade 5 were not enrolled in the study due to their severe clinical conditions as defined in this category.

Patients were evaluated at the time of admission using an extensive standardized-item list. The medical history (including concomitant disease, smoking habit, previous peptic disorders) and complaints (melena, hematemesis, hematochezia, dyspeptic complaints, syncope) were recorded. Concomitant diseases were categorized into six main classes (Table 1). The findings on physical examination were also recorded. Hemodynamic instability

Table 1 Distribution of 272 patients with acute non-variceal upper GI bleeding according to age, sex, and other selected covariates

Covariates		*n* (%)
Sex, male		186 (68.4)
Mean age (yr)		67.4±15.8
<40		19 (7.0)

Transfusion requirements before endoscopy: (number of blood units)	0	229 (84.2)
	1–4	37 (13.6)
	⩾5	6 (2.2)

[1]Shock grade: grade 0 = no shock signs (systolic BP >100, pulse <100), grade 1 = tachycardia (systolic BP >100, pulse >100), grade 2 = hypotension (systolic BP <100, pulse >100). [2]The sum of main symptoms is higher than the number of patients as some patients had more than one main symptom at presentation. [3]The sum does not add up to the total because of some missing values.

was defined as a systolic blood pressure <100×0.133 kpa or a heart rate >100 r/mm.

The Rockall score was calculated from age, hemodynamic characteristics, endoscopic findings, and comorbidity as previously described[21].

Medications before and during the hospital stay [apart from intravenous proton pump inhibitors (PPIs) used for the bleeding episode] as well as the number of units of blood transfused before and after endoscopy were specifically noted.

Endoscopists and endoscopic procedures

We limited the endoscopists to seven gastroenterologists who were on a 24-h call for emergency endoscopy and whose experience was arbitrarily categorized into two levels according to the number of hemostatic endoscopic procedures done at the time of study. Five endoscopists (three consultant gastroenterologists and two senior registrars) had high experience (each one had performed more than 3 000 upper GI endoscopies and more than 100 emergency procedures). The three consultants had been in practice for more than 8 years, whereas the two senior registrars had completed 6 years of training in general gastroenterology and gastrointestinal endoscopy. The other endoscopists (young senior registrars in gastroenterology) had less experience as they had just completed only 4 years of training in general gastroenterology and had performed less than 1 000 upper GI endoscopies and 40–70 emergency procedures, as a principal surgeon before participating in this study. All emergency endoscopies were undertaken by the gastroenterologists on call in a separate endoscopic suite. Endoscopies performed between 8 am and 5 pm from Monday to Friday were defined as done within working hours (routine), whereas those performed at other time points were classified as done out of working hours (on call).

The endoscope employed was a Pentax EG 3440 video endoscope with a large operative channel (3.5 mm, Pentax, GmbH, Hamburg, Germany).

To improve the visual field, gastric lavage with a broad double-bore nasogastric tube was used and continuous normal saline infusion was carried out before endoscopy. Ulcers with bleeding stigmata were cleaned by water irrigation through the biopsy channel. Adherent clots were washed with a jet of water delivered through a catheter passed through the endoscope.

Only ulcerative lesions with endoscopic stigmata of acute bleeding, visible vessels or adherent clot (Forrest Ia–IIc) were included in the present study. Since previous studies have shown medium to poor inter observer variability in assessing endoscopic stigmata of bleeding[21],we attempted at reducing interobserver bias onthe grading of endoscopic stigmata by reviewing the video records of 20 explicative cases at a pre-study meeting.

Endoscopic therapy was standardized as follows: initial injection of 1:10 000 adrenaline around the bleeding lesion (up to a maximum of 20 mL) to achieve a tamponade effect, followed by application of a 3.2-mm heater probe

(Olympus, CD-120 U, Tokyo, Japan) at settings of 30 J per goal until the achievement of a coaptive effect[22]. This method was used whenever endoscopic stigmata of hemorrhage such as acute spurting, oozing, visible vessel or adherent clots were present. Written guidelines containing the above mentioned recommendations concerning the hemostatic maneuvers to be undertaken were circulated among the endoscopists participating in this survey before the study.

The success of endoscopic hemostasis was defined as the cessation of bleeding together with the achievement of cavitation over the lesion after the application of the heater probe.

After endoscopy, the surgeon filled in a specific form with all the details concerning the procedure with specific reference to the appearance of bleeding lesions (according to the Forrest's classification) and the hemostatic maneuvers that were undertaken. Epinephrine solution injected and the number of pulses with the heater probe whenever employed were recorded. The time of endoscopy after admission was also recorded.

No patient was initially treated either with endoscopic band ligation or with hemoclipping, whereas these therapies were occasionally used by a senior endoscopist to obtain hemostasis in case of recurrent bleeding.

All patients received high dose intravenous PPIs: omeprazole or pantoprazole, 80 mg bolus within 12 h of endoscopy followed by 8 mg/h for 3 d [23] and then an oral PPI, 40 mg once daily for the remainder of their hospital stay. Patients were closely monitored and underwent clinical reviews with their blood pressure, pulse, respiratory rate, and urine output measured hourly for the first 24 h followed by close observation for symptoms and signs of recurrent bleeding throughout their stay in the hospital. Subsequent management decision was made by the attending physician. No attempt was made to persuade the attending physician to follow a specific course of action beyond the recommendations quoted above and to determine the length of hospital stay.

Outcome measures

The major outcome parameters were rebleeding, surgical intervention, and mortality. Rebleeding was defined as repeated melena, hematemesis or a drop in hemoglobin concentration (>2 g/dL in 24 h) after a period of stabilization and unexplained by fluid replacement within 28 d of the initial bleeding episode. We performed a second endoscopy to confirm clinical recurrent bleeding which was defined as persistent endoscopic stigmata of acute spurting or oozing, visible vessels or adherent clots with the appearance of blood clots or coffee ground material in the stomach or duodenum. Our study had a result greater than 95% to reject the null hypothesis that the proportion of rebleeding patients was the same in endoscopists with high and low experience.

Surgery was performed in those patients whose bleeding could not be stopped by primary endoscopic hemostasis or by a second or third endoscopic therapy. Interventional radiology was not available for patients who did not respond to endoscopic therapy when the study started. The choice of surgery was left to the individual surgeon though gastrectomy was the most preferred operation for the control of ulcer bleeding. The mortality was defined as death within 28 d of the bleeding episode.

Secondary outcome measures included the number of packed red cell units transfused after endoscopy and the length of hospital stay.

Appropriateness of endoscopic hemostatic maneuvers

The appropriateness of each endoscopic procedure was evaluated jointly by the two consultant gastroenterologists who did not participate in the procedures and were blinded to the outcome of patients and name of the endoscopist. Treatment in accordance with the implemented guidelines[6] was classified as appropriate, treatment in disagreement as inappropriate. In many instances video taping of the cases was also used with regard to the appropriateness.

Statistical analysis

Univariate analysis was performed by the χ^2 test for frequencies and by the Man-Whitney rank sum test for means.

Odds ratios (OR) and corresponding 95% confidence intervals (CI) were estimated by unconditional multiple logistic regression models[24] after adjustment for age (<40 /40-49/50-59/60-69/70-79/≥80 years), sex, Rockall (<6/ ≥6) and Forrest's score (IA,IB/2A-2C), blood transfusion (no/yes), endoscopist's experience (high/low), and time of endoscopy (routine/on-call). Moreover, we estimated ORs after a further adjustment for appropriateness of treatment (appropriate/inappropriate).

The significance of OR estimates was represented by the corresponding 95%CI. If OR did not include unity, the estimate was statistically significant.

RESULTS

Overall results

Between June 2001 and July 2003, we recruited 272 patients (mean age 67.3 years, 186 males, 94% Caucasians) who presented to the A&E, Department of Luigi, Sacco University Hospital for non-variceal AUGB and underwent upper GI endoscopy within 12 h after admission with the presence of endoscopic stigmata of hemorrhage. They satisfied all the inclusion criteria of the study. Table 1 describes the distribution of these patients according to sex, age, and other selected covariates.

Overall, the rebleeding, surgical intervention, and mortality rates were 18.7%, 5.5%, and 13.2%, respectively. Initial endoscopic hemostasis was achieved in 268 of the 272 patients (98.5%) and four patients required immediate surgery for failure of primary endoscopic hemostasis. Fifty-one patients had at least a rebleeding episode after initial hemostasis (Figure 1). Thirty-six patients died within 28 d from the initial episode of bleeding. Their ultimate causes of death were cardiac failure (15), pulmonary failure (9), liver failure (4), multi organ failure (2), renal failure (4), and cerebral edema (2).

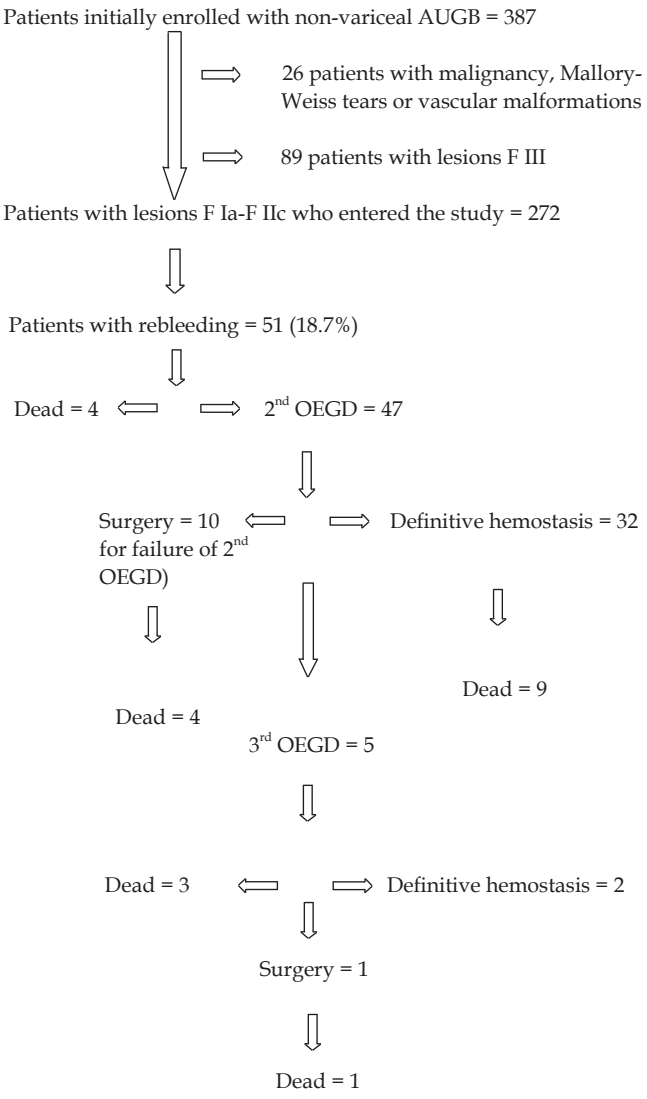

Figure 1 Flow chart illustrates the study design and how the 51 patients who had at least one rebleeding episode were managed and their clinical outcomes.

Outcome of patients

Eighty-one percent of the emergency procedures were performed between 8 a.m. and 5 p.m. whereas only 19% were done out of working hours.

Forrest's classification of lesions at admission did not significantly differ between the two endoscopist categories, though no significant trend towards a higher mean Rockall' s score was found in patients undergoing endoscopy out of working hours.

Univariate analysis showed that higher endoscopist's experience was associated with significant reduction in rebleeding rate (14% *vs* 37%), transfusion requirements (1.8 ± 0.6 *vs* 3.0 ± 1.7 units) as well as the need for surgery (4% *vs* 10%), but not associated with the length of hospital stay and mortality (Table 2). In contrast, outcomes did not significantly differ between the two time periods of endoscopy.

Table 3 shows the distribution of patients according to the experience of endoscopists and the time of endoscopy. Univariate (Table 3) and multivariate (Table 4) analyses showed that low endoscopist's experience was associated with the higher rebleeding rate and transfusion requirements, but not significantly associated with the need for surgery, the length of hospital stay, and higher mortality rate. After adjustment for age, sex, and other selected covariates, the OR of low experienced endoscopist was 4.47 for rebleeding, 6.90 for need of transfusion after endoscopy, 2.36 for need of surgery, 0.47 for mortality, and 0.88 for length of hospital stay, respectively (Table 4). The estimates were statistically significant for rebleeding and need of blood transfusions. However, after further adjustment for appropriateness, the association with rebleeding disappeared (OR = 1.33), whereas it was still significant with the need of transfusion (OR = 5.07). The OR of making endoscopy in non-ordinary time period was 0.94 for rebleeding, 0.89 for need of transfusion after endoscopy, 1.85 for need of surgery, 1.96 for mortality, and 1.51 for length of hospital stay, respectively. None of the estimates were statistically significant even after further adjustment for appropriateness.

Table 5 shows the effect of an inappropriate endoscopic treatment on the occurrence of events of interest. A direct association was found between inappropriateness of treatment and risk of subsequent rebleeding (OR = 43.49),

whereas no significant association was found between inappropriateness and need of transfusion after endoscopy (OR = 2.98), need of surgery (OR = 2.62), mortality (OR = 0.47), and length of hospital stay (OR = 0.60). The latter findings showed that appropriateness of endoscopic therapy rather than the endoscopist experience was the main variable associated with rebleeding. Of course, the lower the endoscopist's experience, the higher the inappropriateness in hemostatic maneuvers. Again, the two time periods of endoscopy were not associated with any of the variables evaluated.

When considering subjects with lesions 2A and 2B of the Forrest's classification, we found a stronger association between low endoscopist's experience and rebleeding, the

multivariate OR being 9.82 (95%CI: 2.62-36.89).

Finally, there was a trend towards more adrenaline injected and a significant difference in the number of heater probe pulses used by endoscopists with high and low experience, respectively. The mean adrenaline injected was 9.4 and 8.6 mL, whereas the median number of heater probe pulses was 7 (range 0-15) *vs* 4 (range 0-10) for high- and low-experienced endoscopists, respectively.

DISCUSSION

Over the past two decades, advances have been made in the management of non-variceal AUGB[5]. Various endoscopic single-modality treatments including epinephrine injection, thermal therapy (heater probe, electrocoagulation, laser, etc.) and their combination are efficacious in achieving hemostasis in clinical trials[7]. These endoscopic procedures can control active bleeding in 85-90% of patients with a significant decrease in the rate of recurrent bleeding and need for surgery[6,7,25]. Therefore, the management decision for preventing recurrent bleeding is a rapid endoscopic diagnosis with adequate hemostasis. Recent data demonstrate that the best predictor of recurrent bleeding is the endoscopic finding of ulcer since the presence of a visible vessel or sentinel clot in the ulcer base indicates a high likelihood of rebleeding (43% and 22%, respectively), whereas ulcers with a clean base have a recurrent bleeding risk that is negligible[25]. The above rebleeding rates can be lowered by 60-80% by the application of aggressive endoscopic therapeutic modalities (such as a combined injection/thermal therapy[26]). However, one should keep in mind that these results are obtained in centers of excellence, often known internationally for their expertise in the treatment of peptic ulcer bleeding. Whether the aforementioned results are reproducible in centers with less endoscopic expertise is currently a matter of debate[15].

The influence of endoscopy time on the outcome of patients with non-variceal AUGB remains a subject of debate as very few studies have addressed the question so far. Adler *et al*[17] showed that complications are significantly more frequent after emergency endoscopy between 7 p.m. and 11 p.m. as compared to regular working hours, which may be due to the fact that during non-working hours endoscopy is performed by more fatigued personnel. Choudari *et al*[16] and Ramage *et al*[18] found that there is no difference in the outcome of patients with non-variceal AUGB who had undergone endoscopy during working or non-working hours and weekdays *vs* weekends, respectively.

The present survey aimed at evaluating the impact of these two single factors (endoscopist's experience and time of endoscopy) on the outcome of patients with non-variceal AUGB presenting at a single large tertiary referral center. We did not include in our study inpatient referrals in order to deal with similar patients and to reduce as much as possible the severe comorbidities usually present in patients during their hospital stay. upper GI haemorrhage while hospitalized for another reason (so-called secondary bleeding) has been associated with an increased risk of rebleeding and death[26].

Findings from our study showed that the endoscopist' s experience was an important independent prognostic factor for the outcome of non-variceal AUGB. Indeed, less experienced surgeon resulted in a significantly higher recurrent bleeding rate and transfusion requirement than highly experienced endoscopists, whereas mortality was not influenced probably due to comorbidities.

We found a direct significant association between low experience endoscopists and risk of rebleeding (multivariate OR = 4.47). After a further adjustment for appropriateness, the association disappeared (OR = 1.33), suggesting that if surgeons with lower experience have a rate of appropriateness of treatment similar to that of high experience endoscopists, we could not obtain any significant difference in terms of rebleeding rate between low and high experience endoscopists.

Moreover, the recurrent bleeding of F2A and F2B ulcers was significantly higher among the less experienced endoscopists as compared to the rate of highly skilled surgeons as well as the value reported in the literature[27]. The evaluation of appropriateness of endoscopic therapy by the two consultants who blindly examined the endoscopic reports might help understand the discrepancy. Planned guidelines of hemostasis were not followed entirely by less experienced staff in 36% of cases, particularly in patients with F2B ulcers, where the most frequent protocol violation was the non removal of an adherent clot. The fear of removing an apparently stable clot adherent to the ulcer base as well as the hypothetical difficulties in managing the subsequent hemorrhage under unfavorable circumstances (i.e, without any supervision) is the most frequently reported explanation by the youngest

endoscopists to justify guideline violations. Independently by the experience of endoscopists, fewer protocol violations have been done for patients with lesions classified as both F1A, F1B, and F2C, which might explain at least in part the lower rebleeding rate in these subjects (13.8% and 7.2%, respectively) as compared to those classified as F2A and F2B (40.2%).

Our findings also add some useful information to a still intricate problem that is the optimum treatment for ulcers with no hemorrhage at the time of endoscopy but present with the stigmata of hemorrhage. While there is no doubt that ulcers with actively bleeding vessels are treated immediately with injection and thermocoagulation by both highly experienced and less expert endoscopists, is the management strategy for intermediate findings (Forrest IIa & IIb) which remains less certain, especially when considering the great benefit of acid suppression in this group[28]. If aggressive endoscopic therapy (clot removal^{+}epinephrine injection and thermal therapy) is superior to non endoscopic intervention in patients with adherent clots receiving oral PPI[29], profound in acid suppression without clot removal is more effective than endoscopic intervention alone[30]. A supplemental jog to this matter was provided by our current survey during which all bleeding patients received the same PPI scheme after endoscopy. We adjusted the paradigm to study the value of high dose in PPI alone over endoscopic therapy^{+} of PPI in F2A and 2B ulcers, showing that combination of appropriate endoscopic therapy with profound acid suppression is better than PPI alone (or PPI plus endoscopic under treatment)[31].

As far as the time of endoscopy is concerned, our findings suggest that emergency endoscopy out of working hours is as safe and effective as endoscopy performed during working hours provided that it is done under optimal conditions as during working hours. The success of procedures out of hours in this study may be related to the existence of a specific bleeding team composed of the endoscopist and two well-trained specialized nurses. It is conceivable that the same results cannot be obtained in other institutions with less endoscopic facilities and untrained assistants (i.e, non-specialized nurses), where examinations may perhaps be delayed by a few hours in order to perform endoscopy more safely during working hours.

In conclusion, endoscopist's experience is an important independent predicting variable for the outcome of non-variceal AUGB, whereas time of endoscopy (working *vs* non working hours) does not make any difference in terms of patients' prognosis. Urgent endoscopy for AUGB should be undertaken by experienced endoscopists because less experienced staff may not achieve hemostasis.

Abstract

AIM: To investigate the seroprevalence of *Helicobacter pylori* (*H pylori*) infection and its more virulent strains as well as the correlation with the histologic features among patients who had undergone surgery for gastric cancer (GC).

METHODS: Samples from 317 (184 males, 133 females, mean age 69±3.4 years) consecutive patients who had undergone surgery for gastric non-cardia adenocarcinoma were included in the study. Five hundred and fifty-five (294 males, 261 females, mean age 57.3±4.1 years) patients consecutively admitted to the Emergency Care Unit served as control. Histological examination of tumor, lymph nodes and other tissues obtained at the time of surgery represented the diagnostic "gold standard". An enzyme immunosorbent assay was used to detect serum anti-*H pylori* (IgG) antibodies and Western blotting technique was utilized to search for anti-CagA protein (IgG).

RESULTS: Two hundred and sixty-one of three hundred and seventeen (82.3%) GC patients and 314/555 (56.5%) controls were seropositive for anti-*H pylori* ($P<0.0001$; OR, 3.58; 95%CI, 2.53-5.07). Out of the 317 cases, 267 (84.2%) were seropositive for anti-CagA antibody *vs* 100 out of 555 (18%) controls ($P<0.0001$; OR, 24.30; 95%CI, 16.5-35.9). There was no difference between the frequency of *H pylori* in intestinal type carcinoma (76.2%) and diffuse type cancer (78.8%). Intestinal metaplasia (IM) was more frequent but not significant in the intestinal type cancer (83.4% *vs* 75.2% in diffuse type and 72.5% in mixed type). Among the patients examined for IM, 39.8% had IM type I, 8.3% type II and 51.9% type III (type III *vs* others, $P = 0.4$).

CONCLUSION: This study confirms a high seroprevalence of *H pylori* infection in patients suffering from gastric adenocarcinoma and provides further evidence that searching for CagA status over *H pylori* infection might confer additional benefit in identifying populations at greater risk for this tumor.

INTRODUCTION

Gastric cancer (GC) is the world's second leading cause of cancer-related mortality[1] but in some countries it represents the most common malignancy in males[2].

GC occurrence in many Italian regions is similar to that in Japan. In Italy, GC is usually discovered at a later stage and therapeutic approaches cannot save a majority of patients. As a consequence, mortality parallels incidence[3].

The most frequent histologic type of GC is adenocarcinoma, which is thought to originate from a continuing and active proliferation of gastric pits following the destruction of glands due to active inflammatory infiltration. The process that has been described by Correa[4] from an inflammatory setting (gastritis) through intestinal metaplasia (IM) and dysplasia, evolves to adenocarcinoma.

In 1994, the International Agency for Research on Cancer defined *H pylori* as a class I gastric carcinogen[5]. Evidence supporting a causal association has been demonstrated by epidemiological data[6], ecologic studies[1] and in experimental animal models[7]. Regarding the first aspect, in a prospective study including 1 526 Japanese subjects during a mean follow-up of 7.8 years (range 1.0-10.6 years), 2.9% of infected persons developed GC *vs* none among uninfected subjects[8]. A combined analysis of 12 case-control studies (with 1 228 GC cases considered) nested within prospective cohorts has found an association between non-cardia GC and *H pylori* infection of 5.9 (95% confidence interval [CI] 3.4-10.3)[9]. A meta-analysis of 21 case-control studies suggested that the risk of GC is increased by threefold in those chronically infected with *H pylori*[10]. More recently, another meta-analysis of case-control studies with age- and sex-matched controls was published by Huang *et al*[11]. In this work, a comprehensive literature search identified 16 qualified studies with 2 284 cases and 2 770 controls. The authors found that *H pylori* and CagA (cytotoxin-associated gene A) protein seropositivity significantly increases the risk for GC by 2.28- and 2.87-fold, respectively.

There is still no final conclusion regarding the association between the infection and the malignancy due to marked geographic variations. Some studies have not found any correlation between seropositivity for *H pylori* antibodies (as an indicator of *H pylori* infection) and GC[12-14]. For example, in the study performed by Rudi *et al*[12] in Germany, 58.6% of patients suffering from GC and 50.6% of control subjects have IgG antibodies against *H pylori*. In Gambia, though more virulent strains of *H pylori* are present, gastric atrophy and IM are rare[15]. Seropositivity for *H pylori* and the CagA antigen cannot explain the differences in the prevalence of precancerous gastric lesions in two Chinese populations with contrasting GC rates[16]. Recently, Wong *et al*[17] found that the incidence in GC development is similar between the subjects receiving *H pylori* eradication treatment and those receiving placebo during a period of 7.5 years in a high-risk region of China. Furthermore, not all the stomach tumors are *H pylori* positive.

In previous local pilot studies in North Italy, a high prevalence of *H pylori* infection has been associated to the presence of GC[18,19]. To investigate the correlation in a vast area of Northwest Italy in more detail, we started a research network on gastric cancer and precursor lesions in 1993, which we named Metaplasia *H pylori* Histology (MHEPHISTO). In this multicenter survey, a prospective case-control study of patients who had undergone surgery for GC in Northwestern Italy was performed. The aim was to ascertain the seroprevalence of *H pylori* infection and its more virulent strains by searching for antibodies against the CagA protein and to establish the correlation with the subtypes of IM.

MATERIALS AND METHODS

Study population

Specimens from 317 (184 males, 133 females, mean age 69±3.4 years) consecutive patients who had undergone surgery for gastric non-cardia adenocarcinoma were included in the study. Five hundred and fifty-five patients (294 males, 261 females) consecutively admitted to the Emergency Care Unit of S. Giovanni Battista (Molinette) Hospital of Torino served as control with a mean age 57.3 ±4.1 years. Cases and controls came from the geographical area of Northwestern Italy.

Methods

Clinical diagnosis of malignancy was established by standard medical examinations including upper GI endoscopy, diagnostic ultrasound and computed tomography (CT) scan. Endoscopic ultrasound (EUS) served as a part of the routine examination.

Histological examination of tumor, lymph nodes and other tissues obtained at the time of surgery represented the diagnostic "gold standard". Pathologists with special interest and experience in GI pathology reviewed the histological sections. Appropriate forms were used to record the pathological findings. All the diagnostic criteria used for our survey were discussed and sample slides were reviewed by the pathologists before the study to minimize interobserver variations as far as possible.

Surgical specimens were immersed in paraffin for routine pathological examination. Microtome sections (7-8 μm thick) were stained with hematoxylin and eosin as well as high iron diamine/alcian blue to identify sialo-and sulfomucins. Adenocarcinoma was diagnosed when the malignant cells invaded the lamina propria in single cells, glandular or solid nest arrangements, usually accompanied with fibrosis of the surrounding tissue. Carcinomas were classified histologically as either intestinal or diffuse type in accordance with Lauren's classification[20]. Intestinal metaplasia classified according to Filipe *et al*[21] was defined as metaplastic transformation of gastric glandular and surface epithelium towards intestinal mucosal elements including goblet, absorptive, and Paneth cells.

Personnel not aware of the histological diagnoses performed serological testing. A commercial enzyme

Table 1 Seroprevalence of anti-*H pylori* antibodies among patients with gastric cancer and controls

Parameters	Gastric cancer (%)	Controls (%)
H pylori positive	261 (82.3)	314 (56.5)
H pylori negative	56	241
Anti-CagA positive	267 (84.2)	100 (18)
Anti-CagA negative	50	455

Table 2 Features of patients suffering from gastric cancer based on tumor subtype

Parameters	Intestinal type carcinoma (%)	Diffuse type carcinoma (%)
H pylori positive	138/181 (76.2%)	67/85 (78.8%)
Intestinal metaplasia	151/181 (83.4%)	64/85 (75.2%)

immunosorbent assay (ELISA, Helori-test® Eurospital, Trieste, Italy) was used to detect serum anti-*H pylori* (IgG) antibodies. The assay sensitivity and specificity were 94% and 87%[22]. Briefly, calibrators, positive and negative controls and diluted (1:200) serum samples were added to the wells coated with purified *H pylori* group-specific antigens. Plates were incubated for 60 min at 37 ℃, and then the liquid was removed completely and washed thrice with 200 μL/well of washing solution. One hundred microliters of anti-IgG conjugate was pipetted into each well. The wells were incubated for 60 min at 37 ℃, washed thrice with 200 μL/well of washing solution and 100 μL of chromogenic substrate was added to each well. The wells were again incubated for 30 min at 37 ℃, the reaction was stopped by adding 25 μL of the stopping solution. Reading was performed at 405 nm and the mean optical density was expressed as a percentage of the optical density of positive control serum assayed on the same plate. To detect the presence of serum IgG against *H pylori* CagA protein, Western blotting technique was used. *H pylori* CCUG 17874 (type strain, CagA positive, CagA mass = 128 ku) was cultured in *Brucella* broth containing 0.2% cyclodextrin at 37 ℃ in a microaerobic environment for 48 h. At the end of incubation, to exclude the presence of contaminants, the broth culture was subcultured onto plain blood agar plates and examined under optical microscope after staining with carbol fuchsin. The broth culture was centrifuged and the pellet was washed twice with phosphate buffered saline (PBS, pH 7.4) at 4 ℃. A whole cell suspension containing approximately 10^{10} bacteria was lysed and denatured in Laemmli buffer at 95 ℃ for 5 min, then run electrophoretically on 10% polyacrylamide gel with sodium dodecyl sulfate. Proteins were transferred onto nitrocellulose sheets saturated with 3% defatted milk in PBS with 0.1% Triton X (PBSMT). Strips were cut and serum samples were assayed at the dilution of 1:100 in PBSMT. After overnight incubation with constant agitation at room temperature, strips were washed with PBSMT and then incubated with an anti-human IgG serum conjugated with peroxidase at room temperature for 90 min. After the washings, the reaction was visualized by adding the substrate (H_2O_2 in a solution of 4-chloro-1-naphthol in Tris buffer 0.05 mol/L, pH 6.8). We used serum samples from patients infected respectively with CagA positive and negative *H pylori* strains as positive and negative controls with or without antibodies to CagA. Specific polyclonal antisera against CagA (kindly donated by Biocine-Chiron, Siena) was used as further controls.

The seroprevalence of anti-*H pylori* as well as the distribution of anti-CagA seropositivity in cases and controls were compared using the χ^2 test. Odds ratio (OR) and 95%CI assessing the risk of GC associated with *H pylori* infection were calculated using the Mantel-Haenszel method. $P<0.05$ was considered statistically significant.

RESULTS

All patients selected were suffering from gastric non-cardia adenocarcinoma (intestinal type in 181, diffuse type in 85 and mixed type in 51). Among these, 261 out of 317 (82.3%) were seropositive for IgG anti-*H pylori* compared to 314 out of 555 (56.5%) controls ($P<0.0001$; OR, 3.58; 95%CI, 2.53-5.07) (Table 1). Moreover, out of the 317 cases, 267 (84.2%) were seropositive for anti-CagA antibody *vs* 100 out of 555 (18%) controls ($P<0.0001$; OR, 24.30; 95%CI, 16.5-35.9) (Table 1).

There was no difference between the frequency of *H pylori* in intestinal type and diffuse type carcinoma. Overall, *H pylori* occurred in 138 out of 181 patients (76.2%) suffering from the former compared to 67 out of 85 (78.8%) suffering from the latter (P = NS) (Table 2). Intestinal metaplasia was more frequently seen in the intestinal type cancer (151/181, 83.4% *vs* 64/85, 75.2% in diffuse type and 37/51, 72.5% in mixed type) but the difference was not statistically significant (P = NS, Table 2). Among the patients examined for IM, 72 out of 181 (39.8%) had IM type I, 15 out of 181 (8.3%) type II, and 94 out of 181 (51.9%) type III, (type III *vs* others $P = 0.4$). Furthermore, among the patients with IM of either body or antral mucosa, 117 out of 151 (77.4%) with intestinal type carcinoma were positive for *H pylori* compared to 59 out of 85 (69.4%) with diffuse type carcinoma ($P = 0.17$).

DISCUSSION

Gastric carcinogenesis involves a slow but continuous stepwise evolution from superficial gastritis and glandular atrophy to metaplasia and dysplasia and finally to adenocarcinoma[23]. The process of carcinogenesis which may well extend over decades provides an excellent opportunity for early detection and intervention to prevent further progression of the sequence of events preceding the development of the neoplasma. This is especially true because *H pylori* (which can be readily treated) is known to be the main factor though not the only[24] etiological agent

and initiating carcinogen.

On the other hand, the prognosis of GC is poor. In most industrialized countries, only around 10% subjects survive for 5 years. The sole exception is Japan where this malignancy is often identified at an early stage and in younger and fitter patients[26]. In Italy, 10-year survival is 12.1% in all GC patients and 20.8% in resected cases. However, though the survival is good when the diagnosis is performed at an early stage, only a few cases are diagnosed at stages when cure by radical surgery is more probable[3].

Regarding the biological plausibility for a causal role, a higher intragastric pH after the development of atrophic gastritis provoked by *H pylori* may favor the production of carcinogens[26]. The generation of reactive oxygen species and increased level of inducible nitric oxide synthase may in turn cause genetic alterations leading to cancer[27]. Nardone *et al*[28] demonstrated by morphometric and immunohistochemical techniques that *H pylori* infection seems to be responsible for genomic instability in patients with chronic atrophic gastritis and eradication of *H pylori* can reverse inflammation, atrophy, metaplasia, and genomic instability.

CagA gene is situated at the end of the large region of the genome identified to be a pathogenicity island (PAI). The strains of *H pylori* expressing CagA protein are considered more virulent, being linked with an increased risk of duodenal ulcer and GC[23]. Moreover, CagA status is associated with a higher prevalence of p53 mutation in gastric adenocarcinoma[29].

This multicenter study showed a significant association between *H pylori* infection in particular by its more virulent strains and the presence of GC. In addition, the results confirmed that type III IM was most frequently associated with *H pylori* infection. These data suggest that CagA status is a helpful parameter in defining a subgroup of *H pylori*-infected patients at increased risk of developing gastric adenocarcinoma. The difference between the rate of *H pylori* infection and more virulent strains can be explained by the fact that CagA antibodies persist for a longer time than *H pylori* IgG surface antibodies. Hence, relying on *H pylori* IgG antibodies alone might misclassify a significant proportion of patients who once had the infection[11].

The established epidemiological association does not prove that there is a direct causal relationship. Therefore, to further confirm a causal role, we are going to evaluate the effect of *H pylori* on the morphological changes of gastric mucosa in patients with precancerous gastric lesions.

In conclusion, seroprevalence of *H pylori* infection is high in patients suffering from gastric adenocarcinoma, which provides further evidence that searching for CagA status over *H pylori* infection might confer additional benefit for identifying populations at greater risk for this tumor.

Abstract

AIM: To investigate the possible involvement of 25-hydroxyvitamin D_3-1α-hydroxylase [1α-25$(OH)_2D_3$] in butyrate-induced differentiation in human intestinal cell line Caco-2 cells.

METHODS: Caco-2 cells were incubated either with 3 mmol/L butyrate and 1 μmol/L 25$(OH)_2D_3$ or with 1 μmol/L 1α-25$(OH)_2D_3$ for various time intervals ranging from 0 to 72 h. Additionally, cells were co-incubated with butyrate and either 25$(OH)_2D_3$ or 1α-25$(OH)_2D_3$. 1α-25$(OH)_2D_3$ mRNA was determined semi-quantitatively using the fluorescent dye PicoGreen. Immunoblotting was used for the detection of 1α-25$(OH)_2D_3$ protein. Finally, enzymatic activity was measured by ELISA.

RESULTS: Both butyrate and 1α-25$(OH)_2D_3$ stimulated differentiation of Caco-2 cells after a 48 h incubation period, while 25$(OH)_2D_3$ had no impact on cell differentiation. Synergistic effects on differentiation were observed when cells were co-incubated with butyrate and vitamin D metabolite. Butyrate transiently upregulated 1α-25$(OH)_2D_3$ mRNA followed by a timely delayed protein upregulation. Coincidently, enzymatic activity was enhanced significantly. The induction of the enzyme allowed for comparable differentiating effects of both vitamin D metabolites.

CONCLUSION: Our experimental data provide a further mechanism for the involvement of the vitamin D signaling pathway in colonic epithelial cell differentiation by butyrate. The enhancement of 1α-25$(OH)_2D_3$ followed by antiproliferative effects of the vitamin D prohormone in the Caco-2 cell line suggest that 25$(OH)_2D_3$ in combination with butyrate may offer a new therapeutic approach for the treatment of colon cancer.

INTRODUCTION

In addition to its well-known role in mineral and skeletal homeostasis, it is widely recognized that the physiologically most active molecular form of vitamin D_3, 1α-25$(OH)_2D_3$, also re-strains cell proliferation, induces differentiation, and apoptosis in a large variety of normal and tumor cells, including cells of the large intestine[1-3]. Most of the long-term pleiotropic actions of 1α-25$(OH)_2D_3$ are mediated by binding to a high-affinity vitamin D receptor (VDR)[3-5], which is a member of the nuclear hormone-receptor superfamily. The growth-restraining anticancer effects of vitamin D on colon cells are conveyed through genomic and post-genomic pathways involving a crosstalk with mediator synthesis and signaling, the mediation of a cell-cycle arrest, and finally the induction of apoptosis[6].

1α-25$(OH)_2D_3$, the active form of vitamin D, is enzymatically formed from its precursor 25$(OH)_2D_3$. The enzyme was thought to exist only in the kidney, until recently it has been identified in other non-renal tissues including the large intestine[7,8]. Further studies demonstrated that in colorectal cancer expression of 1α-25$(OH)_2D_3$ and VDR increases in parallel with ongoing proliferation in the early phase of tumorigenesis, whereas in poorly differentiated late-stage carcinomas only low levels of both genes can be detected[9-11]. It is postulated that through this upregulation, colorectal cancer cells become able to increase their potential for an autocrine counter-regulatory response to neoplastic cell growth in the early stages of malignancy. Thus, 1α-25$(OH)_2D_3$ theoretically represents a suitable target for the prevention of colorectal carcinogenesis.

Short-chain fatty acids, in particular butyrate, have been shown to inhibit growth in colon cancer cell lines. We

have previously shown that butyrate and 1α-25(OH)$_2$D$_3$ act synergistically in inducing differentiation of Caco-2 cells[12,13]. Furthermore, at least some of the anti-proliferative and pro-differentiating effects of butyrate are mediated via an upregulation of VDR with subsequent p21$^{Waf1/Cip1}$ expression[14]. These data prompted us to investigate a possible effect of butyrate on the expression of 1α-25(OH)$_2$D$_3$ in Caco-2 cells.

MATERIALS AND METHODS

Chemicals and supplies

Disposable cell culture was purchased from Nalge Nunc International (Wiesbaden, Germany). Dulbecco's modified Eagle's medium (DMEM), fetal calf serum (FCS), sodium pyruvate, nonessential amino acids, and PBS were obtained from GIBCO BRL (Eggenstein, Germany). Penicillin and streptomycin were obtained from Biochrom (Berlin, Germany). Butyric acid (sodium salt) was purchased from Merck-Schuchardt (Munich, Germany).

25(OH)$_2$D$_3$ and 1α-25(OH)$_2$D$_3$ were dissolved in ethanol (final maximal concentration of ethanol in medium was 1 mL/L to yield a 10 mmol/L stock solution, which was stored at -20 ℃). Butyric acid was dissolved in PBS (final maximal concentration of PBS in medium was 1 mL/L). Control experiments with either 0.1% ethanol or 0.1% PBS were performed to exclude effects of the solvents on the results of our investigations.

Cell culture

Caco-2 cells were obtained from the German Cancer Research Center (Heidelberg, Germany). The stock was maintained in 175-cm^2 flasks in a humidified incubator at 37 ℃ in an atmosphere of 95% air and 50 mL/L CO_2. The medium consisted of DMEM supplemented with 10% FCS, 1% penicillin/streptomycin, 1% sodium pyruvate, and 1% nonessential amino acids. The cells were passaged weekly using Dulbecco's PBS containing 0.25% trypsin and 1% EDTA. The medium was changed thrice per week. Passages 30-38 were used in all the experiments. Cells were screened routinely for possible contamination with mycoplasma by PCR at monthly intervals using the VenorGem mycoplasma detection kit (Minerva Biolabs, Berlin, Germany). For the experiments, the cells were seeded onto plastic cell culture wells in serum-containing medium and allowed to attach for 24 h. Before the treatment, the cells were synchronized in a medium containing 1% FCS. Cells were treated with 3 mmol/L butyrate, 1 μmol/L 25(OH)D$_3$, or 1 μmol/L 1α-25(OH)$_2$D$_3$ for various time intervals ranging from 0 to 72 h. Additionally, cells were co-incubated with butyrate and either 25(OH)$_2$D$_3$ or 1α-25(OH)$_2$D$_3$ or solvent.

Cytotoxicity

Cytotoxicity was assayed by measuring lactate dehydrogenase activity in a cell culture medium using a commercially available kit (LDH kit, Merck, Darmstadt, Germany).

Cell differentiation

Alkaline phosphatase activity was used to assess the differentiation of Caco-2 cells. Enzymatic activity was determined as previously described[12] using the Ecoline alkaline phosphatase assay kit (Merck, Darmstadt, Germany). Cellular protein was determined by Coomassie blue assay using a commercial kit (Bio-Rad Laboratories GmbH, Munich, Germany).

Analysis of 1α-25(OH)$_2$D$_3$ mRNA by semi-quantitative RT-PCR

RT-PCR was conducted with the Gene Amp/Perkin Elmer RNA PCR kit according to the manufacturer's protocol, starting from 2 μg total RNA. Amplification of glyceraldehyde-3-phosphate dehydrogenase (GAPDH) served as control. From the results of preliminary experiments, 20 PCR cycles for GAPDH and 30 cycles for 1α-25(OH)$_2$D$_3$ were selected as optimal amplification conditions to produce a log-linear relationship between the amount of each mRNA and intensity of PCR product. The PCR reaction contained 0.2 mmol/L dNTP and 2.5 U AmpliTaqGold DNA polymerase (Applied Biosystems, NJ, USA) and either 0.1 μmol/L primers for 1α-25(OH)$_2$D$_3$ or 0.2 μmol/L primers for GAPDH. The conditions of the reaction for 1α-25(OH)$_2$D$_3$ were: initial denaturation at 94 ℃ for 15 s followed by annealing at 59 ℃ for 30 s, extension at 72 ℃ for 60 s and a final extension at 72 ℃ for 7 min after the last cycle. The respective annealing temperature for GAPDH was 45 ℃. Primers for amplification were as follows: 1α-25(OH)$_2$D$_3$ sense 5' -CAGAGGCAGCCATGAGGAAC-3', 1α-25(OH)$_2$D$_3$ antisense 5'-GGGTCCCTTGAAGTGGCATAG-3; GAPDH sense 5'-GCACCGTCAAGGCTGAGAAC-3', GAPDH antisense 5'-CCACCACCCTGTTGCTGTAG-3'. The expected sizes of 1α-25(OH)$_2$D$_3$ and GAPDH were 440 and 803 base pairs (bp), respectively. Aliquots of the PCR mixtures (10 μL) were analyzed by electrophoresis using a 1% agarose gel containing 0.5 μg/mL ethidium bromide.

For semi-quantitative analysis of amplified PCR products, the fluorescent dye PicoGreen (Molecular Probes, Goettingen, Germany) was used according to the manufacturer's instructions[15,16]. Two microliters of amplified dsDNA in 100 μL TE buffer was mixed with an equal volume of diluted PicoGreen reagent (5 mL/L in TE buffer). Samples were incubated for 5 min at room temperature and protected from light in a microtiter plate. The fluorescence was measured (λ_{ex} = 485 nm; λ_{em} = 538 nm) in a Spectra Fluor Plus fluorometer from Tecan (Crailsheim, Germany). The standard curve for the quantitative analysis was obtained with λ DNA standard in TE buffer, being linear from 1 to 128 ng/well.

Immunoblot analysis of 1α-25(OH)$_2$D$_3$

For the analysis of 1α-25(OH)$_2$D$_3$ protein expression levels, an equal number of cells was directly lysed in cell lysis buffer (Cell Signaling Technology, Beverly, MA, USA) and aliquots of 5 μg protein in the loading buffer were separated by SDS/PAGE through a 12.5% Tris-HCl-precasted linear gradient gel (Bio-Rad GmbH, Munich,

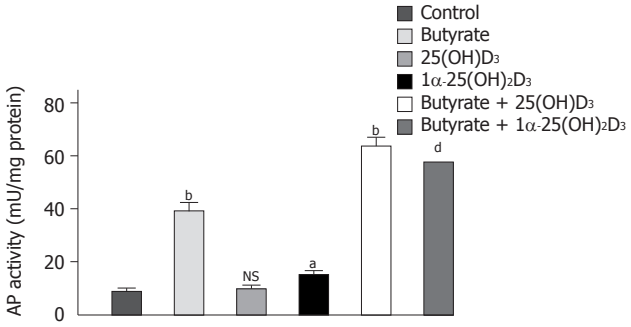

Figure 1 Effects of 1α-25(OH)$_2$D$_3$, 25(OH)$_2$D$_3$ and butyrate on differentiation of Caco-2 cells as assessed by AP activity. Cells were treated for 48 h with a medium supplemented with 10^{-6} mol/L 1α-25(OH)$_2$D$_3$, 10^{-6} mol/L 25(OH)$_2$D$_3$, 3 mmol/L butyrate, or with one of the combinations of butyrate (3 mmol/L) and 1α-25(OH)$_2$D$_3$ (10^{-6} mol/L) or butyrate (3 mmol/L) and 25(OH)$_2$D$_3$, (10^{-6} mol/L). Values are expressed as milliunits of AP activity per milligram cellular protein. ^{a}P<0.05; ^{b}P<0.01; ^{d}P<0.001; NS: non significant.

Germany) and electroblotted onto protran nitrocellulose transfer membranes (Schleicher & Schuell Bioscience, Dassel, Germany). The transfer efficiency was visualized using prestained molecular weight protein standards (Bio-Rad GmbH, Munich, Germany). Membranes were then soaked for 1 h at 25 ℃ in Tris-buffered saline (100 mmol/L Tris-HCl, pH 7.5, 150 mmol/L NaCl) containing 1 mL/L Tween 20 (0.1% TTBS) and 50 g/L dried nonfat milk. The membranes were subsequently washed (2×5 min) in 0.1% TTBS followed by an incubation for 90 min at 25 ℃ with a commercial sheep anti-murine 1α-25(OH)$_2$D$_3$ antibody (Binding Site Limited, Birmingham, UK) at a dilution of 1:500. After washing, the blot was incubated for 1 h at 25 ℃ with a horseradish peroxidase-linked donkey anti-rabbit antibody (Santa Cruz Biotechnology Inc., Santa Cruz, CA, USA) at a dilution of 1:1 000 in 0.1% TTBS and 20 g/L dried nonfat milk. The washing steps were repeated and subsequently enhanced chemiluminescence detection was performed according to the manufacturer's instructions (ECL Plus, Amersham Biosciences, UK). SDS-PAGE immunoblots were quantitated using a luminescent image scanner Desaga CabUVIS and ProViDoc software (Desaga, Wiesloch, Germany).

1α-25(OH)$_2$D$_3$ activity

Cells were seeded (10^6 cells/well/mL) in RPMI medium in a six-well plate. After incubation for 24 h with 5×10^{-8} mol/L 25(OH)$_2$D$_3$, the supernatant and cells were harvested. 1α-25(OH)$_2$D$_3$ was separated from other vitamin D metabolites by extraction columns (J.T. Baker, Phillipsburg, NJ, USA) and determined with a commercially available enzyme-linked immunosorbent assay (Immundiagnostik, Bensheim, Germany), being specific for 1α-25(OH)$_2$D$_3$ and unable to recognize other vitamin D metabolites.

Statistical analysis

All data were expressed as mean±SD. One-way ANOVA was used to compare means. P<0.05 was considered statistically significant.

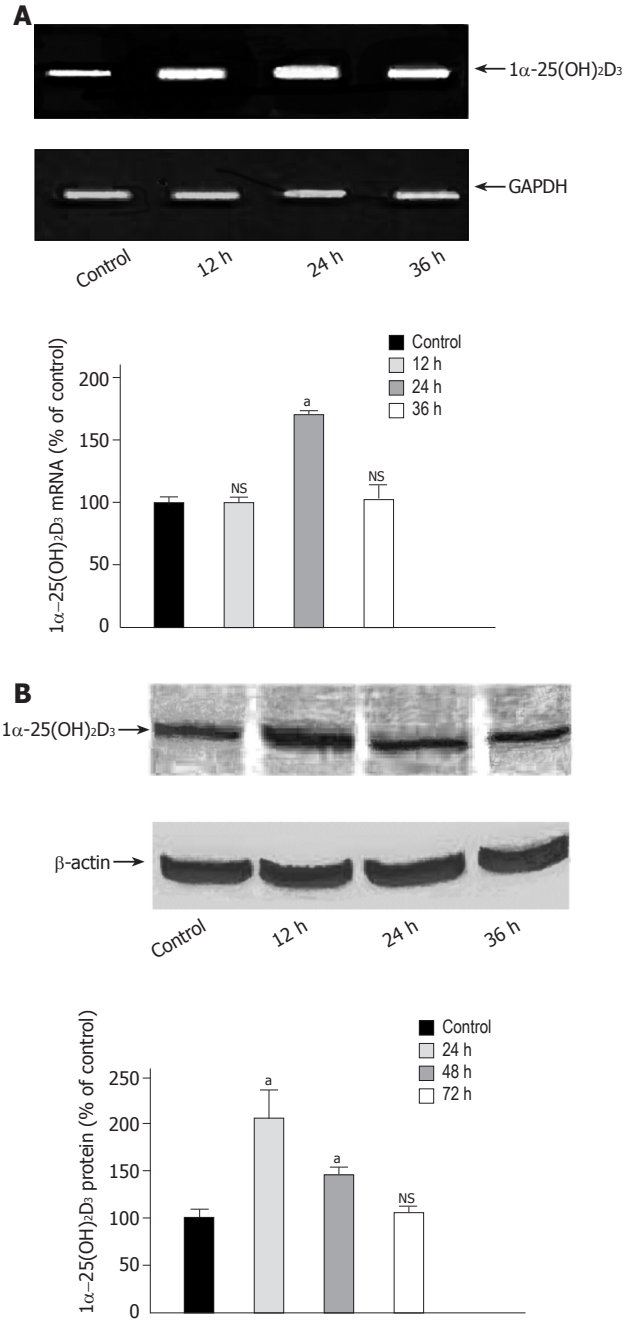

Figure 2 Time-dependent effect of butyrate on 1α-25(OH)$_2$D$_3$ expression. **A**: Caco-2 cells were grown for 36 h in serum-free medium in the absence (lane 1) or presence of butyrate (3 mmol/L) (lanes 2-4). 1α-25(OH)$_2$D$_3$ mRNA was analyzed by semiquantitative RT-PCR with the fluorescent dye PicoGreen. **B**: Caco-2 cells were treated for 72 h in the absence (lane 1) or presence of butyrate (3 mmol/L) (lanes 2-4) and then harvested for immunoblot analysis. The band at approximately 55 ku corresponds to 1α-25(OH)$_2$D$_3$ protein. Quantitation of protein was performed using a luminescent image scanner. ^{a}P<0,05 *vs* control; NS: non significant.

RESULTS

Influence of active vitamin D forms on butyrate-induced cell differentiation

After any cytotoxicity of either substrate was ruled out (data not shown), the influence of the two active vitamin D forms, 25(OH)$_2$D$_3$ and 1α-25(OH)$_2$D$_3$, on butyrate-induced

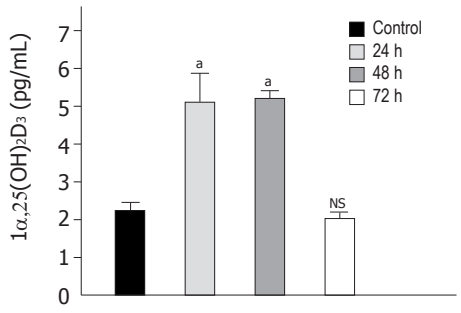

Figure 3 Time-dependent effect of butyrate on 1α-25(OH)$_2$D$_3$ activity. Caco-2 cells were treated for 72 h in the absence (lane 1) or presence of butyrate (3 mmol/L) (lanes 2-4) and then harvested for ELISA. Values are expressed as pg/mL of 1α-25(OH)2D3. [a]*P*<0,05 *vs* control; NS, non significant.

cell differentiation was determined. Figure 1 displays the individual and combined effect of butyrate, 25(OH)$_2$D$_3$ and 1α-25(OH)$_2$D$_3$ on AP activity. As compared to control, butyrate and 1α-25(OH)$_2$D$_3$ significantly stimulated differentiation of Caco-2 cells after a 48-h incubation period, the effect of butyrate being much more prominent (436±27% *vs* 70±7%, respectively). In contrast, 25(OH)$_2$D$_3$ had no impact on cell differentiation. Synergistic effects on differentiation were observed when Caco-2 cells were co-incubated with butyrate and either vitamin D metabolite. In this case, AP activity increased to 633± 7% (butyrate+25(OH)$_2$D$_3$) and 702±107% (butyrate+1α-25(OH)$_2$D$_3$) as compared to control.

Effect of butyrate on 1α-25(OH)$_2$D$_3$ expression

The above mentioned data suggested a possible impact of 1α-25(OH)$_2$D$_3$ mRNA on the synergistic potential of butyrate and vitamin D forms in inducing colonic epithelial cell differentiation. We therefore investigated 1α-25(OH)$_2$D$_3$ mRNA expression in Caco-2 cells treated with butyrate. As shown in Figure 2A, butyrate led to a transient increase of 1α-25(OH)$_2$D$_3$ mRNA by 67.3± 27% as compared to control after 24 h, which returned to basal values after 36 h. Induction of gene expression was increased after 24 h and gradually decreased thereafter (Figure 2B).

Effect of butyrate on 1α-25(OH)$_2$D$_3$ enzymatic activity

We finally assessed whether induction of 1α-25(OH)$_2$D$_3$ mRNA and protein was accompanied with an increased enzymatic capacity of Caco-2 cells. Enzymatic conversion into the active metabolite 1α-25(OH)$_2$D$_3$ was enhanced by a factor of 2.3±0.6 after 24 and 48 h of treatment with 3 mmol/L butyrate as compared to control (Figure 3).

DISCUSSION

The present report provides further experimental evidence that butyrate-induced colonic epithelial cell differentiation at least in part is mediated by the vitamin D signaling pathway. Our data demonstrate that butyrate treatment of the Caco-2 cell line results in an upregulation of gene and protein expression of 1α-25(OH)$_2$D$_3$, followed by an increased enzymatic activity with conversion of 25(OH)$_2$D$_3$ to 1α-25(OH)$_2$D$_3$. The induction of this enzyme then allowed for the matchable differentiating effects of 25(OH)$_2$D$_3$ in comparison to 1α-25(OH)$_2$D$_3$, thereby presenting a possible new chemopreventive mechanism in colon cancer.

We and others have previously shown that some of the antineoplastic effects of the short-chain fatty acid butyrate in colonic epithelial cells are operated by synergistic actions with 1α-25(OH)$_2$D$_3$. It has been demonstrated in various colonic cancer cell lines that butyrate and 1α-25(OH)$_2$D$_3$ act synergistically in reducing proliferation and enhancing differentiation[13,14,17,18]. One molecular mechanism participating in this interplay represents the upregulation of VDR expression, followed by a stimulation of the negative cell cycle regulator p21$^{Waf1/Cip1}$ and a downregulation of cyclins and cdks[12]. The alteration of the expression of a variety of genes as well as by inhibiting histone acetylase[19,20] and phosphorylation by enhancing nonhistone protein phosphorylation[21] and causing hypo- or hypermethylation of DNA[22,23] is the other known molecular mechanism by which butyrate mediates its antitumor effects. Similar additive antiproliferative effects of vitamin D with other histone deacetylation inhibitors such as TSA have also been described in a non-malignant epithelial breast cell line[24].

Evidence from a variety of experimental studies, epidemiological findings and a few human clinical trials indicate that vitamin D can modulate and inhibit carcinogenesis[6]. Vitamin D activity in epithelial cells involves the conversion of 25(OH)$_2$D$_3$ to 1α-25(OH)$_2$D$_3$ during the interaction of 1α-25(OH)$_2$D$_3$ with VDR. Subsequently, activation of VDR leads to repression or activation of specific proto-oncogenes or tumor-suppressor genes that are related to proliferation and differentiation in a large variety of normal and tumor tissues including the small and large intestine[1–5,25]. In addition, post-genomic pathways also seem to be involved in growth regulation. VDR seems to undergo specific alterations in expression during the development and progression of colon cancer. Compared to normal colon mucosa, VDR density is increased in hyperplastic polyps and in early stages of tumorigenesis, but declines in late-stage neoplasia[9-11]. As a further support to this stage-dependent expression, Belleli *et al*[26] found that the number of 1α-25(OH)$_2$D$_3$-binding sites is significantly decreased in the colon of carcinogen-treated rats.

1α-25(OH)$_2$D$_3$ is believed to exist solely in the kidney and it has also been identified in other non-renal tissues including the large intestine[7,8].

Due to its higher affinity to VDR, 1α-25(OH)$_2$D$_3$, the active form of vitamin D, is about 500-1 000-fold more active than its precursor 25(OH)$_2$D$_3$. Though there exists a large body of evidence, that 1α-25(OH)$_2$D$_3$ exerts pleiotropic antitumor effects against several malignancies *in vitro*, its clinical use as a chemopreventive agent is limited by hypercalcemia. For example, the concentrations of

1α-25(OH)$_2$D$_3$ required to inhibit colon cancer in tissue culture are in the range of 10^{-6}-10^{-9} mol/L[27-29]. Therefore, several groups have searched for other vitamin D-related anti-neoplastic therapeutic strategies. Recently, Schwartz *et al*[30] have demonstrated not only the expression of 1α-25(OH)$_2$D$_3$ and VDR in normal and malignant pancreatic tissue but also antiproliferative effects of the prohormone 25(OH)D$_3$[30]. Furthermore, prostatic 1α-25(OH)$_2$D$_3$ has been found to be largely unregulated by serum levels of parathyroid hormone and calcium[31]. Due to the large therapeutic window of 25(OH)$_2$D$_3$ compared to 1α-25(OH)$_2$D$_3$, the authors concluded that 25(OH)$_2$D$_3$ could play a role in the prevention of both pancreatic and prostate cancers. In our experimental setting, 25(OH)$_2$D$_3$ was not able to exert antiproliferative effects in Caco-2 cells as a result of the weak expression of 1α-25(OH)$_2$D$_3$. However, the induction of this enzyme by butyrate provoked the same impact on the differentiation of this colon cancer cell line as 1α-25(OH)$_2$D$_3$. Whether these activities are specific for Caco-2 cells or represent tissue-specific peculiarities of colonic epithelium has to be determined.

Abstract

AIM: To investigate the use of PCR and DGGE to investigate the association between bacterial translocation and systemic inflammatory response syndrome in predicted severe AP.

METHODS: Patients with biochemical and clinical evidence of acute pancreatitis and an APACHE II score ≥ 8 were enrolled. PCR and DGGE were employed to detect bacterial translocation in blood samples collected on d 1, 3, and 8 after the admission. Standard microbial blood cultures were taken when there was clinical evidence of sepsis or when felt to be clinically indicated by the supervising team.

RESULTS: Six patients were included. Of all the patients investigated, only one developed septic complications; the others had uneventful illness. Bacteria were detected using PCR in 4 of the 17 collected blood samples. The patient with sepsis was PCR-positive in two samples (taken on d 1 and 3), despite three negative blood cultures. Using DGGE and specific primers, the bacteria in all blood specimens which tested positive for the presence of bacterial DNA were identified as *E coli.*

CONCLUSION: Our study confirmed that unlike traditional microbiological techniques, PCR can detect the presence of bacteria in the blood of patients with severe AP. Therefore, this latter method in conjunction with DGGE is potentially an extremely useful tool in predicting septic morbidity and evaluating patients with the disease. Further research using increased numbers of patients, in particular those patients with necrosis and sepsis, is required to assess the reliability of PCR and DGGE in the rapid diagnosis of infection in AP.

Pearce CB, Zinkevich V, Beech I, Funjika V, Ruiz AG, Aladawi A, Duncan HD. Using the polymerase chain reaction coupled with denaturing gradient gel electrophoresis to investigate the association between bacterial translocation and systemic inflammatory response syndrome in predicted acute severe pancreatitis. *World J Gastroenterol* 2005; 11(45): 7142-7147 http://www.wjgnet.com/1007-9327/11/7142.asp

INTRODUCTION

Infection and septic complications are the major factors contributing to the poor outcome in acute severe pancreatitis. They cause up to 80% of deaths and occur in 5-10% of patients[1-3]. It is thought that in the majority of cases infection is caused by bacterial translocation from the gut lumen[4-7], a hypothesis which animal experiments have generally supported[8-10]. Unfortunately attempts to confirm the link between bacterial translocation and morbidity and mortality in acute pancreatitis in human beings have been largely unsuccessful[11,12].

Conventional microbiological blood culture methods are currently used widely[13-15], but may fail to yield positive results, if the causative organism is fastidious in nature, cell dependent or has a fungal etiology. It is thought that 60-70% of the bacteria in the human intestinal tract cannot be cultured[16,17]. Molecular-based diagnostic approaches are therefore being increasingly employed, especially when a quick diagnosis is required[18-21].

The use of the polymerase chain reaction (PCR) to identify microbial DNA in clinical specimens has been described by many investigators[22-25]. PCR using 16S rRNA-specific primers has identified bacterial DNA in blood after the surgery[26]. 16S rRNA is a highly conserved region of bacterial DNA, found in all Gram-positive and Gram-negative bacteria[27]; if these primers are used, the majority of pathogenic bacteria can theoretically

be detected and identified by subsequent cloning and sequencing. From a practical point of view blood cultures can take days to yield a result, whereas PCR can produce results within hours.

PCR without subsequent cloning can identify the bacterial genus leaving the species undefined, which may cause difficulties, for instance, if the therapeutic guidelines for the species are different. Polymicrobial infections can also be problematic due to the inability of PCR to identify several microorganisms in a single specimen[28]. These problems can be solved by denaturing gradient gel electrophoresis (DGGE)[27], which uses the presence of unique heterodiplexes in DNA affecting migration to separate different DNA fragments[29].

Our investigation was carried out to assess the potential of PCR and DGGE as rapid tools for the detection and identification of systemic bacterial translocation in blood samples of patients with acute severe pancreatitis. The study also aimed to elucidate the relationship between the presence or absence of clinical infection; manifested as either sepsis or infected necrosis, and the detection of translocated bacterial DNA.

MATERIALS AND METHODS

Sample collection and subjects

Patients who were admitted with a diagnosis of acute pancreatitis predicted to have severe disease during the study period were enrolled. Patients were only considered if their duration of symptoms was 48 h or less on admission. Pancreatitis was defined as appropriate clinical signs and symptoms with hyperamylasemia of more than three times the upper limit of normal. Patients predicted to have severe disease were identified by an APACHE II score of eight or more on admission[30].

Blood samples were taken on d 1, 3, and 8 of admission for examination by PCR and DGGE techniques. Standard microbial blood cultures were taken only when there was a clinical evidence of sepsis or when felt to be clinically indicated by the supervising team to limit the number of venesections patients enrolled in the study would need to volunteer. The supervising teams were not aware of the PCR results.

Blood samples

Blood was transferred from Na_2 EDTA tubes (Sigma, UK) to sterile 1.5 mL Eppendorf tubes (Sigma, UK), and purified using the QIAamp DNA Blood Mini Kit (Qiagen, Hilden, Germany), according to the manufacturer' s instructions. Whole blood samples were processed in aliquots of 400 μL for DNA extraction.

DNA extraction

The DNA from human blood samples and from different bacterial strains was purified, and bacterial DNA was amplified using PCR with primers specific for (i) the bacterial 16S rRNA region, (ii) *E coli,* and (iii) *Bacteroides* spp., as outlined below. Enzymatic amplification for DGGE was performed on human blood samples tested PCR positive for the presence of bacterial DNA.

Bacterial cells

Prior to DNA extraction, bacterial cells were cultured in LB medium (10 mL) overnight at +37 ℃ inside an incubator shaker (New Brunswick Scientific). Chromosomal DNA was extracted using the QIAGEN Genomic DNA Purification Kit (QIAGEN, Hilden, Germany), according to the manufacturer's instructions.

Oligonucleotide primers for PCR

The oligonucleotide primers were synthesized by Sigma Aldrich Co. The primer pairs, sequences, gene targets and size of the product amplified after PCR are listed in Table 1. The primer pair designated BD-1 and BD-2 is specific for a highly conserved region of different bacterial DNA coding for 16S ribosomal RNA. The second primer pair BG-1 and BG-4 was derived from the β-galactosidase gene of *E coli*, which is found in most *E coli* strains. The third primer pair used BFR-1 and BFR-2 targets specifically for the ubiquitous glutamine synthase gene found in many *Bacteroides* spp[26]. The fourth primer pair F3 and Rev 2 was used for amplification of variable V3 region of 16S rDNA gene[29].

Microbial DNA amplification by PCR

PCR was performed with minor modification following the protocol of Kane *et al*[26]. Extracted DNA (20-30 μL) was placed in 0.5 mL sterile Eppendorf tube to which the

	PCR	Negative		Negative			

NB: patient no. 6 was discharged before d 8. Patient no. 5 was treated with antibiotics on d 2.

PCR reaction mixture was added to make a final volume of 50 μL per tube. The mixture consisted of the following: 5 μL of 10× PCR reaction buffer, 1 μL each of (10 μmol/L) designated primers, 1 μL of a mixture of 10 mmol/L deoxynucleotide triphosphate (dNTP), 0.2 μL of 1 unit/μL Super Taq DNA polymerase (HT Biotechnology Ltd) and nuclease free dH_2O (Sigma Chemical Ltd) up to the final volume.

PCR amplification was carried out using a Techne (Progene) machine through the cycles as follows: an initial cycle of 95 ℃/3 min, 60 ℃/45 s, and 72 ℃/10 min was followed by 35 cycles of 95 ℃/45 s, 60 ℃/45 s, and 72 ℃/1 min; an extension period of 72 ℃/10 min completed the cycling sequence.

PCR amplification of 16S rDNA fragments for DGGE

Enzymatic amplification for DGGE was performed on samples positive for bacterial DNA. PCR reaction quantifications were outlined as above. The amplification was performed as follows: an initial cycle of 95 ℃ for 15 min was followed by 35 cycles each of 1 min at 94, 60, and 70 ℃, respectively; an extension period of 72 ℃ for 5 min completed the cycling sequence.

Agarose gel electrophoresis

All PCR products were separated by electrophoresis on 1% agarose gel in 1× TAE buffer (0.04 mol/L Tris-acetate, 0.002 mol/L EDTA). The gels were stained with ethidium bromide (0.5 μg/mL) for 30 min, washed twice with distilled H_2O and photographed under UV light using a UVP gel documentation system. A 1-kbp DNA ladder (Sigma) was used as a molecular weight marker. All reagents were purchased from Sigma, UK.

DGGE analysis

DGGE was performed using Ingeny Phos system (Leiden, The Netherlands). A 10 μL volume of each PCR product was applied directly onto 9% (wt/vol) polyacrylamide gels in 0.5× TAE (20 mmol/L Tris-acetate, 10 mmol/L sodium acetate, 0.5 mmol/L Na_2-EDTA) with gradients which were formed with 9% (wt/vol) acrylamide, 37:1) and which contained 0 and 100% denaturant [7 mol/L urea (GIBCO BRL)] and 40% (wt/vol) formamide. The gel was subjected to 200 V for 10 min at 60 ℃ and 85 V for 16 h. After electrophoresis, the gel was stained in ethidium bromide solution (0.5 μg/mL) for 30 min, washed twice by distilled H_2O and analyzed under UV light using UVP gel documentation system.

Blood cultures

Conventional blood cultures were processed using the BacT/ALERT® system manufactured by BioMerieux©. BacT/ALERT® aerobic (SA) and anaerobic (SN) culture media bottles were taken peripherally from patients under aseptic conditions and a BacT/ALERT® 3D analyzer was used to process the samples. Positive samples were Gram stained, and subcultured onto appropriate solid culture media, which was examined at 24 and 48 h.

Ethics

The study was performed as part of a larger study into enteral nutrition in acute pancreatitis. Written informed consent was a condition of entry into the study. The local ethics committee (Portsmouth, Hampshire, UK) approved the study.

RESULTS

Of the six patients tested one developed septic complications; pneumonia, respiratory failure and severe systemic inflammatory response syndrome, although this patient subsequently made a full recovery (patient

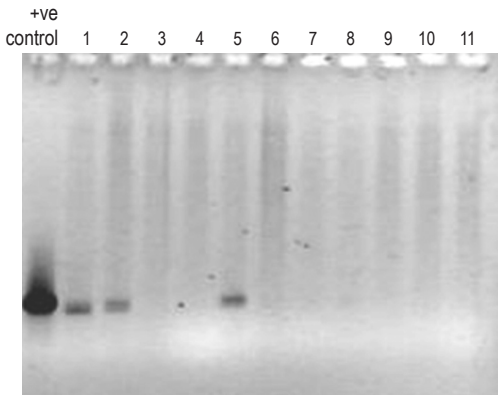

Figure 1 PCR profiles of total DNA recovered from human blood samples and of *E coli* DNA (control) obtained using primers BD1 and BD2 specific for bacterial 16S rRNA region. Positive control: Chromosomal DNA from *E coli*. Lanes 1-11: total DNA extracted from human blood samples.

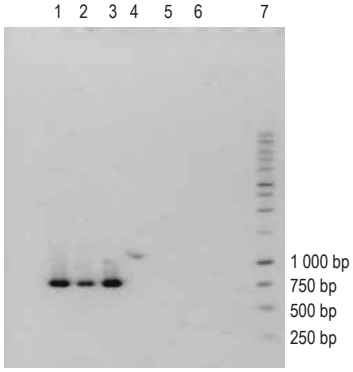

Figure 2 PCR profile of *E coli* chromosomal DNA. Lanes 1-3: DNA amplified using primers BG1 and BG4 specific for *E coli*. Lanes 4-6: DNA amplified using primers BFR1 and BFR2 specific for *Bacteroides* spp. Lane 7: 1 kb standard DNA ladder.

no. 5, Table 2). This was the only patient in the group that retrospectively developed severe acute pancreatitis according to the Santorini Consensus definitions[31]. This patient did not, however, require ventilatory support, and did not develop necrosis, infected or otherwise. The other patients had uneventful illness.

PCR detected the presence of bacteria in 4 of the 17 samples (23.6%). The blood samples from the patient with sepsis tested PCR-positive for bacterial DNA in specimens collected on d 1 and 3. This patient had three sets of standard blood cultures taken on d 1, 3, and 5, all of which were negative; he/she was the only patient in our study in whom standard blood cultures were taken.

When the incidence of the systemic inflammatory response syndrome (SIRS), C-reactive protein (CRP) levels and septic complications were compared with the PCR results there was no observed correlation between the presence of bacterial DNA in the blood, as confirmed by PCR, and SIRS or CRP data (Table 2).

The PCR profiles of DNA recovered from human blood samples and of *E coli* DNA (positive control), treated with general bacterial primers (Table 1) are depicted in Figure 1 (lanes 1 and 2-13, respectively). The appearance

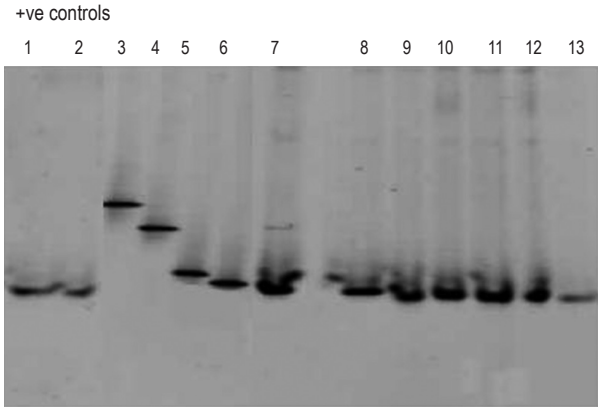

Figure 3 DGGE profiles of the amplified region of bacterial DNA coding for 16S rRNA using primers F3 and Rev 2. Positive controls: Lane 3. *Staphylococcus aureus*; Lane 4. *Pseudomonas aeruginosa*; Lane 5. *Bacillus cereus*; *Lane* 6. *E coli*; Lanes 1-2 and 7-13: bacterial DNA present in human blood samples.

of characteristic bands indicative of the presence of bacterial DNA (lane marked positive control) can be seen in human blood samples (lanes 1-11). Figure 2 (lanes 1-6) illustrates the profile of *E coli* DNA obtained using two different pairs of primers (Table 1); one pair specific only for *E coli* (lanes 1-3) and another pair for *Bacteroides* spp. (lanes 4-6, negative control). The treatment of *E coli* DNA with *Bacteroides* specific primers resulted in a blank PCR profile (i.e. no bands were observed in lanes 4-6), while the use of *E coli* specific primers resulted in the appearance of characteristic PCR product (lanes 1-3).

Human blood samples treated with *Bacteroides* specific primers did not reveal any bands when subjected to PCR (data not shown).

Subsequent analysis employing DGGE (Figure 3, lanes 1-13) revealed that the blood samples which tested PCR positive for bacterial DNA (lanes 1-2 and 7-13) contained DNA fragments of the identical size as the one characteristic for *E coli* DNA (lane 6). DGGE profiles of DNA from bacterial strains, such as *Staphylococcus aureus* (lane 3), *Pseudomonas aeruginosa* (lane 4) and *Bacillus cereus* (lane 5) served as negative controls.

DISCUSSION

These results from our preliminary investigation reveal that although conventional blood cultures techniques fail to demonstrate bacterial infection, using PCR and DGGE it is possible to detect bacterial DNA in the blood in patients with acute severe pancreatitis and also to identify the species present. The number of patients tested in the study is inadequate to make inferences regarding the connection between the presence of bacteria, systemic inflammatory response syndrome and morbidity.

Based on the obtained results it seems plausible to propose that the bacteria detected on d 1 and 3 in patient no. 5 were related to the infectious complications and sepsis. It is unlikely that the pneumonia was caused by *E coli* (sputum cultures were negative). The detection of bacterial DNA was probably indicative of a higher degree

of bacterial translocation, which led to other infections as well as the possible *E coli* sepsis. The positive PCR profile of blood samples taken on admission from patient no. 4 is also not surprising. This patient represented a case of relatively severe disease with a high CRP and probably also had bacterial translocation.

The DGGE profile of the samples from all the patients was exactly the same, i.e. positive exclusively for *E coli*. Interpretation of these results in view of the low numbers of subjects has to be treated with great caution, and it is not until more samples are taken from a larger cohort of patients that statistically valid interpretations can be offered.

To the best of our knowledge, prior to our study, reports on PCR detection of bacterial DNA in patients with acute pancreatitis are limited to two publications[11,12]; neither of these investigations used DGGE as a method of identifying bacteria.

Zhang *et al*[12] performed a PCR on blood specimens on patients only with acute necrotizing pancreatitis. They reported a PCR detection of bacterial DNA in 8 out of 22 tested samples (33.35%), but the samples were taken exclusively during periods of likely sepsis. The lower PCR positive rate of 23.6% in our study probably reflects the fact that blood specimens from patients were collected in a sequential fashion i.e. from the time of admission onwards, and from patients with predicted severe pancreatitis, rather than diagnosed necrotizing disease. Similarly to our study all of the positive blood samples tested were found to contain *E coli*.

Ammori *et al*[11] failed to find any bacterial DNA by performing PCR on blood samples from 26 patients with acute pancreatitis. Blood cultures that tested positive for bacterial infection revealed the presence of *E coli* and *Enterococcus* in blood of one patient, and coagulase negative *Staphylococcus* in the blood of another. The reasons for the negative PCR results reported by Ammori *et al*. are not clear, but may include contamination by substances which inhibit the polymerase reaction.

In acute pancreatitis it is perhaps what separates necrotizing from non-necrotizing disease and what differentiates infected necrosis from sterile necrosis which is of most interest. The controversy surrounding when to operate on necrotizing pancreatitis illustrates this[32-34]; a debate which centers on whether it is necessary to prove infection before operative therapy. The diagnosis of infection is not straightforward, and the currently recommended method of diagnosis, i.e. needle aspiration[34], carries its own risk due to the inherent interventional nature of the procedure. It is possible that more sensitive non-invasive methods of detecting infection such as PCR could improve diagnostic accuracy.

The presence of *E coli* DNA in blood specimens does not necessarily mean that the intestine is the source of infection. It is conceivable that these organisms arose from, for example, the biliary tract due to cholangitis. Moreover, the PCR detection method simply demonstrates the presence of bacterial DNA, and does not specify genera and species. DNA extraction methods provide total DNA that could originate from dead or living microorganisms in the blood or microbes that have been engulfed, or subsequently released by the phagocytes. This approach cannot differentiate between controlled and invasive infections.

The importance of PCR techniques with respect to clinical application will depend on establishing a relationship between the presence or absence of clinical infection and the presence of bacterial DNA in the blood. The PCR detection of bacterial DNA may provide information about the nature of the inflammatory response in acute pancreatitis when traditional methods fail to detect bacteria, even in the absence of culture-positive complications. This type of research may also reveal more about the nature of susceptibility towards infective complications in pancreatitis. In addition, the sensitivity and accuracy of PCR could help target antibiotic therapy in the future.

It is anticipated that in a cohort study including patients with sepsis or septic necrosis, and with the development of more sophisticated quantitative PCR techniques, the proposed approach could offer considerable diagnostic potential.

Abstract

AIM: To study the association of gastro-esophageal reflux disease (GERD) with the absence from work and to estimate the extent of loss in gross domestic product due to inability to work.

METHODS: Analysis was based on the prospectively gathered data of a large European cohort study involving 6 215 symptomatic GERD patients (ProGERD). Among these patients, 2 871 were initially employed. The calculation of the loss of gross domestic product was based on the assumption that the prevalence of GERD was about 15% in Germany. According to the German Federal Statistical Office, the mean gross wage of employees was 150 €/d in 2002.

RESULTS: The data of 2 078 employed patients who were prospectively followed up for over 2 years were analyzed. At study entry, the patients reported a mean of 1.8 d per year of inability to work. During the prospective follow-up under routine clinical care, the proportion of patients reporting days with inability to work decreased from 14% to 6% and the mean number of days per year with inability to work decreased to 0.9 d. Assuming a prevalence of troublesome GERD of 15% in the employed German population, the loss of gross domestic product amounted to 668 million €/year in Germany.

CONCLUSION: GERD causes a relevant impairment on the national economics by absence from work. The presented data demonstrate the importance of GERD, not only for patients and health insurance companies, but also for the community at large.

Key words: Gastro-esophageal reflux; Sick leave; Medical economics

INTRODUCTION

With a prevalence of 15-40%, gastro-esophageal reflux disease (GERD) is a common adult condition in Western countries[1-3]. GERD may be associated with a marked decrease in quality of life, a loss of productivity and impairment of daily activities[4]. In some patients symptoms may be severe enough to prevent the patient from going to work. The resulting decrease in working time is associated with a significant loss in productivity. In North America, up to 10% of GERD patients have to be absent from work[5,6] and the indirect costs in the USA caused only by time away from paid labor resulting from consumption of health care were 470 million US$ in 1998[7]. The complete costs of labor lost have to be borne by employers and/or health insurance companies, and there is an accompanying decrease in the gross domestic product. The aim of the present investigation was to estimate the extent of such losses on the basis of the data of a large prospective European trial in patients with symptomatic GERD.

MATERIALS AND METHODS

The ProGERD study is an ongoing prospective, multicenter cohort study comprising an initial treatment phase and a 5-year follow-up phase. Patients (n = 6 215) were recruited from centers (n = 1 253) in Germany (more than 90%), Austria and Switzerland. The majority of these patients were recruited by gastrointestinal specialists in private practice. The protocol of the study was designed to include half of the patients with erosive reflux disease (ERD) and half with non-erosive reflux disease (NERD). Barrett's esophagus was not an exclusion criterion and in 702 patients this condition was diagnosed. The patients were treated with esomeprazole for up to 8 wk, and in

the follow-up period at the discretion of their physicians. After 2 years of follow-up, 64% of the patients were still on proton pump inhibitor (PPI) medication (continuous PPI or on demand treatment).

At study entry and every year, the patients completed a standardized questionnaire that assessed demographic, medical, and social characteristics and quality of life. One section of the questionnaires dealt with the patient' s inability to work (IW) caused by reflux symptoms in the year prior to inclusion in the study and to the last year before the study visit. The patients were carefully instructed about the aims and the methods of the study, including repetition of the initial questionnaire. Further details of the ProGERD trial have been published elsewhere[8].

The most reliable assumption of the frequency of GERD in Europe was available from a large population-based telephone survey performed in 5 046 randomly chosen persons[1]. More than 1 000 persons per country (Germany, France, Italy, Sweden, and UK) were interviewed. Reflux symptoms occurred in 28% of German adults with about 58% of them claiming impaired quality of life. This means that the overall frequency of GERD is 16% in the entire adult population of Germany[9].

The number of overall IW days reported in the ProGERD trial was projected on the overall German employed population, based on the data from the German Federal Statistical Office. Germany has 82.5 million inhabitants and the labor force is composed of 36.5 millions, of whom some 33 millions are compulsorily insured. The mean gross wage of employees was 150 €/d in 2002.

In this study, the human capital method was used to calculate the indirect costs of GERD, a method that uses the full replacement costs independent of whether the worker is replaced or not[10]. We assumed a loss of the gross domestic product in the same amount of the whole mean gross wage of employees. The basis for the calculation of the decrease of gross domestic product was the number of IW days caused by GERD symptoms reported in the ProGERD trial.

We conducted an explorative analysis of potential patient-associated predictors (gender, age, BMI, consumption of alcohol, smoking, and severity of the GERD disease) of IW days using univariate statistics as appropriate. The level of significance was 5%.

RESULTS

Data about employment were available from 5 965 out of 6 215 patients (96.0%). At the beginning of the trial, 2 871 out of 5 965 (48.1%) patients were gainfully employed, 2 103 retired (35.3%), and 991 without employment (16.6%). After a 2-year follow-up period, the data about employment of 5 286 patients were available (2 312 employed, 2 097 retired, 877 without employment). We included the data of 2 078 patients who were gainfully employed and answered the respective questions about inability to work due to GERD at the initial visit and during the 2-year follow-up period. This excluded the data of those who lost their work or retired in the follow-up period or did not answer the questions at both time points of investigation.

Initially 14% of the employed patients were admitted retrospectively to IW due to reflux symptoms during the past year. During the 2-year follow-up period, the percentage decreased to 6% under routine clinical care. The mean number of IW days was 2.5/yr prior to inclusion in the study (mean value 2.5 d in 12 mo and adjusted with the exclusion of the weekend period: 1.8 d), and decreased to 1.2/yr during the prospective follow-up period (mean value 1.2 d in 12 mo and adjusted with the exclusion of the weekend period: 0.9 d). There was no significant relationship between IW and gender, age, BMI, consumption of alcohol, smoking, and severity of GERD. In Germany, the labor force is composed of 36.5 millions, of whom some 33 millions are compulsorily insured. The mean gross wage of employees is 150 €/d (source: German Federal Statistical Office 2002). Based on the human capital method for calculating costs of illness, the total loss of gross domestic product is shown in Tables 1 and 2 assuming different frequencies of GERD in the labor force. Table 1 shows the retrospective data before entering into the follow-up period, and Table 2 lists the prospective data after the 2-year follow-up period.

Table 1 Loss of gross domestic product due to inability to work (IW) in patients with untreated GERD in Germany on the basis of three different frequency assumptions

Prevalence of GERD in the adult population	10%	15%	20 %
Total days of inability to work	5.9 million	8.9 million	11.9 million
Loss of gross domestic product	891 million €	1.34 billion €	1.78 billion €

Table 2 Loss of gross domestic product due to inability to work (IW) in patients with GERD under routine clinical care in Germany on the basis of three different frequency assumptions

Prevalence of GERD in the adult population	10%	15%	20 %
Total days of inability to work	2.97 million	4.46 million	5.94 million
Loss of gross domestic product	446 million €	668 million €	891 million €

DISCUSSION

ProGERD is a large prospective cohort study designed to examine the endoscopic and symptomatic progression of GERD in routine care as well as the economic burden of the disease. With more than 6 000 included patients, the study is the largest prospective clinical trial in this field and could answer several questions on a high level of confidence. The influence of GERD on the gross

domestic product, being part of the indirect costs of the disease, was estimated in this analysis. On the basis of these data, the total costs of the economy of GERD, due to loss of gross domestic product were reliably assessable. Assuming a prevalence of 15% of the disease in the employed German population, costs amounted to 668 million €/yr under routine clinical care. The costs in the same population were twice as high in the year before entering the trial. These calculations highlight the great economic importance of GERD, which is not only a problem for patients and health insurance companies, but also has a major impact on the community at large. The total loss of gross domestic product estimated by our analysis was, for example, close to the total yearly PPI sales of 842 million € in Germany in 2003[11].

Our calculation was based on the human capital method for calculating the costs of illness. Another approach to calculating indirect costs is the friction cost method, which measures the amount of production lost due to the disease based on the time span organizations needed to restore the initial production, so that production losses are assumed to be confined to the period needed to replace a sick worker[10]. A stated advantage of the friction cost method is that, unlike the human capital method, it takes into account the fact that employees with long-term illness or disabilities can be replaced in markets with less than full employment. There is no general agreement on whether the human capital or friction cost method is more valid for measuring the productivity costs of illness. Long-term sick leave due to GERD symptoms is probably rare-none of the patients included in the ProGERD study reported long-term sick leave because of GERD symptoms during the prospective follow-up period-and replacement of the worker is an exceptional event. Therefore, the human capital method might be the more reliable approach. Even assuming more conservative estimates of indirect costs based on the friction cost method, GERD is certainly still associated with a considerable social and economic burden.

As expected, only a limited portion of about 14% of the GERD patients even got admitted to IW caused by reflux symptoms. The symptoms are mostly mild to moderate, though the quality of life in patients with GERD is markedly decreased[12], the level is comparable to other chronic or even life-threatening diseases[13]. In the follow-up period, the portion of patients with IW declined to 6%. Other trials from the USA have reported partially a lower portion of 2-10%[5,6], suggesting that socioethical factors might influence the willingness to be absent from work.

The follow-up data indicated the effectiveness of the treatment of GERD in reducing the IW days. The mean number of IW days decreased from 2.5 to 1.2 in the 2-year observation period. The patients were treated in the follow-up period at the discretion of their physicians, and around two out of the three patients were still on PPI treatment after the 2-year follow-up period.

GERD is nowadays the disease with the highest direct costs in the USA (9.3 billion US$)[7]. European data are available from Sweden that includes the costs for dyspepsia and peptic ulcer disease. Therefore, it is difficult to compare them with our findings[14].

Our calculation of the loss of gross domestic product was based on the statement of the patients using a long recall period of one year, and it might result in an underestimation of disease-related absence from work. A recall bias on self-reported work productivity occurs more often already after a 4-wk recall period compared with a 2- or 1-wk recall period[15]. Therefore, our calculation can be considered as conservative, and the loss might be significantly higher. A recent study showed that the impact of GERD on the costs of reduced productivity is even higher compared to that on the costs of absence from work[16]. Therefore, it is highly possible that our calculation might further underestimate the overall loss of gross domestic product due to GERD, because we only referred to the IW days instead of estimating the reduced productivity.

The exact calculation of the indirect costs is somehow difficult. Typically indirect costs include costs associated with the lost or impaired ability to work or to enjoy leisure activities because of morbidity, the time required by the patient's family to receive medical care, and loss of future earning potential owing to premature death. Data about impaired ability to work due to GERD are insufficient. In a small cross-sectional study from the USA, about 41% of GERD patients reported that they have lost some work productivity[6]. The authors have reported here in addition that the time off for physician visits and reduced productivity are the most costly losses from GERD. Our main focus was on the additional part of costs due to absence from work.

The impact of GERD on the economy differs widely between different countries depending on several factors (like cultural, socioeconomic, and economical status). Nevertheless, our data clearly suggest that the loss of gross domestic product due to GERD-related IW days might be higher compared to the total sale volume of PPI in Western countries in general. Definite data on this topic are lacking. It would, therefore, be interesting to study the impact of effective pharmacotherapy not only on clinical symptoms and healing of lesions but also on the loss of productivity.

Abstract

AIM: To describe an Internet-based data acquisition facility for a European 10-year clinical follow-up study project of a population-based cohort of inflammatory bowel disease (IBD) patients and to investigate the influence of demographic and disease related patient characteristics on response rates.

METHODS: Thirteen years ago, the European Collaborative study group of IBD (EC-IBD) initiated a population-based prospective inception cohort of 2 201 uniformly diagnosed IBD patients within 20 well-described geographical areas in 11 European countries and Israel. For the 10-year follow-up of this cohort, an electronic patient questionnaire (ePQ) and electronic physician per patient follow-up form (ePpPFU) were designed as two separate data collecting instruments and made available through an Internet-based website. Independent demographic and clinical determinants of ePQ participation were analyzed using multivariate logistic regression.

RESULTS: In 958 (316 CD and 642 UC) out of a total number of 1 505 (64%) available IBD patients, originating from 13 participating centers from nine different countries, both ePQ and ePpPFU were completed. Patients older than 40 years at ePQ completion (OR: 1.53 (95%CI: 1.14-2.05)) and those with active disease during the 3 mo previous to ePQ completion (OR: 3.32 (95%CI: 1.57-7.03)) were significantly more likely to respond.

CONCLUSION: An Internet-based data acquisition tool appeared successful in sustaining a unique Western-European and Israelian multi-center 10-year clinical follow-up study project in patients afflicted with IBD.

Key words: Internet; Questionnaire; IBD; Cohort study; Population-based

INTRODUCTION

Data acquisition in multi-center epidemiological follow-up studies traditionally has been dependent on postal paper form questionnaires filled out by study subjects and on paper form extraction files for relevant medical information completed by physicians and/or research assistants. Great advantages of the use of the Internet as a platform for health status measurements have been reported since the mid-1990s[1]. Internet-based facilities supporting data acquisition in studies concerning patients with inflammatory bowel disease (IBD) have been performed from then onwards[2-4]. Traditionally, in multi-center studies, questionnaires in paper format are forwarded from patients and centers to central database-hosting facilities, where data are manually transformed

into electronic databases. This multi-step process is time- and labor-consuming and prone to errors. Paper form data acquisition utilities normally contain question flow instructions for study subjects and for physicians that can easily be misinterpreted resulting in missing or wrong answers. Furthermore, the physical transformation of large numbers of paper format data into an electronic database adds to the risk of human errors.

For the purpose of a large multi-center follow-up study of a European population-based cohort of patients with IBD[5], we created an Internet-based data acquisition facility, in order to avoid the above-mentioned methodological imperfections and to assure data quality. The design of the mentioned study as well as practical and technical details and implications of the new electronic instrument are described and discussed. The influence of demographic and disease-related patient characteristics on the patient questionnaire response rates is also analyzed.

History of the cohort

After 3 years of preparation, between October 1991 and September 1993, the European Collaborative study group of IBD (EC-IBD) gathered a population-based prospective inception cohort of 2 201 uniformly diagnosed IBD patients within 20 well-described geographical areas in 12 European countries[6]. Initially it was hypothesized that a North-South incidence gradient in IBD existed, which could be proved[5]. Later, in the context of this registry, a 1- and 4-year clinical follow-up[7,8] were studied, as well as the occurrence of rheumatologic manifestations[9] and the relationship between quality of care and quality of life[10].

The currently executed 10-year clinical follow-up study project was planned since 1998, granted by the European Commission, and was started in 2001.

MATERIALS AND METHODS

Materials

In order to optimize data acquisition in this European multi-center study project, electronic data acquisition tools were designed for Internet-based access. The development of the tools and the subsequent data management leading to an analyzable dataset involved a five-step process; (1) a "patient questionnaire" (PQ) and "physician per patient follow-up form" (PpPFU) were prepared as two separate data collecting instruments and originally constructed for the purpose of this study. The information obtained by the PQ was derived from direct questioning of the patients, whereas physicians and research assistants extracted data from patient files into the PpPFU. PQ items were demographics, life style factors, disease activity and use of medication, family history, data on pregnancy and fertility, health care consumption, disability, and quality of life (SF-36 was used). PpPFU items, as observed during the 10-year follow-up period, were vital status, cause of death, disease activity (change of immunosuppressive medication and surgical events were used as indicators due to the retrospective nature of data acquisition), disease location and behavior, use of medication, surgery, health care consumption, colorectal cancer, and dysplasia. Members of the original study group and additional investigators formed "working groups" to deal with various research topics of the follow-up, including genotype-phenotype, course of disease, pregnancy and fertility, cancer, health care consumption and costs, and dissemination of messages to the medical and lay public. A central body of senior representatives from the EC-IBD group constructed final comprehensive versions of both instruments based on the input of all the members of the working groups. The electronic patient questionnaire (ePQ) questions were translated into the nine languages of the participating countries by a professional translation agency and subsequently checked for correctness by a representative from every participating country from within the EC-IBD study group. For the PpPFU, the language used was English; (2) a tailor-made innovative high performance data entry application was designed, assuring maximum flexibility for programmers and users. The ePQ was designed by the construction of a questionnaire design module, where questions and answers could be directly introduced in different languages with needed routings. The final ePQ contained 747 questions and could be used in nine different languages including Hebrew. The electronic physician per patient follow-up form (ePpPFU) was designed to receive an unlimited number of entries on multiple topics on a 10-year time scale. Graphic design using simple colors in order to visually discriminate users' choices improved user friendliness; (3) the PQ questions and the PpPFU items, originally constructed on paper, were introduced into the electronic facilities. A pre-designed compulsive question flow was implemented in the ePQ. This implicated that patients filling in the ePQ were automatically guided towards a subsequent question, based on a given previous answer thus skipping irrelevant questions. Electronic guidance facilities concerning mandatory and optional fields were embedded in the ePpPFU. In this way, physicians and/or research assistants completing the ePpPFU of a particular patient were not allowed to close and finalize the document concerning an individual patient before having collected all the minimally required information; (4) the electronic data acquisition facilities were made available to all data collecting centers through a username-password secured and firewall protected Internet-based website. Links to ePQ statistics and ePpPFU statistic pages displayed real time counts of both instruments for all centers together showing instantaneous, comparative and cumulative progress of data inclusion, accessible to every member involved in the data inclusion of this project; (5) after completion of the data acquisition phase, export files from the Internet questionnaire program were imported into the database environment. The database was situated in Maastricht. Database validation took place at this center before the distribution of the final database to all working groups. The validation was done by logical comparison of the crude database with existing databases of previous EC-

IBD projects in terms of numbers of patients per center with known diagnosis, sex, age, and disease behavioral characteristics. The results of this data validation effort were summarized in a logbook that was distributed to all the project members for possible revisions that subsequently were implemented as changes in the database. Final data sets were available for analysis promptly after closing the data acquisition phase.

Methods

Before the start of the data collection, a minimally required response rate per center was set at 60% identification of the patients to have both ePQ and ePpPFU completed. Centers that did not comply with this minimum response rate were analyzed separately from those that did.

UC patients were grouped for disease location at diagnosis as: (1) rectum only; (2) rectum and sigmoid and/or descending colon; and (3) disease location beyond the splenic flexure. The CD patients were classified for disease location at diagnosis, according to the Vienna classification[11], into: (1) upper gastrointestinal (esophagus and/or stomach and/or duodenum and/or jejunum); (2) (terminal) ileum; (3) ileocolonic; and (4) colon only.

Independently, both demographic and clinical determinants of ePQ participation (diagnosis, gender, center, disease location at diagnosis, age at ePQ completion, and disease activity during 3 mo period previous of ePQ completion) were analyzed using univariate and multivariate logistic regression models. All potential predictors were included in both models. A $P \leqslant 0.05$ was considered to be statistically significant in the multivariate analysis. The statistical package for the social sciences (SPSS 11.5.1 for Windows; SPSS Inc., Chicago, IL, USA) was used for the analysis.

The Ethics Committees of all the participating centers approved the study protocol, and all subjects gave their informed consent before the start of the study.

RESULTS

During the data collection period from August 1st 2002 to January 1st 2004, the electronic data entry facilities appeared to be well-equipped and flexible tools for data entry and storage. However, the data export facility used in order to enable fast provision of stored data into formats prepared for analysis showed some initial deficiencies. Questions, answer categories and formal control rules, used for feedback during insertion, were not always automatically incorporated in the export process. This could, however, be repaired by the information management team.

All centers that originally participated in the EC-IBD cohort had been approached to take part in the follow-up study. Thirteen out of the original twenty centers distributed over nine countries participated. In 958 (316 CD and 642 UC) out of a total number of 1 505 IBD patients eligible for follow-up (64%), both ePQ and ePpPFU were completed (Table 1). When considering the entire cohort of both CD and UC patients, nine centers complied with the minimal 60% response threshold rendering 855 out of 1 141 patients (75%). Table 1 summarizes the details of the total number of IBD (both CD and UC) patients in the cohort. In the CD category, 10 of the participating 13 centers complied with the minimal 60% response threshold leaving 378 patients of whom 288 (76%)had completed both ePQ and ePpPFU (Table 2). In the UC category, nine centers complied leaving 776 patients of whom 575 (74%) had completed both instruments (Table 3).

Table 2 shows two Beer Sheeva patients indicated as "no IBD" in the ePQ, who were not classified as such in the ePpPFU. Review of available clinical data revealed that both patients have CD. An identical discrepancy concerning one Dublin patient in the "no IBD" category could not be clarified. This patient was considered to have CD. In the UC category (Table 3) divergences between ePQ and ePpPFU for patients indicated as "no IBD"

regarding one patient from Beer Sheeva and five patients from Oslo could not be clarified. These six patients were considered to have UC. Discrepancies between total numbers of patients for ePQ and ePpPFU also occurred because of Internet disruptions during the insertion process in the CD category regarding two patients from Heraklion (Table 2), and in the UC category regarding five patients from Heraklion, one from Oslo, one from Reggio Emilia, one from South-Limburg and one from Dublin (Table 4). The answers given by these patients were lost and these patients were excluded from the database. Disease location at diagnosis was known for 739 of 766 UC patients and 363 of 378 CD patients.

In the 60% of complying centers, 126 of 1 141 patients [11%] refused to participate without a large difference between the age groups (79/707 [11.2%] in patients older than 40 years at ePQ completion and 47/434 [10.8%] in patients equal to or younger than 40 years at ePQ completion). 10.7% of the patients lost to follow-up for the ePQ were indicated as untraceable. Of patients aged >40 years at ePQ completion, 56/707 [7.9%] could not be traced. In those ⩽40 years at ePQ completion, 66/434 [15.2%] of patients could not be traced.

In the UC patient group, age >40 years and in the combined CD and UC patient groups active disease recorded within 3 mo previous to ePQ completion were significant positive predictors of ePQ response. Gender, center, diagnosis, age at diagnosis and disease location showed no significant differences in ePQ response in centers that had complied with the 60% minimal ePQ

response in neither the uni- nor multivariate analyses. Details of the results of these analyses are displayed in Tables 4, 5, and 6.

Results of identical analyses performed in the patients of non-complying centers revealed no different viewpoints.

DISCUSSION

An Internet-based data acquisition tool sustaining a unique European multinational multi-center 10-year clinical follow-up study in patients afflicted with IBD appeared successful. User-friendly tailor-made software applications facilitated remote data inclusion, making it a one-step process, thereby minimizing the risk of human error, optimizing efficiency and convenience of the study effort and rendering continuous transparency of the project progress. The data management procedure made a reliable analyzable data set available promptly after the completion of the data acquisition phase. Overall 67% and 74% follow-up rates were observed for ePQ and ePpPFU, respectively. UC patients older than 40 years at the moment of ePQ completion and UC and CD patients with active disease in the 3 mo period previous to ePQ completion were significantly more likely to respond.

Does the use of Internet-based data acquisition instruments compare to or even outweigh the traditionally available methods? Some comparative studies are available in this field. In one study comprising UC patients, it appeared possible to use direct electronic mail contact to conduct follow-up research; response rates appeared to be related to the number of messages sent, the age of the recipients and the time since the initial contact[12]. The use of Internet tools in psychological research and Web-based assessments of personality constructs have proven to render outcome scores comparable to those of traditional

methods[13,14]. In one study the traditional paper-and-pencil questionnaire resulted in a higher number of errors compared with the Web-based questionnaire[15]. Two other studies compared several student populations that were similar in terms of age, gender, and racial backgrounds with regard to differences in outcome for Web-based and traditional questionnaires[16,17]. In these studies outcome scores of the Internet-based questionnaire and the traditional paper-and-pencil based questionnaires were not different. The time- and cost-effectiveness, convenience for both patients and researchers, the possibilities of immediate availability of data for analysis, and the structural prevention of missing data and incomplete responses by a priori programmed configuration, are important advantages related to the use of Internet-based data inclusion instruments as already discussed elsewhere[18,19].

The type of survey population addressed is of importance in this context. In open Web-based surveys, selection bias occurs due to the non-representative nature of the Internet population, and - more importantly - through self-selection of participants, also called as the 'volunteer effect'[18]. Furthermore, exact measurement of response rates is not possible, because the original size of the patient population is unknown. In quantitative epidemiological research, averages are measured of pre-defined patient populations, and therefore representative patient samples and adequate response rates are needed[20]. In the present study a finite 'closed' patient sample with known socio-demographic details was approached for follow-up for the fourth time in its disease history. In this way the exact response rate could easily be calculated. The patients could not log on to the username-password secured web site by themselves, but were guided by a project representative who assisted with the insertion procedure according to the patients' individual needs.

The patient group under study, being a population-based cohort, was representative by its nature. High follow-up rates were observed in the majority of the centers complying with the minimally required 60% response rate. This reduced selection bias. Thirteen of the original twenty EC-IBD centers participated in this FU study. The remaining seven had to refrain because of technical and/or logistic reasons. This did not jeopardize the population-based character of the study, since all participating centers had individually met the criteria for population based patient inclusion when the cohort was formed in the period of 1991-1993. In the present study, centers not reaching the minimally required 60% follow-up rate were analyzed separately acknowledging their effort and also securing the intent of overall population based methodology. The original population size of almost 930 000 inhabitants negatively influenced the follow-up rates in Dublin. The magnitude of the Irish project covering six university and six private hospitals made sufficient follow-up percentages, 10 years after the diagnosis, unrealistic. Most areas that reached the 60% follow-up rate threshold had original population sizes between 300 000 and 500 000 inhabitants, suggesting that this size enables successful long-term follow-up. Considering the broad European multi-center nature of this study and the fact that the entire patient population had been diagnosed 10 years earlier, the high response rates must be regarded as excellent.

UC patients who responded to the ePQ were significantly older than those who did not. This reflects most probably the higher dedication and availability of this age group compared to the younger patients. In the CD group, there was no difference between the age groups. The expected drop of response of the elderly because of supposed computer anxiety could not be confirmed in this study. Eleven percent of the patients indicated to have been lost to follow-up for the ePQ were in fact traced, but refused to participate without a difference between the age groups. The need of physical presence to complete the ePQ could explain at least part of the observed refusal rate. Furthermore, active disease within 3 mo period from ePQ completion was shown to be a clear positive predictor of ePQ participation in both UC and CD, and the majority of patients (1 073/1 162 [92.3%]) were in clinical remission during this period. Most probably, disease activity accompanies increased concern and increases motivation to participate. This observation could be an important factor of bias that has to be controlled for in the quality of life analyses planned in this project. 10.7% of the patients lost to follow-up for the ePQ were indicated to be untraceable. Patients equal to or younger than 40 years at ePQ completion were less likely to be traced, compared to those patients being older than 40 years at ePQ completion. This difference could be explained by the high mobility characteristic of younger people.

Apart from 11 occasions of system failure and some initial inconsistencies of the data export facility, this electronic facility appeared to be a well-equipped flexible tool for data entry and storage. Possibilities for an efficiency gain in terms of a better fit between Internet questionnaire application and the data management process had been described before[21] and could be confirmed in this study.

In conclusion, an Internet-based electronic data acquisition application successfully sustained a unique multinational multi-center study project in patients afflicted with IBD. The application has high potential for future use in follow-up studies of this cohort and could serve as a template for other multi-national follow-up studies.

Abstract

AIM: To explore the association of serum insulin, insulin resistance, and β-cell dysfunction with gallstone disease (GSD) in type 2 diabetics.

METHODS: We used a community-based study conducted between 1991 and 1993 in Kinmen, Taiwan to identify type 2 diabetics. A screening program for GSD was performed in 2001 by a panel of specialists who employed real-time ultrasound sonography to examine the abdominal region after the patient had fasted for at least 8 h. Screening was conducted in 2001 on 848 patients diagnosed with type 2 diabetes. The HOMA method was used to compare the profile differences for insulin resistance (HOMA IR) and β-cell dysfunction (HOMA β-cell).

RESULTS: We studied 440 type 2 diabetics who attended sonography check-ups. After excluding eight insulin-treated diabetics, the prevalence of GSD among the remaining 432 was 13.9% (26/187) among males and 14.7% (36/245) among females. After adjustment for other GSD-associated risk factors in addition to age and obesity, GSD risk increased among females with levels of serum insulin [4th *vs* 1st quartile odds ratios (OR) = 4.46 (95%CI: 1.71-11.66)] and HOMA IR [4th *vs* 1st quartile OR = 4.46 (95%CI: 1.71-11.66)]. Better HOMA β-cell function was significantly related to decreased risk of GSD [4th *vs* 1st quartile OR = 0.16 (95%CI: 0.03-1.70)]. Among males, age and central obesity were the most significant risk factors for GSD. No association of GSD with serum insulin, HOMA IR, and HOMA β-cell was observed among males.

CONCLUSION: Serum insulin, insulin resistance, and β-cell dysfunction are risk factors for GSD in females, but not males with type 2 diabetes.

INTRODUCTION

Clinically, type 2 diabetes with concomitant gallstone disease (GSD) increases the incidence of acute cholecystitis and has a higher probability for progression to septicemia. It is generally believed that subjects with diabetes secrete more lithogenic bile than non-diabetics; i.e., diabetes and GSD might be viewed as closely linked diseases[1]. Indeed, several community-based epidemiologic studies have demonstrated that not only diabetics have an increase in GSD-related morbidity[2-4], but also, our previous report showed that the prevalence of overall GSD among type 2 diabetics was higher as compared with

other general Chinese populations when using the same methods of GSD assessment[5]. In order to reduce health-care expenditures caused by GSD, organized preventive strategies are recommended.

Insulin resistance syndrome, initially described by Reaven[6], is a cluster of risk factors for coronary artery disease. This pathological condition is characterized by an inadequate physiological response of peripheral tissues to circulating insulin, and results in metabolic and hemodynamic disturbances[7]. Hyperinsulinemia has also characteristically been found in subjects with type 2 diabetes as a result of insulin resistance, which is considered to be of primary importance in the pathogenesis of diabetes. In addition, impairment of β-cell function, which becomes most evident during insulin resistance due to increased demands for insulin, is also well known now as a major factor influencing the progression from normal glucose tolerance, through impaired glucose tolerance to frank type 2 diabetes[8,9]. Results of the epidemiological studies have shown that increased insulin resistance and decreased insulin secretion are strongly related to the risk of developing type 2 diabetes[10-12].

The insulin-related factors responsible for the development of GSD remain to be clarified. Although it has been suggested that serum insulin affects the development of this co-disease in the general population[13,14], few community-based studies have been conducted to explore the direct effect of serum insulin, insulin resistance, and β-cell dysfunction to GSD among the diabetics. Additionally, other factors, including diabetic duration and glucose toxicity, have been proposed to affect the development of GSD in type 2 diabetics[3]. Using the community-based study in Kinmen, Taiwan, we aimed to determine whether serum insulin, insulin resistance, and β-cell dysfunction, were independently related to GSD among type 2 diabetics.

MATERIALS AND METHODS

Organization of community-based gallstone disease screening for type 2 diabetes

We used baseline data from a community-based screening for type 2 diabetes targeted to subjects aged 30 years or more in Kinmen, Taiwan, between January 1991 and December 1993. The details of the study design and execution have been described in detail elsewhere[15]. The identification of type 2 diabetes was based on the WHO definition in 1985[16]: subjects with fasting plasma glucose (FPG) ≥7.8 mmol/L (≥140 mg/dL) or 2 h postload ≥ 11.1 mmol/L (≥200 mg/dL) were defined as individuals with type 2 diabetes. Subjects with a history of type 2 diabetes and who received medication were defined as known cases. However, in the GSD screening done in 2001, the patients that fulfilled the criteria of the revised WHO criteria (revised in 1999) were enrolled. Patients with FPG ≥7.0 and <7.8 mmol/L in 1991 to 1993 were also recruited[17]. A total of 1 123 type 2 diabetics aged 30 and above were identified based on the population survey carried out by the Yang-Ming Crusade in Kinmen. After excluding those who migrated or died, the remaining 858 type 2 diabetics formed a cohort who were eligible for abdominal ultrasound sonography. These 858 subjects were invited by telephone calls or invitation letters in 2001 to be screened for GSD. Informed consent was obtained from all participants before the survey[5].

Information concerning biochemical markers and diagnosis of gallstone disease

The details of the data collection have also been described in detail elsewhere[5]. In brief, baseline information including demographic and biochemical variables was collected in the period 1991-93. Face to face interviews were conducted by the Yang-Ming Crusade, a volunteer organization of well-trained medical students of National Yang-Ming University. Fasting blood samples were drawn by public health nurses. Overnight fasting serum and plasma samples (preserved with EDTA and NaF) were collected and kept frozen (-20 ℃) until analysis. FPG concentrations were determined using the hexokinase-glucose-6-phosphate dehydrogenase method with a glucose (HK) reagent ldt (Gilford, Oberlin, OH, USA). Higher systolic blood pressure (SBP) was defined as SBP ≥140 mmHg, and higher diastolic blood pressure (DBP) was defined as DBP ≥90 mmHg. Obesity was defined by a body mass index (BMI) ≥25 kg/m^2, an abnormal total cholesterol was defined as ≥5.17 mmol/L (≥200 mg/dL), a raised triglyceride as ≥2.24 mmol/L (≥200 mg/dL), a raised blood urea nitrogen (BUN) as ≥7.14 mmol/L (≥20 mg/dL), a high level of uric acid was defined for males as ≥0.42 mmol/L (≥7 mg/dL) and for females as ≥0.36 mmol/L (≥6 mg/dL), and central obesity as a waist circumference ≥90 cm in males or ≥80 cm in females[18].

The follow-up screening regime for GSD was performed in 2001. GSD was diagnosed by a panel of specialists using real-time ultrasound sonography to examine the abdominal region, after fasting for at least 8 h, for the presence of "movable hyperechoic material with acoustic shadow". Cases of GSD were classified as follows: single gallbladder stone; multiple gallbladder stones; and cholecystectomy, excluding gallbladder polyps. Cases were identified as any type of GSD among type 2 diabetics. Furthermore, in order to ensure consistency of GSD diagnosis among the specialists, the Kappa statistic was used to assess the agreement of interobserver reliability among study specialists. A pilot study was performed with 50 randomly selected type 2 diabetics who were not study subjects. For interobserver reliability, the Kappa value for diagnosis of GSD was 0.77 (95%CI: 0.50-0.96).

Assessment of insulin resistance and β-cell dysfunction

The HOMA method was used to compare differences in the profiles for insulin resistance (HOMA IR) and for β-cell dysfunction (HOMA β-cell) in subjects with and without GSD[19]. The HOMA model assumes that the control of FPG and fasting insulin (FI) is governed by a self-contained feedback loop between the pancreas, liver, and insulin-sensitive and insulin-insensitive glucose

Table 1 Crude and age-adjusted odds ratios of baseline-associated factors of GSD among type 2 diabetics in Kinmen

	GSD (yes *vs* no)							
	Male				Female

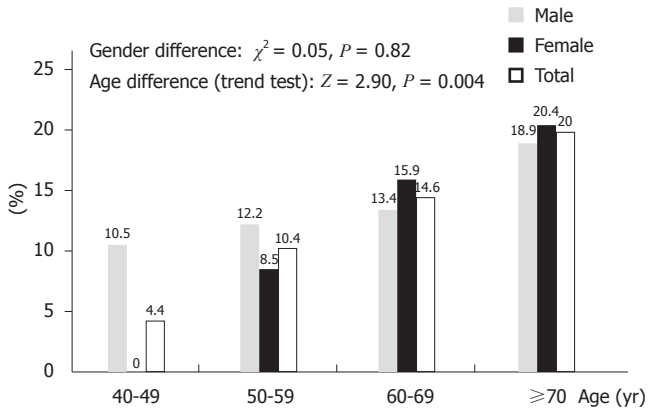

Figure 1 Sex and age-specific prevalence of gallstone diseases among type 2 diabetics in Kinmen.

metabolizing tissues[19]. The formulas were developed and validated against the hyperinsulinemic-euglycemic clamp for insulin resistance and the hyperglycemic clamp for insulin secretion[19]. The details are as follows:

$$\text{Insulin resistance(HOMA IR)} = \frac{\text{FI}\times\text{FPG}}{22.5}$$

$$\beta\text{-cell function(HOMA }\beta\text{-cell)} = \frac{20\text{-FI}}{\text{FPG-3.5}}$$

Because the HOMA model is not applicable to type 2 diabetics treated with insulin, eight insulin-treated subjects were excluded from the HOMA analysis. In addition, due to skewed distributions, the values of the HOMA model were subjected to log transformation in further analysis and re-transformed for tabulations.

Statistical analysis

Statistical analysis was performed using SAS version 9.0 (SAS Institute Inc., Cary, NC, USA). In the univariate analysis, crude and adjusted OR (adjustment for sex and age) were estimated and 95% confidence intervals (CI) were used. Multiple logistic regression was used to investigate whether insulin resistance and β-cell dysfunction were independently associated with GSD after adjustment for confounding factors. A P value <0.05 was considered statistically significant. In addition, HOMA IR, and HOMA β-cell scores were divided into quartiles after log transformation.

RESULTS

In our earlier study in 2001, 440 of 858 type 2 diabetic subjects (51.3%) had received real-time ultrasound sonography of the abdomen[5]. Using this cohort in the present study, and after excluding eight type 2 diabetics who had been treated with insulin, we determined the distribution of GSD among the remaining 432 participants. Figure 1 shows the sex- and age-specific prevalence of all types of GSD among type 2 diabetics. The sex-specific prevalence values [male: 13.9% (26/187); female: 14.7% (36/245)] were not significantly different (χ^2 = 0.05, P = 0.82). The prevalence of all types of GSD was significantly increased with age [Z (trend) = 2.90, P = 0.004]. Among the subjects aged 40-59 years, males had a higher prevalence of GSD than females. Conversely, among subjects aged 60 and above, females had a higher prevalence of GSD than males.

Table 1 presents the crude and age-adjusted OR for the association between certain relevant baseline-associated risk factors and GSD. Among males, baseline factors that were significantly related to GSD included age (≥65 *vs* <65 years, crude OR = 3.14, 95%CI: 1.32-7.47) and central obesity (yes *vs* no, age-adjusted OR = 2.36, 95%CI:

Other independent variables controlled in model included age, type of cases, SBP, DBP, cholesterol, triglyceride, BUN, uric acid, AST, and ALT.

1.01-5.97). According to univariate analysis in which the highest quartile was compared with the lowest, the female diabetics with GSD (compared to those without GSD) were older (≥65 *vs* <65 years, crude OR = 2.25, 95%CI: 1.04-4.90), were more obese (yes *vs* no, age-adjusted OR = 2.88, 95%CI: 1.24-6.70), had higher AST values (≥40 *vs* <40 U/L, age-adjusted OR = 3.93, 95%CI: 1.04-10.89), had greater serum insulin values (4th *vs* 1st quartile, age-adjusted OR = 5.32, 95%CI: 2.08-13.64) and had higher log HOMA IR values (4th *vs* 1st quartile, age-adjusted OR = 2.59, 95%CI: 1.01-6.76).

Associations between baseline serum insulin, insulin resistance, β-cell dysfunction, and GSD in each gender after adjustment for confounding factors were examined using a multiple logistic regression model. Fasting insulin was correlated with HOMA IR and HOMA β-cell dysfunction. These correlations were shown to be independent through the use of separate models. Furthermore, because the level of significance was very similar for raw (non-transformed) and log transformed data, in order to interpret the results more easily, the results for serum insulin were calculated for raw values. As shown in Table 2, older age was significantly associated with GSD in both males and females. Among males, there was a statistically significant association of GSD with central obesity, but no association of GSD with serum insulin, log HOMA IR, or log HOMA β-cell. Among females, not only obesity, but also serum insulin ($P<0.0001$ for trend test) and log HOMA IR ($P = 0.02$ for trend test) were significantly related to GSD (after adjustment for confounding variables). The association of GSD with serum insulin (4th *vs* 1st quartile, OR = 4.46, 95%CI: 1.71-11.66) and log HOMA IR (4th *vs* 1st quartile, OR = 2.81, 95%CI: 1.03-7.91) was revealed when the highest quartile was compared with the lowest. Although an association between log HOMA β-cell dysfunction and GSD was not found in the multivariate model, the test for trend was still strongly significant ($P = 0.01$).

DISCUSSION

Consistent with other epidemiologic studies[3,5], our study also revealed that age is a significant risk factor for GSD among type 2 diabetics (after adjustment for confounding factors). Larger amounts of cholesterol secreted by the liver and a decrease in the catabolism of cholesterol to bile acid were observed in the elderly population[20]. Long-term exposure, such as longer duration of type 2 diabetes, also might account for the increased risk of developing GSD among the elderly population[21]. In addition, the present study also showed the interaction between sex and age to prevalence of GSD. Further epidemiological and etiological investigations are clearly needed in order to clarify the pathophysiological mechanisms of interactive effects between sex, age, and GSD among type 2 diabetics.

Obesity might raise the saturation of bile by increasing biliary secretion of cholesterol, with the latter probably depending on a higher synthesis of cholesterol in obese subjects[5,22]. Our data demonstrated a significant association between obesity and GSD among females.

As in other studies, both univariate and multivariate analyses showed significantly higher BMI among females when compared to controls[23,24]. However, among males, the present study failed to find a positive association between higher BMI and GSD, whereas central obesity was significantly associated with GSD. These results are consistent with those of other population-based studies[25,26]. It has been suggested that BMI might not be as good an indictor of obesity among males as among females[27]. Some studies have also suggested that failing to find a relationship between BMI and GSD among males reveals a tendency for a positive association with other indices of obesity, such as slimming treatment and skinfold thickness[27,28]. Another possible reason is that loss of muscle bulk might be associated with GSD among males, i.e., males with GSD had gained less weight during adult life than non-GSD males despite having more abdominal fat, suggesting that they had lost more lean body mass[26]. Because central obesity was shown to be an important predictor of type 2 diabetes and various metabolic abnormalities, further study is needed to determine the contribution to and pathophysiological mechanisms of the formation of GSD in type 2 diabetics.

The results of this community-based study provide further support for an association between hyperinsulinemia and insulin resistance with GSD among females. Female diabetics with GSD had significantly higher baseline serum insulin, higher HOMA IR and lower HOMA β-cell function in comparison to controls without GSD pathology. This relationship persisted even after controlling the most common confounding factor of the association, such as central obesity, which was related to GSD and serum insulin[3]. Males showed no significant differences from controls regarding insulin resistance or its surrogates, lending support to a proposed interaction of these factors and sex with regard to lithogenesis. Previous clinical case-control studies and epidemiologic studies also showed similar results in the general population and in the diabetic population[3,13,29]. The mechanism underlying the interaction between insulin and gallstone formation is undetermined, though it has been speculated that decreased GSD motility and increased cholesterol saturation of bile are involved[29]. Gallstone motility had been demonstrated to be impaired in diabetics, favoring cholesterol gallstone crystal formation and growth[30]. Insulin may inhibit basal and cholecystokinin-stimulated gallbladder motility[31]. Another possible reason for the lack of an association between serum insulin and GSD among males is abdominal adiposity, which probably explains the hyperinsulinemia as the association of serum insulin with the disappearance of GSD. In addition, the fact that the HOMA model was used to estimate insulin resistance could be viewed as showing an interaction between serum insulin and FPG. The higher insulin levels mean the greater insulin resistance. Insulin resistance related to GSD with response to the duration of type 2 diabetes would also increase the risk of prevalent GSD[3].

Among females, a positive relationship between serum C-peptide and GSD was obtained in previous studies[13]. Measurement of C-peptide under standardized conditions provides a sensitive, well accepted and clinically validated assessment of β-cell function[32]. The intravenous glucose tolerance test (IVGTT) is widely used to test pancreatic β-cell function. Plasma C-peptide concentration is measured and used to infer insulin secretion since it is secreted in equimolar amounts with insulin, and its extraction by the liver is negligible[33]. In the present study, HOMA β-cell dysfunction was strongly related to GSD among females but not among males, implying that insulin secretion might act differently in relation to GSD formation in males and females, even among those with type 2 diabetes.

The present study took advantage of several important and valuable methods. First, most previous studies were hospital-based, and Berkson's bias (selection bias) was inevitable. A community-based study design, such as the one we used, could diminish this kind of selection bias. Second, potential information bias was reduced because GSD screening for type 2 diabetics in 2001 was collected without the knowledge by the specialists of results of the baseline biochemical factors in 1991-1993. Third, we used ultrasound examination instead of clinical history of GSD as used in the previous study[3]. Because of this, we should have improved diagnostic accuracy and diminished underestimation and misclassification of GSD. Nevertheless, associated biochemical markers of GSD were obtained retrospectively, and the causal relationship between serum insulin, insulin resistance, β-cell dysfunction and GSD could not be clarified in our study. Baseline characteristics pertinent to the risk of type 2 diabetes for attendants were not significantly different from those for non-attendants except for age, which means that the 51.3% who participated may also be representative of those refusing to join our study (after adjustment for age)[5]. But the relatively lower response rate still might be caused by decreased statistical power. In addition, due to the complications and expense associated with the clamp technique (which prohibited its use in our community-based epidemiologic studies that had substantial sample sizes), the measurements of insulin resistance and β-cell dysfunction were based on an indirect method (the HOMA model). However, previous studies confirmed that the HOMA method and clamp-measured insulin resistance were highly correlated, implying that we could also obtain unbiased results using less sophisticated methods[34,35].

In conclusion, the present study shows that there are gender differences with regard to the relationships between serum insulin, insulin resistance, β-cell dysfunction and GSD among type 2 diabetics (after adjustment for confounding factors). These observations suggest that factors related to type 2 diabetes might need to be considered separately in male and female diabetic patients in the pathogenic mechanism of increased risk of GSD.

Abstract

AIM: (1) To gain information on immune responses to an accelerated schedule of 0, 1, and 2 mo in paramedical staff and BDS students who are at an increased risk of getting hepatitis B infection and come under high risk groups. (2) To assess the efficacy and safety of *Enivac-HB* in different age groups, using genetically modified yeast strain *Pichia pastoris,* a new recombinant hepatitis B vaccine developed and manufactured in India.

METHODS: A prospective, comparative, and single blinded trial of rapid (0, 1, and 2 mo) hepatitis B immunization schedulewas reported. A total of three hundred and seven (212 females and 95 males) healthy volunteers divided into three age groups (18-29, 30-39, and 40-49) were enrolled after screening for markers of hepatitis B. All the volunteers received 20 mg of the vaccine intramuscularly at 0, 1, and 2 mo.

RESULTS: Geometric mean titers were calculated pre and post vaccination. Before immunization the GMT was 0.0124 mIU/mL. One month after the administration of the third dose of recombinant vaccine 296/307 (96.5%) subjects achieved seroprotective levels of anti-HBs. The geometric mean anti-HBs titers achieved after one month of the third dose was 2 560.0 mIU/mL. The geometric mean anti-HBs titer of males was 2 029.0 mIU/mL, while that of the females was 2 759.0 mIU/mL. In the age group of 18-29 years, anti-HBs titer was 3 025.0 mIU/mL, while that in the age group of 30-39 years was 2 096.0 mIU/mL. In third age group of 40-49 years, anti-HBs titer was 1 592.0 mIU/mL. Hyper-responses (anti-HBs$\geqslant$100 mIU/mL) were shown in 88.0% (271/307) of subjects. Eleven (3.5%) subjects responded poorly to the vaccine in the age group of 40-49 years. There was only mild pain at the site of injection otherwise there were no other adverse drug reactions (ADRs).

CONCLUSION: This vaccine (*Enivac-HB*) is safe and efficacious, providing significant protection after the third dose and rapid hepatitis B immunization schedule of 0, 1, and 2 mo can be recommended whenever rapid protection is the goal.

Key words: *Enivac-HB*; *Pichia pastoris*; Anti-HBs antibody; Hepatitis B vaccine

INTRODUCTION

Hepatitis B virus (HBV) infection is responsible for a high proportion of the worlds cases of cirrhosis, and is the cause of up to 80% of all cases of hepatocellular carcinoma (HCC)[1,2]. The situation is grim in developing countries like India, where blood bank infrastructure is non-existent outside the major metropolitan cities and safe blood handling practice standards are low[3]. The weighed prevalence of hepatitis B in India has been estimated to be 4.7%[4,5], which makes this an intermediate prevalence country.

Hepatitis B vaccination has been one of the success stories of the 20th century and has been extensively used in a wide range of groups throughout the world. Hepatitis B vaccination program have successfully reduced the prevalence of hepatitis B, in Taiwan[6] where universal HBV vaccination has led to a significant reduction of hepatitis B prevalence and incidence of hepatocellular carcinoma in children. The immunogenicity, efficiency, and safety profile of hepatitis B vaccine has been well established. More than 90% seroconversion has been achieved in adult populations consistently[7-10]. The safety profile of the recombinant hepatitis B vaccine has been very good[11].

Numerous genetically engineered hepatitis B vaccines are available in India today. However, vaccines do differ in terms of latency (time taken for the production of effective antibodies), reactogenicity and price. Newer technologies involving more advanced yeast strains like *Pichia pastoris*[12] used for manufacturing the vaccines are today revolutionizing genetically engineered hepatitis B vaccines.

The aim of the study was (1) to gain information on immune responses to an accelerated schedule of 0, 1, and 2 mo in paramedical staff and BDS students who are at an increased risk of getting hepatitis B infection and come under high risk groups. (2) To assess the efficacy and safety of *Enivac-HB* in different age groups, using genetically modified yeast strain *P pastoris,* a new recombinant hepatitis B vaccine developed and manufactured in India.

MATERIALS AND METHODS

Blood samples

The study was conducted in Maulana Azad Medical College, New Delhi for over the period of 6 mo (October 2002-April 2003). Five milliliters of blood sample was taken by venipuncture with the informed consent of all the 317 volunteers. Serum sample was separated and stored at -20 ℃ to perform various serological tests.

Clinical protocol

Permission to conduct this study on adult human volunteers was obtained from Drugs Controller of India. The Institute Ethics Committee approved the study protocol. The study population consisted of 317 volunteers. The following inclusion criteria had to be met. The subjects had to be tested negative for hepatitis B surface antigen (HBsAg), anti-hepatitis B surface antibody (anti-HBs), and anti-hepatitis B core antibody, IgM anti-HBe, IgG anti-HBe and subjects had to be at least 18 years of age and had to sign an informed consent. Subjects were excluded from the study if they had been previously vaccinated with HBV vaccine; or if they were presently taking immunosuppressive drugs; or had a history of hypersensitivity to yeast; or had to receive immunoglobulins, blood or blood products within the previous 6 mo. Subjects who were pregnant, who had significant hematological, hepatic, renal, cardiac or respiratory diseases or who had participated in any other trial 30 d before or during the present study were excluded. Physical examination such as pulse, blood pressure, temperature, and edema were checked. All the 307 healthy seronegative volunteers of the age ranging between 18 and 49 years were recruited for participating in the vaccination schedule of 0, 1, and 2 mo.

HBV vaccination

Of the 317 volunteers, 307 volunteers, who were negative for all the serological markers of hepatitis B infection, completed the hepatitis B vaccination program. Seven were positive for HBV markers and three volunteers had high anti-HBs titers. All the 307 volunteers received the three doses of HBV vaccination. The subjects were administered 1 mL (20 mg of recombinant DNA) of hepatitis B (*Enivac-HB*) vaccine intramuscularly in the deltoid muscle according to the following schedule: 1st dose-0 d, 2nd dose -30 d after the 1stdose, 3rddose-60 d after the 1stdose. Vaccinees were monitored for adverse events closely for 3 d after each dose, i.e. fever, pain at the site of injection, erythema, and swelling, nausea, rash, fatigue, bodyache, and scored as absent, mild, moderate or severe. Samples for anti-HBs antibody titers were determined at 0 and 90 d. Anti-HBs antibodies were done using a commercially available quantitative ELISA kit (AUSAB-EIA, Abbot Labs, USA). Protection with hepatitis B vaccination was considered to be achieved when the concentration of anti-HBs antibody titers was $\geqslant$10 mIU/mL. A non-response was defined as anti-HBs antibody titers $\leqslant$10 mIU/mL[13], responders were those with titer levels $\geqslant$10 mIU/mL and $\leqslant$100 mIU/mL, high responders were those with anti-HBs titers $\geqslant$100 mIU/mL, and those with titers $\geqslant$1 000 mIU/mL was hyper-responder[13].

Vaccine

A new recombinant DNA hepatitis B vaccine (*Enivac-HB*, Panacea Biotec, India) containing hepatitis B surface antigen (s-gene) produced in genetically engineered yeast *P pastoris* cells[12] was evaluated. A derivative of the plasmid V322 carrying hepatitis B viral DNA was used to amplify the HBsAg. The s-gene isolated from hepatitis B was placed in *P pastoris* cell. The HBsAg nucleotide sequence[14] was purified to >95% by adsorption by the antigen in the cellular extract to colloidal silica, followed by its desorption, ion exchange chromatography and ultracentrifugation. The vaccine was prepared by adsorbing the purified HBsAg onto aluminum hydroxide gel (0.5 mg aluminum per dose) and thiomersal was added as a preservative to a final concentration of 0.05 mg/dL. *P pastoris* is the most advance second generation yeast strain with proven advantages over other yeast strains like *Saccharomyces cerevisiae*[12] which is used in the manufacturing process of many commercially available genetically engineered hepatitis B vaccines in India. The yeast strain *P pastoris* can grow at a highly acidic pH that becomes a barrier for growth of many contaminating microbes during the process of fermentation[12]. In short, the manufacturing process itself is a purification procedure. The yield of hepatitis B surface antigen obtained with this strain of *P pastoris* is higher and it means per liter more surface antigen is obtained with *P pastoris* than with many other strains[12]. *Enivac-HB* is manufactured using a technology that is free from toxic substances like cesium chloride[12]. Some commercially available vaccines in India are known to use technology that involves the usage of cesium chloride[12]. This advantage automatically translates into lesser contamination and hence, lesser chances of reactogenicity[12].

Statistical analysis

Seroconversion and seroprotection were compared by

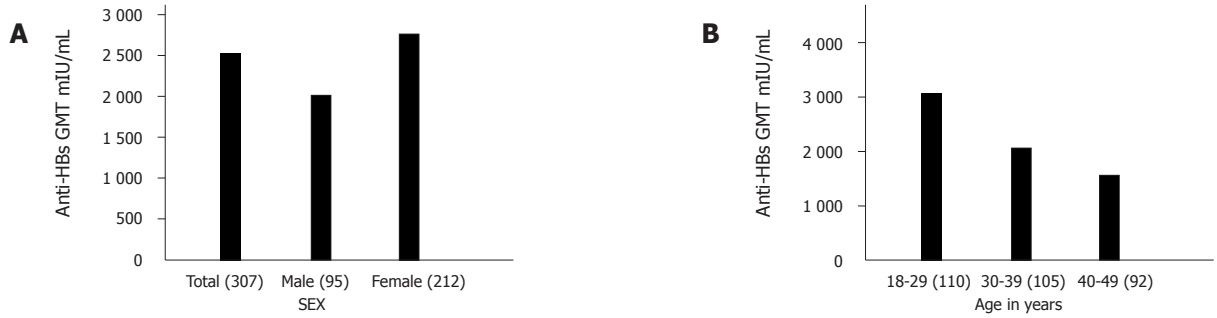

Figure 1 Efficacy of *Enivac-HB* in study participants by gender variation (**A**) and age (**B**) on the 90th d evaluation after the initial vaccination. The anti-HBs titer is expressed in milli-international unit per milliliter.

descriptive statistics. Geometric mean titers (GMTs) pre and post-vaccinations were compared by Student's *t* test. $P<0.05$ was compared as statistically significant (95%CI).

RESULTS

A total of 317 subjects were screened, 307 subjects negative for all the serological markers of hepatitis B were enrolled in the study. The mean age of the study group was 33.5±9.4 years, with 95 male subjects and 212 female subjects. Dose schedules were 0, 1, and 2 mo. Adverse events were recorded by specifically interviewing each subject during the entire duration of the study. The adverse drug reactions (ADRs) were assessed closely for 3 d after each dose and that no vaccinee had fever or any other designated systemic complaint with only mild pain at the site in 79%, 84.9%, and 75.4% of the vaccinees following doses 1, 2, and 3, respectively. Hematological and biochemical parameters were normal in all the subjects at the end of the study compared to the baseline value. None of the patients became HBsAg and/or anti HBe positive during the follow-up period. "The geometric mean anti-HBs titer" at the initiation of the vaccination program was 0.124 mIU/mL. One month after the administration of the third dose of recombinant vaccine, 296/307 (96.5%) subjects achieved seroprotective levels of anti-HBs antibodies. "The geometric mean anti-HBs titer" achieved after one month of the third dose was 2 560.0 mIU/mL geometric mean titers. "The geometric mean anti-HBs titer" of males was 2 029.0 mIU/mL, while that of females was 2 759.0 mIU/mL as shown in Figure 1A. In the age group of 18-29 years, anti-HBs titer was 3 025.0 mIU/mL, while that of 30-39 years was 2 096.0 mIU/mL. In 40-49 years of age, anti-HBs titer was 1 592.0 as shown in Figure 1B. The above value is statistically significant with $P<0.05$, and had 95%CI. Hyper-responses (anti-HBs ≥100 mIU/mL) was shown by 88.0% (271/307; $P<0.05$) of subjects. Twenty subjects all in the age group of 40-49 were (11/307; 3.5%) non-responders, with the geometric mean anti-HBs titers 8.60 mIU/mL. The mean age of the 11 non-responders was 46.4±6.9 years, 1.3% (4) males and 2.2% (7) females were non-responders but the difference was not statistically significant.

DISCUSSION

Accelerating the vaccination schedule against hepatitis B is appealing because it may increase patient compliance and provide earlier protection for the people who are already in a high risk group or environment. A comparative Indian study of HBV vaccine in three age groups, 18-29, 30-39, and 40-49 years, was done. The experimental data obtained during the course of the trial indicated that seroprotection one month[15] after the third dose was (96.5%) with mean geometric anti-HBs titers 2 560.0 mIU/mL. Twenty subjects all in the age group of 40-49 years (11/307; 3.5%) showed low response to the vaccine and demonstrated an antibody titer of 8.60 mIU/mL. While all the subjects in rest of the age group achieved 100% seroconversion. Risk factors that have been associated with non-response to hepatitis B vaccine include increasing age, male gender, obesity, history of smoking, administration of vaccine in buttock rather than deltoid[5]. The relationship of hepatitis B vaccination response with age is controversial. Our study suggests that seroconversion in age group >40 years is 79% which is considered high compared to most other studies[16,17] where seroconversion rate of 60% has been reported. However, as all the above studies, we too found a decreasing seroconversion rate with increasing age. These findings favor the hypothesis that increasing age decreases seroprotective antibody formation after vaccination.

In the present clinical study, it was observed that female volunteers showed a better response in comparison to male volunteers ($P<0.001$). Jilg *et al*[18] reported a slightly lower response in males and Dentico *et al*[19] also reported that the sex factor is one of the parameters influencing the response following vaccination. Whether or not there exists a sex related variation of the immunogenic response is still controversial.

The vaccination schedule (0, 1, and 2 mo) employed in the present study has been well studied in the other trials[15-19]. Marsano *et al*[20] have established that the 0, 1, and 2 mo schedule of vaccination gives a rate that is quicker than and identical to the rate of seroprotection of the standard schedule of vaccination of 0, 1, and 6 mo and is much quicker. The recombinant yeast-derived vaccine evaluated did not produce any severe adverse reactions. There was only mild pain at the site of injection otherwise

it was completely safe with no adverse drug reactions.

From the present data, we can confirm that the *Enivac-HB* is highly immunogenic. This new indigenously manufactured vaccine using *P pastoris* as yeast strain is safe and provides effective titers against hepatitis B. In a country with an estimated 40 million or more carriers of the hepatitis B virus and an estimated 18 million newborns each year, the availability of an indigenously manufactured vaccine would probably make it easier to include the vaccine in a community-based program.

The study conclusively proves that the recombinant DNA hepatitis B vaccine (*Enivac-HB*) produced using genetically engineered yeast cell *P pastoris* appears to be highly immunogenic and safe and confers a seroprotection of 96.5% of the subjects with 88.0% showing hyper-response. The study suggests that the vaccine appears to be well tolerated and the rapid vaccination schedule of 0, 1, and 2 mo can be recommended whenever rapid protection is the goal.

ACKNOWLEDGMENTS

The vaccines and finance for the clinical study were provided by Panacea Biotec Limited, New Delhi, India. The authors are grateful to Mrs Alice Jacob, a member of PCR Hepatitis Laboratory, New Delhi, India for helping us during the study.

Abstract

AIM: To investigate the change of bone parameters in a new model of experimentally induced liver cirrhosis and hepatocellular carcinoma (HCC) in growing rats.

METHODS: Fischer-344 rats (n = 55) were used. Carbon tetrachloride (CCl_4), phenobarbital (PB), and a single diethylnitrosamine (DEN) injection were used. Animals were killed at wk 8 and 16. Bone mineral content, femoral length, cortical index (quotient of cortical thickness and whole diameter) and ultimate bending load (F_{max}) of the femora were determined. The results in animals treated with DEN+PB+CCl_4 (DPC, n = 21) were compared to those in untreated animals (UNT, n = 14) and in control group treated only with DEN+PB (DP, n = 20).

RESULTS: Fatty liver and cirrhosis developed in each DPC-treated rat at wk 8 and HCC was presented at wk 16. No skeletal changes were found in this group at wk 8, but each parameter was lower (P<0.05 for each) at wk 16 in comparison to the control group. Neither fatty liver nor cirrhosis was observed in DP-treated animals at any time point. Femoral length and F_{max} values were higher (P<0.05 for both) in DP-treated animals at wk 8 compared to the UNT controls. However, no difference was found at wk 16.

CONCLUSION: Experimental liver cirrhosis and HCC are accompanied with inhibited skeletal growth, reduced bone mass, and decreased mechanical resistance in growing rats. Our results are in concordance with the data of other studies using different animal models. A novel finding is the transiently accelerated skeletal growth and bone strength after a 8-wk long phenobarbital treatment following diethylnitrosamine injection.

INTRODUCTION

Metabolic bone disease is a common complication of chronic liver diseases[1-4]. However, the pathogenesis is not fully understood and is scarcely investigated in an animal model. Both increased bone resorption[5-7] and decreased bone formation[8-11] have been described in chronic liver diseases. Decreased bone density[10] and impaired microarchitecture[12] are associated with increased fracture risk[13]. Though several methods are available to examine different aspects of bone metabolism, there is not a single test to define the quality of bones. We have investigated how the bone mineral content (BMC), cortical thickness, bone length, and mechanical loading capacity of femora were changed during the development of experimentally induced fatty liver, liver cirrhosis, and HCC in growing rats. No published data are available on simultaneous measurements of these parameters in growing rats. We used a new cirrhosis model in this study. Our results are in concordance with those of other studies. Novel finding is the transiently accelerated skeletal growth and bone strength after a 8-wk long phenobarbital treatment following diethylnitrosamine injection.

MATERIALS AND METHODS

Animals and induction of liver diseases

A total of 60 male Fisher-344 rats, weighing 273.3±38.7 g, were included and 55 rats survived the study protocol.

Table 1 Serum parameters and body weight in UNT, DP-treated control and DPC-treated rats at wk 8 and 16 (mean±SD)

Parameter	UNT control (wk 8) $n = 8$	UNT control (wk 16) $n = 6$	DP control (wk 8) $n = 10$	DP control (wk 16) $n = 10$	DPC (wk 8) $n = 10$	DPC (wk 16) $n = 11$
Bilirubin (mmol/L)	1.8±1.2	2.1±1.3	1.85±0.9	0.88±0.3	48.14±66[a]	1.31±0.5

[a]$P<0.05$ *vs* for comparison between DPC and both UNT and DP controls at wk 8.

The animals were housed in steel cages (5 rats/cage) in an air-conditioned room with a relative humidity of 55%. Tap water and pelleted rodent chow (CRLT/N, Farmer Product Ltd, Hungary) were available *ad libitum*. The Animal Care and Use Committee of Semmelweis University, Faculty of Medicine approved all the animal procedures.

Fatty liver and liver cirrhosis were induced by the administration of CCl_4 (0.5 mL/kg body weight, dissolved in sunflower oil, administered thrice a week by intragastric tube) and phenobarbital (PB, phenobarbital-Na; Sigma, St. Louis, MO, USA, tap water was replaced by 0.05% of PB-solution after a 12-h fasting, daily) throughout the 8-wk treatment following a single injection of diethylnitrosamine (DEN; Serva, Heidelberg, at a dose of 200 mg/kg body weight, dissolved in 0.9% NaCl solution). HCC developed at wk 16 as described earlier[14]. Animals were killed at wk 8 and 16 under light ether-anesthesia (all animals were fasted for 24 h prior to killing).

Results in animals treated with DEN+PB+CCl_4 (group DPC, $n = 21$) were compared to those in untreated animals (group UNT, $n = 14$) and in control group treated only with DEN+PB (group DP, $n = 20$).

Biochemical tests

Serum bilirubin, alkaline phosphatase (ALP), aspartate aminotransferase (AST), and alanine aminotransferase (ALT) as well as albumin were measured using the Olympus AU600 autoanalyzer (Olympus Ltd, Japan).

Pathological investigation of liver

Livers were macroscopically and histologically investigated. Slices from the removed liver were fixed in 8% buffered formalin and embedded in paraplast. Picrosirius red, H&E, and PAS staining were used for histological examination[14]. Hepatic fibrosis, cirrhosis[15], and lesions[16] were classified according to the international recommendations.

Bone investigation

Partial carcass preparation was performed. The left rear limb was carefully dissected free from the iliac acetabulum with the head of the femur preserved. Then, the isolated femur was prepared by dissecting from the tibia along with the remaining muscles and ligaments and stored in saline-soaked gauze at -20 ℃ until further testing.

Radiological studies

Soft radiographs were performed using an X-ray imaging system (Siemens Mammomat 3000, Germany) with exposure at 25 kVp, 10 mAs on the femur. Femora were carefully positioned anteroposteriorly. Exposure period was 0.3 s. Exposed plates (Agfa, Germany) were analyzed using OSIRIS imaging software. Femoral length (mm) was measured and the values were validated by an aluminum phantom (1 mm in diameter). Each exposure included both the phantoms and the investigated bone. Cortical index was calculated: cortical thickness divided by the whole diameter at the mid-point of medial diaphysis.

Bone densitometry

Using an I-125 source (1 000 MBq initial activity from Nordion), a water-bath system (single photon absorption, SPA) device (NK364/A, Gamma Technical Corporation, Budapest, Hungary) was used to determine the BMC in mg/cm. A precise, replaceable and narrow collimator was made for the source holder for the *in vitro* animal experiments. Aluminum phantoms (Gamma Technical Corporation, Budapest, Hungary) were used for the calibration. The femora were fixed by sellotape on a water equivalent plastic sheet and then placed on the attenuation block. The attenuation block was 2 cm wide. BMC value was measured at the mid-point of the medial diaphysis.

Biomechanical testing

Biomechanical tests were carried out by a computer-controlled testing device (Zwick-020, Zwick, Ulm, Germany) using the whole bone specimens. The anteroposterior three-point bending test of the femoral shaft was performed as previously described[17]. The femur was placed on a testing bearer, and the distance between the supporting rods was fixed at 15.7 mm. Force was elicited by a rod at a constant deformation rate of 2 mm/min at a right angle to the anterior midpoint of the femoral midshaft. We determined the ultimate bending load of the whole bone specimen (F_{max}, N). The F_{max} was corrected by BMC (load/density, N/mg/cm) and cortical index (described above, load/cortical index, N/mm/mm) of femoral midshafts avoiding the impact of BMC and cortical index on bone strength.

Statistical analysis

Mann-Whitney test was used for intergroup comparisons.

Table 2 Femur length, cortical index, BMC, and ultimate bending load of femoral mid-diaphysis and corrected loading data for cortical index and BMC in UNT, DP-treated control and DPC-treated rats at wk 8 and 16 (mean±SD)

Parameter	UNT control (wk 8) $n = 8$	UNT control (wk 16) $n = 6$	DP control (wk 8) $n = 10$	DP control (wk 16) $n = 10$	DPC (wk 8) $n = 10$	DPC (wk 16) $n = 11$

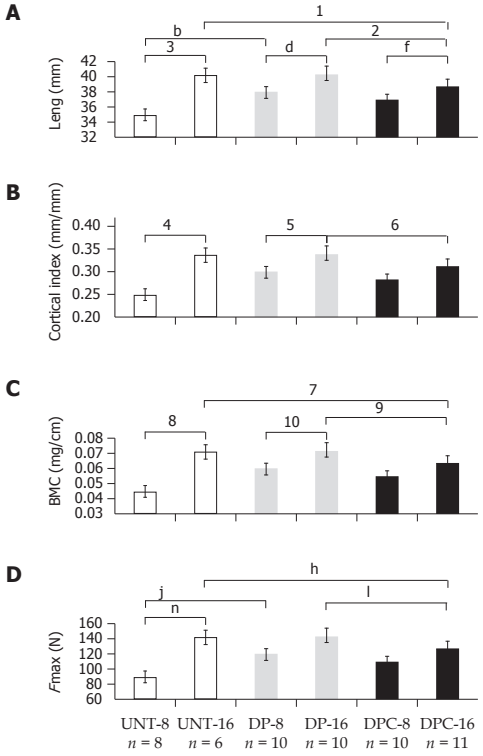

Figure 1 Mean±SD of femur length (**A**), cortical index of femoral midshaft (**B**), BMC of femur in mid-point of medial diaphysis (**C**), and ultimate bending load of femoral midshaft (**D**) in UNT, DP-treated control and DPC-treated rats at wk 8 and 16. A: [1]$P = 0.020$, [2]$P = 0.002$ *vs* DPC-16, [3]$P = 0.001$ *vs* UNT-8, [b]$P<0.001$ *vs* UNT-8, [d]$P<0.001$ *vs* DP-8, [f]$P<0.001$ *vs* DPC-8; B: [4]$P = 0.018$ *vs* UNT-8,[5]$P = 0.013$ *vs* DP-8, [6]$P = 0.004$ *vs* DPC-16; C:[7]$P = 0.001$ *vs* DPC-16, [8]$P = 0.002$ *vs* UNT-8, [9]$P = 0.016$ *vs* DPC-16, [10]$P = 0.003$ *vs* DP-8; D: [h]$P<0.001$ *vs* DPC-16, [j]$P<0.001$ *vs* UNT-8, [l]P<0.001 *vs* DPC-16, [n]$P<0.001$ *vs* UNT-8.

Pearson's parametric correlation test was applied for measuring the strength of a relationship between the two variables. $P<0.05$ was considered statistically significant. All statistical analyses were performed using SPSS version 10.0 for Windows (Chicago, IL, USA). Results were expressed as mean±SD.

RESULTS

Biochemical results, body weight, and liver histology

Serum parameters and body weight of UNT, DP- and DPC-treated rats are shown in Table 1. DPC-treated rats had elevated bilirubin, ALP, AST, and ALT ($P<0.001$ for each parameter) compared to UNT and DP-treated rats at wk 8. Serum albumin was decreased in DPC-treated animals at wk 8 compared to the other two groups ($P<0.001$). There were no differences in the laboratory values between the study groups at wk 16. No differences were found between DP-treated and UNT groups neither at wk 8 nor at wk 16.

Increased body weight was observed in UNT and DP-treated controls and DPC-treated rats from wk 8 to 16 ($P<0.001$). However, weight was reduced in DPC-treated in comparison to DP-treated group at wk 8 ($P<0.001$) and 16 ($P = 0.016$). DP-treated group had significantly higher body weight at wk 8 than UNT controls ($P<0.001$).

Liver histology showed inflammatory cell infiltrates, necrosis, fatty changes, regenerating nodules and cirrhosis in DPC-treated rats at wk 8 (10 out of 10 rats). Neoplastic nodules were found in five samples. Cirrhosis and HCC (11 out of 11) developed in DPC-treated group at wk 16. Normal hepatic histology was found in all UNT and DP-treated control rats.

Bone length, cortical index, bone mineral content and ultimate bending load of the femora

The femoral length increased in each group from wk 8 to 16 (Table 2, Figure 1A). However, animals treated with DPC had shorter femora than controls at wk 16. Femora were longer in DP-treated rats than in UNT controls at wk 8. Femoral length correlated with body weight ($r = 0.824$, $P<0.001$).

Significant increases of cortical index were seen in both UNT and DP-treated control rats (Table 2, Figure 1B). At wk 16, cortical index was smaller in DPC-treated animals than in DP-treated rats. Poor but significant correlation was measured between cortical index and BMC ($r = 0.362$, $P = 0.008$).

BMC increased only in UNT control rats from wk 8 to 16, indicating the physiological bone mineralization (Table 2, Figure 1C). DPC-treated rats had lower BMC than DP-treated rats at wk 8. BMC was lower in DPC-treated animals than in UNT and DP-treated control rats at wk 16. Body weight strongly correlated with BMC ($r = 0.748$, $P<0.001$).

Ultimate bending load increased from wk 8 to 16 in UNT controls (Table 2, Figure 1D). F_{max} in DP-treated rats was greater than that in UNT rats at wk 8. At wk 16,

F_{max} was smaller in DPC-treated rats than in both UNT and DP-treated controls. However, when we corrected the ultimate bending load by BMC or cortical index, no differences were found between the groups. Strong correlation was found between BMC and ultimate bending load ($r = 0.842$, $P<0.001$). Relationship was also found between F_{max} and cortical index ($r = 0.548$, $P<0.001$). F_{max} correlated with body weight ($r = 0.758$, $P<0.001$) and femoral length ($r = 0.751$, $P<0.001$).

DISCUSSION

Using a new model, we have found that bone disorders due to diethylnitrosamine, phenobarbital, and CCl_4 administration were characterized by decreased femoral length, reduced bone mass, and increased fragility after 16-wk long treatment in growing rats. Our findings on cortical bone mass are in concordance with other studies using different models of experimentally induced liver cirrhosis[18-21]. van der Merwe *et al*[22] found that the femoral length, the bone mass and the midshaft thickness were lower in CCl_4-treated rats after portosystemic shunting. Muguerza *et al*[23] found that the femoral density, the anteroposterior and lateromedial diameters and the ultimate bending load decreased in CCl_4-induced cirrhotic rats, but no significant differences were observed in the bone length. In our experiment, the age-dependent growth of femoral length, BMC and ultimate bending load were arrested as cirrhosis progressed and HCC developed. Tanaka *et al*[24] also found that longitudinal bone growth is reduced on the femora of rats with CCl_4-induced liver cirrhosis. Decreased bone mineral density has been observed in growing rats with liver cirrhosis induced by the administration of CCl_4 and phenobarbital[20].

In our study, DP-treated rats had longer femora and increased ultimate bending load than untreated control rats at wk 8, nevertheless BMC and cortical index did not differ from untreated controls. The stimulating skeletal effect of DP treatment at wk 8 might be caused by the enzyme inductor effect of phenobarbital. It is well known that phenobarbital induces not only xenobiotic-metabolizing cytochrome P450 (e.g. CYP2B1)[25] but also estrogen and vitamin D_3 synthesizer cytochrome P450 enzymes (CYP19A1, CYP27A1 CYP27B1, CYP3A4, CYP2D)[26-28]. Therefore, the increased longitudinal bone growth and ultimate bending load in DP-treated rats may be the consequence of enhanced estrogen and vitamin D activation. However, the increase in ultimate bending load was stunted after 8 wk in DP-treated rats. It is possible that bone maturation has become adapted to the accelerated skeletal growth and mineralization after 8 wk. In DPC-treated rats, only a tendency towards both longitudinal bone growth and ultimate bending load was observed in comparison to untreated controls at wk 8, suggesting that the adverse skeletal effect of CCl_4 does not allow to reveal stimulating effect of phenobarbital.

The biochemical parameters of liver function showed serious inflammation in DPC-treated rats at wk 8 corresponding to the histology showing fatty liver and inflammatory cell accumulation beyond the regenerating nodules. The decrease in serum albumin level at wk 8 in DPC-treated rats indicates the reduced synthetic capacity of the liver. Though biochemical and histological symptoms of steatohepatitis were present, it had no detectable negative effect on bone mass, bone length, cortical index and ultimate bending load at this time point, which is in concordance with results of van der Merwe *et al*[22] who did not find detectable bone disease in early stage liver dysfunction. Similar to human liver diseases, longer time is needed for the development of metabolic bone disease. Biochemical and histological signs of inflammation ceased in DPC-treated rats at wk 16, while fibrosis, cirrhosis with regenerative nodules and HCC foci dominated the histological picture. However, femoral length, BMC and ultimate bending load were stunted at this time point, which is in concordance with results of Figueiredo *et al*[29]. The mechanism is complex. The high level of hyperbilirubinemia detected at wk 8 could be one of the factors, since bilirubin has a direct inhibitory effect on osteoblast proliferation[30].

Bone fractures depend not only on BMC but also on bone quality, size and shape[31-33]. The decrease of F_{max} at wk 16 clearly showed the altered bone metabolism. Since correlation was found between F_{max} and cortical index, femoral length and BMC and there was no difference in F_{max}/cortical index and F_{max}/BMC ratios between the different groups, the increased fragility should be the consequence of stunted longitudinal and cortical growth and arrested mineralization in growing rats with liver cirrhosis and HCC.

The mechanism by which liver cirrhosis arrests skeletal growth and influences other features of bone metabolism is not fully understood. Whether the bone alteration is caused by a direct toxic effect of the applied agents on bones or it is a secondary consequence of the experimentally induced liver cirrhosis remains unknown.

In conclusion, experimentally induced liver cirrhosis and HCC are accompanied with inhibited growth, reduced BMC and cortical index and decreased mechanical resistance in growing rats. Our results are in concordance with the data of other studies using different animal models. A novel finding is the transiently accelerated skeletal growth and bone strength after a 8-wk long phenobarbital treatment following diethylnitrosamine injection.

Abstract

AIM: To determine the serum levels of c-reactive protein (CRP), transferrin (TRF), a2-macroglobulin (A2M), ceruloplasmin (CER), a1-acid glycoprotein (AAG), pre-albumin (P-ALB) and retinol-binding protein (RBP) in gastric carcinoma patients and to explore their possible correlation with underlying *Helicobacter pylori* (*H pylori*) infection.

METHODS: We measured the serum levels of CRP, TRF, A2M, CER, AAG, P-ALB, and RBP in 153 preoperative patients (93 males; mean age: 63.1±11.3 years) with non-cardia gastric adenocarcinoma and 19 healthy subjects.

RESULTS: The levels of CRP, CER, RBP, and AAG in cancer patients were significantly higher than those in healthy controls (P<0.0001), while no difference was found regarding the TRF, P-ALB, and A2M levels. Cancer patients with *H pylori* infection had significantly lower RBP values compared to non-infected ones (P<0.0001) and also higher values of CRP and AAG (P = 0.09 and P = 0.08, respectively).

CONCLUSION: High serum levels of CRP, CER and AAG in cancer patients do not seem to be related to *H pylori* infection. Retinol-binding protein seems to discriminate between infected and non-infected patients with gastric carcinoma. Further studies are needed to explore if it is directly involved in the pathogenesis of the disease or is merely an epiphenomenon.

INTRODUCTION

Though the incidence of gastric adenocarcinoma has decreased during the last 50 years, it still remains one of the most common cancers worldwide. Even though the exact molecular mechanisms leading to gastric carcinogenesis are incompletely understood, the current school of thought accepts a multifactorial model in which various dietary and non-dietary factors (i.e. *Helicobacter pylori* infection) operate at different steps in the process.

Epidemiological studies in the early 1990s demonstrated an up to sixfold increased risk of developing gastric adenocarcinoma in patients infected with *H pylori*[1-4]. More than 10 years ago, *H pylori* was classified as a type I carcinogen for human beings by the World Health Organization, being recognized in this way as a crucial player in the gastric carcinogenesis. Increased epithelial cell proliferation and oxidative damage of the gastric mucosa are the two main mechanisms that seem to operate as a result of *H pylori* infection[5].

Table 1 Characteristics of studied populations and demographic data

Group	Number of subjects	Sex (M/F)	Mean age(yr)	Tumor location (antrum/body)
Gastric cancer	153	93/60	63.1	125/28
Infected	82	46/36	64.2	64/18
Non-infected	71	42/29	62.4	56/15
Healthy controls	19	10/9	62.2	

M, male; F, female.

The other environmental factor that has been shown to play a significant role in gastric carcinogenesis is diet. Diets with low intake of fruits, vegetables and milk and high intake of smoked or salted foods, dried fish, cooking oil, and complex carbohydrates have been shown to increase the risk for gastric cancer[6,7]. Contrary to that, intake of antioxidants has been associated with decreased risk of gastric cancer[8].

The search for useful biomarkers that can help in the diagnosis of cancer and add prognostic information to that already provided by the tumor staging is a field of active research. Even though numerous studies have been published, no single substance has been found to be clinically useful in the management of patients with gastric carcinoma. Immunohistochemical analysis of gastric tumors has shown that they contain protease inhibitors such as a2-macroglobulin[9,10] or a1-acid glycoprotein[11-13] and suggests that they may serve as markers of tumor aggressiveness. Some data also suggest that the acute phase reactants CRP and AAG may have prognostic value[13,14]. Stored sera from patients that later develop gastric cancer contain lower values of ferritin, while transferrin values were not different[15]. Ceruloplasmin has been shown to be useful in some studies[16] but not in others[15-17]. Serum interleukin-6 (IL-6) level correlates with the disease status of gastric cancer, suggesting that it may be used as a new tumor marker for monitoring the response to treatment[18]. Other studies even suggested that IL-6 might have a direct role in the pathogenesis[19,20]. A recent study[21] confirmed that IL-6 is a useful parameter for the diagnosis and grading of gastric cancer, but also suggested a role for malonyldialdehyde (MDA), nitric oxide (NO) and, especially vascular endothelial growth factor (VEGF). Finally, inconclusive data surround the usefulness of the so-called negative acute phase reactants, pre-albumin, and retinol-binding protein, in the assessment of cancer patients[22-26]. Retinol-binding protein was also included in our analysis because retinol and its ligand has been associated with lower risk of gastric cancer in some studies[27] but not in others[28].

The aim of this prospective, observational study was to measure the serum levels of the acute phase reactants a1-acid glycoprotein, transferrin, a2-macroglobulin, ceruloplasmin, retinol-binding protein, pre-albumin, and c-reactive protein in patients with gastric adenocarcinoma and to explore their correlation with *H pylori* infection.

MATERIALS AND METHODS

Patients

One hundred and fifty-three patients (93 men, 60 women) with a mean age of 63.1±11.3 years and histologically confirmed non-cardia gastric cancer were included in the study. In each case we recorded the location of the tumor, the histological type and the lymph node involvement. One hundred and twenty-five malignant tumors were located in the antrum and 28 in the body of the stomach. None of the patients had any gross metastatic disease as determined by chest and abdomen CT scans and received chemotherapy or radiation therapy prior to surgery. The histological diagnosis was based on morphologic examination of hematoxylin/eosin-stained specimens. Table 1 summarizes the demographic data and characteristics of the studied populations. Nineteen healthy volunteers (10 men, 9 women) with a mean age of 62.2±13.1 years were used as controls. We defined "healthy" status as the absence of a cardiovascular disorder, malignancy, gastrointestinal pathology, and *H pylori* infection. Neither patients nor controls had any evidence of infection or received antibiotics for at least 2 mo prior to serum collection with only the use of antacids. Sera from 48 patients were prospectively collected, the rest of the sera were collected in the previous 17 mo and kept frozen at -70 ℃.

The study was approved by the Institutional Review Boards of the participating hospitals and all study individuals gave their informed consent.

Determination of H pylori serology

All enrolled subjects (cancer patients and controls) underwent an enzyme-linked immunosorbent assay (ELISA) IgG serologic test for *H pylori* (Allergy Immunotechnologies Inc., Newport Beach, CA, USA) in accordance with the manufacturer's instructions. The specificity and sensitivity of the serology test validated in our local population were 95% and 90%, respectively. *H pylori* antibody titers higher than 155 mU/L were considered positive and lower than 155 mU/L negative.

Determination of acute phase proteins

Concentrations of the specific acute-phase proteins (c-reactive protein, a1-acid glycoprotein, ceruloplasmin, transferrin, a2-macroglobulin, prealbumin, and retinol-binding protein) were measured by nephelometric method on a Dade Behring nephelometer BNII (Dade Behring, USA), using Dade Behring antibodies and standard reagents. The intra- and inter-assay coefficients of variation were in the range of 2% and 5%, respectively.

Examined parameters

Serum levels of the acute phase reactants were recorded from healthy controls and patients suffering from gastric cancer. These patients were grouped according to whether they were infected with *H pylori* or not. Normal values for the examined parameters were as follows: c-reactive protein (CRP) <50 mg/L, A1-acid glycoprotein (AAG) <1

Table 2 Mean levels of TRF, A2M, AAG, CER, RBP, P-ALB, and CRP in cancer patients and controls

Parameter (mg/dL)	Cancer patients (n = 153)	Controls (n = 19)	P
TRF	265,43	274,95	NS
A2M	263,25	233,11	NS
AAG	245,48	94,79b	<0.001
CER	53,26	41,74b	<0.001
RBP	23,78	3,77b	<0.001
P-ALB	23,04	17,74	NS
CRP	9,32	2,92b	<0.001

[b]P<0.001 *vs* controls, NS: not significant.

Table 3 Mean levels of TRF, A2M, AAG, CER, RBP, P-ALB, and CRP between infected and non-infected cancer patients

Parameter (mg/dL)	Non-infected (n = 71)	Infected (n = 82)	P
TRF	276.46	255.88	NS
A2M	281.49	247.46	NS
AAG	238.21	251.77	NS
CER	52.03	54.32	NS
RBP	31.89	16.75[b]	<0.001
P-ALB	22.35	23.64	NS
CRP	7.99	10.47	NS

[b]P<0.001 *vs* infected, NS: not significant.

200 mg/L, ceruloplasmin (CER) <550 mg/L, transferrin (TRF) <4 300 mg/L, A2-macroglobulin (A2M) <3 200 mg/L, pre-albumin (P-ALB) <450 mg/L and retinol-binding protein (RBP) <60 mg/L.

Statistical analysis

The nonparametric Mann-Whitney *U*-test was employed to study the differences in values between cancer patients and controls and to compare the significance of values' differences between infected and non-infected patients. P<0.05 was considered statistically significant. All analyses were completed using the Statistical Package for Social Sciences (SPSS 11.5).

RESULTS

The assessed parameters found between cancer patients and healthy controls and between infection and non-infection groups of cancer patients are shown in Tables 2 and 3, respectively. Out of a total of 153 cancer patients participating in the study, 82 (53.6%) were infected with *H pylori*. The levels of CRP, CER, RBP, and AAG in cancer patients were significantly higher than those in healthy controls (P<0.0001), while no difference was found regarding the TRF, P-ALB, and A2M levels. Cancer patients with *H pylori* infection had significantly lower RBP (P<0.0001) and higher CRP and AAG (P = 0.09 and P = 0.08, respectively) than those without *H pylori* infection.

DISCUSSION

In the current study, we have measured the serum levels of a group of acute phase reactants in patients with adenocarcinoma localized in the non-cardia part of the stomach. We separated these patients to either antibody-positive or antibody-negative to *H pylori*. From the examined acute phase reactants, we found that the levels of c-reactive protein, ceruloplasmin, a1-acid glycoprotein and retinol-binding protein in cancer patients were significantly higher than those in healthy controls, while no difference was found regarding the transferrin, prealbumin and a2-macroglobulin levels. However, only retinol-binding protein was significantly related to *H pylori* infection as its values were significantly lower in infected patients than in non-infected ones. The etiology of these biochemical aberrations is probably multifactorial.

Numerous studies have shown that gastric cancer patients have significantly higher levels of CRP[14,21] than healthy controls. A previous study[13] has even showed that elevated CRP levels have a prognostic significance and a recent study suggested that CRP levels contribute to the diagnosis of infection in cancer patients[21]. Our data confirm that CRP is elevated in cancer patients, but we cannot comment on its usefulness in the diagnosis of infection in cancer patients, as this was not the aim of our study. Though it was not different between infected and non-infected patients with *H pylori* (P = 0.09), one possible explanation is that chronic *H pylori* infection did not cause the elevation of CRP with acute infections as pneumonia or bacteremia. The other explanation is that our study did not have the statistical power to detect any difference.

Immunohistochemical analysis of the tumor epithelium showed that the protease inhibitor a2-macroglobulin is related to the invasive growth of gastric cancers[9,10]. Similar preliminary data exist for a1-acid glycoprotein[11-13]. Our data do not support routine measurement of A2M, but confirmed that AAG is a potentially useful marker as it was consistently higher in cancer patients and showed a trend to reach statistical significance in *H pylori*-infected patients (P = 0.08).

The role of iron-carrying protein transferrin is undetermined. Studies showed that there is no difference in the mean TRF values between controls and patients while ferritin values are significantly different[15,29], suggesting that TRF may not be a prognostic factor for future gastric carcinogenesis but its role remains uncertain. In accordance with previous studies, our data did not require measuring transferrin in gastric cancer patients whether they were infected with *H pylori* or not.

Finally, we decided to include the so-called nutritional indices (prealbumin and retinol-binding protein) in our analysis to explore their relation to cancer or *H pylori* infection. In patients with colon cancer, the levels of serum prealbumin, retinol-binding protein, transferrin, and albumin were interrelated and tended to show a similar pattern of change. More specifically, in metastatic colon cancer, prealbumin was the most sensitive indicator of nutritional status and its levels and rates of change

had a prognostic significance. A rapid fall of prealbumin often occurs 2-3 mo prior to death of the patients and this preterminal phase is also frequently heralded by a progressive rise in the CRP level in the absence of any obvious infection[30]. Prealbumin concentration has a prognostic importance in women with epithelial ovarian carcinoma[24] and a general cancer population as well[23]. We cannot confirm the data on the usefulness of prealbumin testing because we did not perform any formal assessment of nutritional status in our study population.

Serum ceruloplasmin levels are higher in gastric and lung cancer[16] and our data have confirmed this finding. We did not find any correlation of *H pylori* infection with ceruloplasmin levels and cannot suggest a pathogenetic role for this copper-chelating protein apart from being a marker of systemic inflammation.

The most interesting findings of our study are the significantly higher levels of retinol-binding protein in gastric cancer patients than healthy controls, the only marker being statistically different between infected and non-infected patients with *H pylori* (it was lower in *H pylori*-infected patients). Our findings are novel and in contrast with previous studies showing decreased RBP levels in the lung[25] and colorectal cancer[17]. Retinol, the ligand of retinol-binding protein, is required to maintain immunity and epithelial turnover and is a key micronutrient needed for combating infection. Studies have shown a good correlation between RBP and retinol even in the context of infection and protein malnutrition[31]. Retinol deficiency could either directly disrupt epithelial integrity or indirectly increase susceptibility to the damaging factors contained in either tobacco smoke (in the case of lung cancer) or diet (in the case of gastric and colorectal cancer). One would expect a lower and not a higher retinol-binding protein value in gastric cancer patients.

A fundamental difference between stomach cancer and other types of cancer is the involvement of *H pylori* in the former. There is evidence that *H pylori* infection *per se* is associated with the abnormalities of the nutritional markers even in the absence of malignancy. Aguilera *et al*[32] studied the relationship between *H pylori* infection, anorexia and malnutrition in 48 peritoneal dialysis patients and found that infected patients with anorexia have lower lymphocyte counts, pre-albumin, transferrin, serum albumin, normalized equivalent of protein-nitrogen appearance and residual renal function. Eradication of *H pylori* could significantly improve the clinical syndrome and the biochemical abnormalities implying a causative role, but unfortunately retinol-binding protein was not measured in that study. The significant decrease in the activity of class IV alcohol dehydrogenase (ADH) in the antrum and corpus of stomachs of men and women infected with *H pylori* may be one of the underlying mechanisms as class IV ADH is the major isoenzyme controlling the production of retinoic acid from retinol and its supply to the human gastric mucosa[33,34]. It has been shown in animal models that the inflammatory response to infection and tissue injury is associated with low concentrations of plasma retinol and its specific transport proteins, retinol-binding protein and pre-albumin[35], suggesting that inflammation-induced hyporetinemia is attributed to a reduction in the hepatic synthesis of RBP and secretion of the retinol-RBP complex. The marked depressing effect of infections on serum retinol and retinol-binding protein has also been shown in human beings[36,37]. We speculate that *H pylori* infection in gastric carcinoma patients can lead to a decrease of retinol-binding protein by one of the above mechanisms but it remains unclear why uninfected patients with gastric cancer still have higher RBP levels than healthy controls.

The role of retinoids in gastric carcinogenesis has been studied in epidemiologic studies with conflicting results[27,28], but the molecular mechanisms that operate at either healthy or disease states have begun to be elucidated. Retinol has been shown to enhance differentiation of the gastric cell lineage in developing rabbits[38] and the reduction of retinoic acid signal has been implicated in the development and evolution of pre-malignant lesions of the human gastric mucosa[39]. The activation of the retinoic acid receptor induces cell differentiation and may antagonize cancer progression. Cellular retinol-binding protein I (CRBP-I) functions in retinol storage and its expression is lower in human cancers than in normal cells. A very recent study[40] showed that CRBP-I downregulation in human mammary epithelial cells chronically compromises retinoic acid receptor activity, leading to the loss of cell differentiation and tumor progression. The fact that class IV ADH is the major isoenzyme responsible for retinoic acid production from retinol and the more significantly decreased enzyme in the presence of *H pylori* infection associated with morphologic changes in the human gastric mucosa is intriguing. The retinoic acid pathway may be one of the missing links in the interplay of *H pylori* infection with gastric carcinogenesis.

In conclusion, gastric cancer patients with *H pylori* infection have significantly lower retinol-binding protein values than non-infected ones and both infected and non-infected groups have higher retinol-binding protein values than healthy controls. This finding may add to our understanding and management of this dreadful disease.

Abstract

AIM: To evaluate the effect of interferon alpha (IFN-α) treatment on the liver histology in children with chronic hepatitis B and to evaluate the usefulness of various histological scoring systems of liver histology in this group of patients.

METHODS: Fibrosis stage and inflammation grade were assessed according to Batts and Ludwig, Ishak *et al*, and METAVIR (only fibrosis stage) before and 12 mo after IFN-α treatment termination in 93 children aged 2-16 years with chronic hepatitis B.

RESULTS: None of the three numerical scoring systems for liver fibrosis showed statistically significant differences in liver fibrosis, while evolution of inflammatory activity revealed statistically significant improvement in the whole group of children with chronic hepatitis B treated with IFN-α and in responders. Significantly positive correlations were found between fibrosis stage and inflammation grade in the respective scoring systems.

CONCLUSION: Treatment with IFN-α did not improve histological fibrosis but decreased inflammatory activity in children with chronic hepatitis B. The three semiquantitative scoring systems seem to be comparable in the estimation of the inflammation grade and fibrosis stage in this group of children.

Key words: Children; Chronic hepatitis B; Interferon alpha; Fibrosis stage, Inflammation grade; Semiquantitative scoring systems

INTRODUCTION

Interferon alpha (IFN-α) is currently used as a standard treatment for chronic hepatitis B in children. According to Bortolotti[1], the clearance of HBeAg and HBV DNA from serum, normalization of serum ALT activity and improvement of liver histology within 12 mo after treatment discontinuation are considered as the most important endpoints in therapy efficacy evaluation.

Several semiquantitative histological scoring systems have been used in the morphological evaluation of chronic viral hepatitis. The most widely used are the scoring systems according to Ishak *et al*[2], Batts and Ludwig[3], Desmet *et al*[4] and METAVIR[5], which is contrary to the scale proposed by Knodell *et al*[6], definitely separate inflammation grade from fibrosis stage.

The aim of the study was to evaluate the effect of IFN-α treatment on liver histology in children with chronic hepatitis B and to assess the usefulness of different scoring systems of liver histology in pediatric patients. This is the first morphological analysis using different histological semiquantitative scoring systems performed on such a large material obtained from children.

MATERIALS AND METHODS

Patients

The study was carried out prospectively on 93 consecutive children (range 2-16 years, mean age 7.1 years; 69 boys and 24 girls) with biopsy-verified chronic hepatitis B (HBs/+/, HBe/+/, DNA/+/ for at least 12 mo; mean 39±27 mo). Mean ALT activity was 95±79 IU/L. Patients with diagnosed autoimmune hepatitis, liver cirrhosis or HCV coinfection were excluded from the study. None of the children were treated with antiviral or immunomodulating drugs during the 12-mo period before entering the study. IFN-α was applied in the dose of 3 MU thrice a week subcutaneously for 20 wk (this schedule is accepted for children in Poland by Polish Interferon Study Group[7]). The presence of HBeAg/antiHBe seroconversion 1 year after therapy discontinuation was considered to be the criterion of treatment efficacy. Informed consent was obtained from all parents of the patients. The study protocol was approved by the local ethical committee.

Table 1 Morphological evaluation of liver biopsies in children with chronic hepatitis B treated with IFN-α (*n* = 93)

Scoring system	Baseline biopsy	Final biopsy
Batts grade	1.516±0.619	1.312±0.51[a]
Batts stage	1.892±0.598	1.839±0.631
Ishak grade	4.054±1.683	3.344±1.514[b]
Ishak stage	2.462±1.006	2.398±1.034
METAVIR stage	1.667±0.712	1.645±0.702

[a]$P<0.05$ *vs* baseline biopsy; [b]$P<0.01$ *vs* baseline biopsy.

Table 2 Morphological evaluation of liver biopsies in children with chronic hepatitis B treated with IFN-α in the subgroups of responders (*n* = 35) and nonresponders (*n* = 58)

Scoring system	Subgroups	Baseline biopsy	Final biopsy
Batts grade	Nonresponders	1.431±0.596	1.379±0.524
	Responders	1.657±0.639	1.2±0.473[b]
Batts stage	Nonresponders	1.793±0.554	1.81±0.606
	Responders	2.057±0.639	1.886±0.676
Ishak grade	Nonresponders	3.81±1.503	3.43±1.403
	Responders	4.457±1.899	3.2±1.694[b]
Ishak stage	Nonresponders	2.293±0.878	2.431±0.901
	Responders	2.743±1.146	2.343±1.255
METAVIR stage	Nonresponders	1.62±0.644	1.638±0.667
	Responders	1.743±0.816	1.657±0.764

[b]$P<0.01$ *vs* baseline biopsy.

Table 3 Correlations between staging and grading according different histological scoring systems

Scoring system	Batts grade	Batts stage	Ishak grade	Ishak stage	METAVIR stage
Batts grade	-	$r = 0.385$ $P = 0.00014$	$r = 0.825$ $P = 0.0000001$	$r = 0.392$ $P = 0.0001$	$r = 0.405$ $P = 0.00005$
Batts stage	$r = 0.385$ $P = 0.00014$	-	$r = 0.522$ $P = 0.0000001$	$r = 0.713$ $P = 0.0000001$	$r = 0.713$ $P = 0.0000001$
Ishak grade	$r = 0.825$ $P = 0.0000001$	$r = 0.522$ $P = 0.0000001$	-	$r = 0.409$ $P = 0.000045$	$r = 0.41$ $P = 0.000045$
Ishak stage	$r = 0.392$ $P = 0.0001$	$r = 0.713$ $P = 0.0000001$	$r = 0.409$ $P = 0.000045$	-	$r = 0.758$ $P = 0.0000001$
METAVIR stage	$r = 0.405$ $P = 0.00005$	$r = 0.713$ $P = 0.0000001$	$r = 0.41$ $P = 0.000045$	$r = 0.758$ $P = 0.0000001$	-

Histological analysis

The percutaneous liver biopsies were obtained immediately before the treatment and 12 mo after the end of the IFN-α treatment. The liver biopsies were fixed in 10% buffered formalin and embedded in paraffin. Four-micrometer histological sections were prepared and stained with hematoxylin and eosin, Masson's trichrome, Masson's-Goldner and reticulin stain. Fibrosis stage and inflammation grade were assessed in a blinded fashion by a single pathologist according to Batts and Ludwig[3] and Ishak *et al*[2]; METAVIR scoring system[5] was additionally used for assessing only fibrosis.

Statistical analysis

The results were expressed as mean±SD. Differences in the respective groups were analyzed using Wilcoxon's test for pairs. Spearman's correlation coefficient was used to define correlations between the examined scoring systems. Differences were considered statistically significant at $P<0.05$.

RESULTS

Table 1 shows the results of morphological evaluation of hepatic inflammation and fibrosis in children with chronic hepatitis B prior to the IFN-α treatment (baseline biopsy) and 12 mo after IFN-α therapy discontinuation (final biopsy).

There was a significant improvement of histological inflammation both in the system of Batts and Ludwig ($P = 0.039$) and Ishak *et al* ($P = 0.0019$). However, there were no significant differences in liver fibrosis of the three semiquantitative scoring systems used.

HBeAg/antiHBe seroconversion 12 mo after therapy termination was observed in 38% of treated children. Therefore, two subgroups were distinguished: responders (35 children) and nonresponders (58 children).

The results of morphological examinations of liver biopsy before the treatment in both subgroups showed more severe intensification (although statistically insignificant) of the inflammation grade and the stage of fibrosis in the subgroup of responders. There was significant improvement of histological inflammation only in the subgroup of responders ($P = 0.0058$ according to Batts and Ludwig; $P = 0.0039$ according to Ishak *et al*), but there were no significant changes in liver fibrosis in either subgroup according to the three respective scoring systems (Table 2).

Significantly positive correlations were found between fibrosis stage and inflammation grade in the respective systems (Table 3).

DISCUSSION

The improvement of liver morphology evaluated not earlier than 12 mo after treatment discontinuation in

comparison to the baseline biopsy is one of the criteria of IFN-α therapy efficacy.

The comparison of three histological scoring systems used to evaluate chronic hepatitis in children with HBV infection revealed a high coefficient of positive correlation between the respective scales. Thus, the systems seem comparable in the estimation of the inflammation grade and stage of fibrosis in children and therefore they can be used according to the preferences of a hepatological center. In adults, Rozario and Ramakrishna[8] were in agreement with our results; they concluded that concordance between Ishak and METAVIR scoring systems was good for necroinflammatory change and excellent for fibrotic change. We also showed a close correlation between liver fibrosis and inflammatory activity, which is in agreement with Lu *et al*[9]. Assy and Minuk[10] also confirmed good correlation between the previously and currently used histological assessment of chronic hepatitis, according to the International Group[11] and Desmet *et al*[4]. As no comparative analysis of the above systems in children have been known to the authors, the current study may inspire further analysis performed on a large group of patients in order to make up the standard morphological estimation of liver biopsy in childhood.

We found no significant changes in the stage of liver fibrosis in children with chronic hepatitis B, neither in responders nor in nonresponders to IFN-α, while a statistically significant decrease was noted in the intensification of necrotic-inflammatory process in the whole group and in the subgroup of responders.

The inhibition of HBV replication was most widely discussed in the previous reports on the treatment of HBV infections in children[12,13]. Considerably less attention was paid to the changes in the morphological picture of liver biopsy after antiviral therapy (changes in necrotic-inflammatory process intensification were mainly evaluated); single reports discuss the changes of liver fibrosis. So far, a statistically significant decrease has been reported in the inflammation grade[14-20], which is in agreement with our analysis. In literature, the reduction in inflammatory activity in IFN-α treated children is estimated at 80%[16,17].

Only a few studies in the world literature analyze the effect of IFN-α therapy on the stage of fibrosis in children with chronic hepatitis B. Most authors did not show improvement of the stage of liver fibrosis caused by antiviral treatment[14,20,21]. Gregorio *et al*[15] found significant improvement only in staging in the responders. But these trials included a relatively small number of liver biopsies. Further studies by Ruiz Moreno *et al*[19] were conducted on a representative group of 60 children with chronic hepatitis B treated with IFN-α, who underwent two liver biopsies (baseline and final). They found that when biopsies were obtained within 12 mo after HBeAg clearance, the degree of histological fibrosis was significantly higher than that seen in biopsies taken after 12 mo. These data seem to indicate that in order to achieve a reliable evaluation of final hepatic fibrosis, histological examination should be performed not earlier than 12 mo after HBeAg/antiHBe seroconversion. In the present study, the liver biopsies were taken not earlier than after 12 mo of IFN-α therapy discontinuation, as this length of time seems sufficient to evaluate the therapy efficacy determined by histopathological analyses.

Studies conducted on the population of adults with chronic hepatitis B and C also do not provide a satisfactory answer to the question whether IFN-α treatment reduces the stage of liver fibrosis. Many authors have shown no significant changes of liver fibrosis due to this cytokine[22-24]; others, however, have proved a beneficial effect of IFN-α therapy on the reduction of the stage of fibrosis[25-29], particularly in responders[30-32]. Yet, they all underline the effect of IFN-α on the reduction of inflammation grade. The analysis of natural history of HBV infection shows that the inflammatory process in the liver is a triggering mechanism preceding fibrosis. It also seems that the IFN-α-induced reduction in fibrosis is preceded by the regression of inflammatory activity. Considerable divergence in the evaluation of the effect of IFN-α on fibrotic lesions in the liver of patients with chronic viral hepatitis seems to suggest that longer observation period (a few years) prior to the final biopsy is necessary to properly evaluate therapy-induced changes in fibrotic processes.

In conclusion, the treatment with IFN-α did not improve histological fibrosis but decreased inflammatory activity in children with chronic hepatitis B. The various semiquantitative histological scoring systems seem to be comparable in the estimation of the inflammation grade and fibrosis stage in this group of children.

Abstract

AIM: To evaluate the effects of *Helicobacter pylori* infection on gastric epithelial cell kinetics in patients with chronic renal failure (CRF).

METHODS: Forty-four patients were enrolled in this study and divided into four groups with respect to their *Helicobacter pylori (H pylori)* and CRF status. Groups were labeled as follows: 1a: normal renal function, *H pylori* negative (n = 12), 1b: normal renal function, *H pylori* positive (n = 11), 2a: CRF, *H pylori* negative (n = 10), 2b: CRF, *H pylori* positive (n = 11). Upper gastrointestinal endoscopy was done in all the patients involved in the study. During endoscopical investigation, antral biopsy specimens were taken from each patient. In order to evaluate the cell apoptosis and proliferation in gastric epithelial cells, Bax and proliferating cell nuclear antigen (PCNA) labeling indexes (LI) were assessed with immunohistochemical staining method.

RESULTS: For groups 1a, 1b, 2a, and 2b, mean Bax LI was identified as 34.4±13.7, 44.1±16.5, 46.3±20.5, 60.7±13.8, respectively and mean PCNA LI was identified as 36.2±17.2, 53.6±25.6, 59.5±25.6, 67.2±22, respectively. When the one-way ANOVA test was applied, statistically significant differences were detected between the groups for both Bax LI (P = 0.004 <0.01) and PCNA LI (P = 0.009 <0.01). When groups were compared further in terms of Bax LI and PCNA LI with Tukey's HSD test for multiple pairwise comparisons, statistically significant difference was observed only between groups 1a and 2b (P = 0.006 <0.01).

CONCLUSION: In gastric epithelial cells, expression of both the pre-apoptotic protein Bax and the proliferation marker PCNA increase with *H pylori* infection. This increase is more evident in patients with uremia. These findings suggest that uremia accelerates apoptosis and proliferation in gastric epithelial cells.

INTRODUCTION

Helicobacter pylori (H pylori) is the most common chronic infection in human beings. *H pylori* infection has been related to peptic ulcer disease, gastric lymphoma and stomach cancers[1,2]. It is an important problem for public health as it can cause several diseases.

Gastrointestinal mucosa is characterized with rapid epithelial cell turnover and homeostasis that is mainly provided by apoptosis[3]. Therefore, it can be considered that the impaired apoptosis may have a role in the pathogenesis of many gastrointestinal system diseases.

In many studies, it has been shown that apoptotic cells are increased after colonization of *H pylori* in the stomach[4-7], and those increased apoptotic cell levels decrease to normal levels after *H pylori* eradication[5,8,9]. Increase in apoptotic cell rates causes compensatory hyperproliferative response in order to maintain gastric mucosal tissue mass[10-12].

The mechanisms by which *H pylori* induces apoptosis of gastric epithelial cells have remained unclear. It has been suggested that many bacterial products might be inducing apoptosis[5,13-15]. One of the factors that has been responsible for apoptosis of gastric epithelial cells is ammonia, which is produced via the degradation of urea by the urease enzyme of *H pylori*[5,16]. Because of high intragastric urea concentrations in patients with chronic renal failure (CRF), levels of ammonia produced by *H pylori* are significantly high[16]. Therefore, disorders associated with excessive ammonia production are more

prevalent[17,18].

Although the relationship of *H pylori* with apoptosis and proliferation in gastric epithelial cells has been mostly studied in cases with normal renal functions, gastric epithelial cell kinetics in patients with CRF still remains unknown. This study aims to investigate the effect of *H pylori* on gastric epithelial cell kinetics in patients with CRF.

MATERIALS AND METHODS

Subjects

The study included 44 patients, of whom 23 with normal renal function and 21 with CRF who were on hemodialysis treatment.

Those with gastric and/or duodenal ulcers as confirmed by upper gastrointestinal endoscopy were excluded from the study. None of the patients included had a history of gastric surgery. Patients who had been treated for *H pylori* or who had used any antibiotics, proton-pump inhibitor, H_2 receptor blocker or any compound that includes bismuth during the last one month were also excluded from the study.

The CRF patients were on a thrice-weekly hemodialysis program. The dialysis prescription included 4-5 h of bicarbonate hemodialysis with standard cuprophane membranes (hollow fiber 1-1.2 m2 surface area, Gambro, Sweden).

We divided the patients into four groups based on their *H pylori* and renal function status:

Group 1a: normal renal function, *H pylori* negative (12 patients)
Group 1b: normal renal function, *H pylori* positive (11 patients)
Group 2a: CFR, *H pylori* negative (10 patients)
Group 2b: CRF, *H pylori* positive (11 patients)

Endoscopy method

All patients were examined by using the upper gastrointestinal endoscopy (video-endoscope Olympus GIP Q240) after premedication with intravenous midazolam (2.5-7.5 mg), after an overnight fast.

During upper gastrointestinal endoscopy, multiple biopsy materials were taken from the antral region of the stomach. The biopsy specimens were transferred to the pathology laboratory in 10% buffered formalin. This study was conducted after getting permission from the local ethics committee of the Baskent University School of Medicine, Ankara, Turkey.

Identification of H pylori infection

H pylori was detected under microscopy on the histological sections stained with Giemsa staining method.

Laboratory methods

After a 12-h fasting period, venous blood samples were taken from the forearm-superficial veins of the patients in the morning. In the HD patients, the blood samples were taken before HD session. Serum levels of creatinine (normal <1.2 mg/dL) and blood urea nitrogen (BUN, normal <20 mg/dL) were measured in the central laboratory of our hospital by using routine automated techniques.

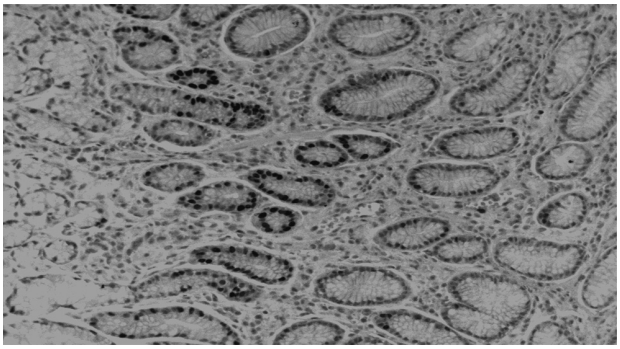

Figure 1 Proliferating cell nuclear antigen (PCNA) immunostaining of the gastric mucosa, original magnification ×250.

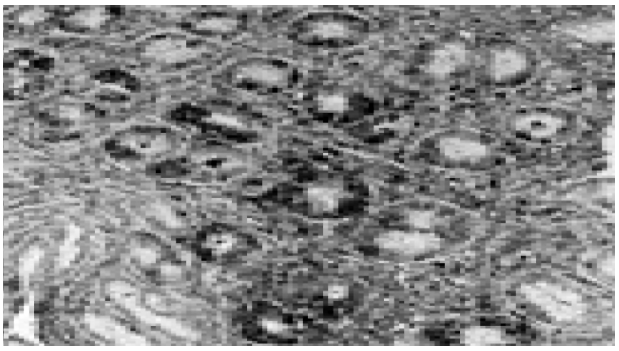

Figure 2 Bax immunostaining of the gastric mucosa, original magnification ×400.

Immunohistochemical staining for proliferating cell nuclear antigen and Bax

All biopsies were fixed in formalin, embedded in paraffin and processed routinely. Briefly, 4-mm-thick sections were deparaffinized and mounted on poly-L-lysine-coated slides. The sections in a citrate buffer (0.01 mol/L, pH 6) were heated in a microwave oven for 15 min at a maximum power (700 W), and then cooled at room temperature for 20 min. A standard three-step immunoperoxidase avidin-biotin peroxidase complex (ABC) technique was used to identify the proliferating cell nuclear antige (PCNA) (PC10, Neomarkers, CA, USA) (Figure 1). A catalyzed signal amplification (CSA) system was used to detect the polyclonal antibody Bax (K1500, Dako, Denmark) (Figure 2). PCNA and Bax positive cells were counted in the glandular neck region, which corresponds to the area of cell proliferation[19,20]. The field to be counted was chosen under ×400 magnification from the well-labeled area. About 1 000 cells were counted in each case to determine the PCNA and Bax labeling indexes (LI). The percentage of positively stained cells over total cells counted was then calculated and used as a labeling index for PCNA and Bax expression[21,22]. All histological slides were reviewed by the same experienced pathologist. The pathologist who rated the PCNA and Bax LI was unaware of the *H pylori* and renal function status of the patients.

Statistical analysis

Statistical analyses were carried out using the program SPSS 9.0 for Windows. To compare the groups, we used Student's *t*-test, Mann-Whitney *U* test, one-way ANOVA and Tukey's HSD test when appropriate. *P* values <0.05 were considered statistically significant.

RESULTS

The number of patients, their mean ages and HD duration are shown in Table 1 for each group separately. There were no statistically significant differences between the groups with regard to mean ages, gender, and HD duration ($P>0.05$).

Creatinine levels were 0.7±02, 0.8±0.2, 7.3±1.1, 7.1±1.3 mg/dL, and BUN levels were 13.8±3.5, 15.4±4.1, 98.7±12.2, 96.1±11.5 mg/dL in groups 1a, 1b, 2a, 2b, respectively (Table 2). Considering the creatinine and BUN levels, there were no statistically significant differences between the groups 1a and 1b ($P>0.05$), and between the groups 2a and 2b ($P>0.05$) but levels were higher in groups 2a and 2b than 1a and 1b ($P<0.001$).

Table 1 Number, gender, mean age, and hemodialysis duration of patient groups

	Group 1a	Group 1b	Group 2a	Group 2b
Patients (*n*)	12	11	10	11
Sex (M/F)	7/5	6/5	5/5	6/5
Mean age (yr)	37±7	39±7	35±8	36±11
Hemodialysis duration (mo)	–	–	10.4±4.5	9.3±4.4

Group 1a: normal renal function, *H pylori* negative; group 1b: normal renal function, *H pylori* positive; group 2a: CRF, *H pylori* negative; group 2b: CRF, *H pylori* positive.

For groups 1a, 1b, 2a, 2b, mean Bax LI was identified as 34.4±13.7, 44.1±16.5, 46.3±20.5, 60.7±13.8, respectively, and mean PCNA LI was identified as 36.2±17.2, 53.6±25.6, 59.5±25.6, 67.2±22, respectively.

When the one-way ANOVA test was applied, statistically significant differences were detected between the groups for both Bax LI ($P = 0.004 <0.01$) and PCNA LI ($P = 0.009 <0.01$). When groups were compared further in terms of Bax LI and PCNA LI with Tukey's HSD test for multiple pairwise comparisons, statistically significant difference was observed only between groups 1a and 2b ($P = 0.006 <0.01$).

In patients with *H pylori* infection and CRF, Bax LI and PCNA LI were found to be increased. However, the increase was more prominent in patients with CRF compared to patients with *H pylori* infection.

Table 2 Creatinine, BUN, Bax, and PCNA LI in different patient groups

	Group 1a	Group 1b	Group 2a	Group 2b
Creatinine	0.7±0.2	0.8±0.2	7.3±1.1[a,b]	7.1±1.3[c,d]
BUN	13.8±3.5	15.4±4.1	98.7±12.2[a,b]	96.1±11.5[c,d]
Bax labeling index	34.4±13.7	44.1±16.5	46.3±20.5	60.7±13.8[e]
PCNA labeling index	36.2±17.2	53.6±25.6	59.5±25.6	67.2±22.1[e]

Group 1a: normal renal function, *H pylori* negative; group 1b: normal renal function, *H pylori* positive; group 2a: CRF, *H pylori* negative; group 2b: CRF, *H pylori* positive. [a]$P<0.001$ group 1a *vs* 2a; [b]$P<0.001$ group 1b *vs* 2a; [c]$P<0.001$ group 1a *vs* 2b; [d]$P<0.001$ group 1b *vs* 2b; [e]$P<0.01$ group 1a *vs* 2b.

DISCUSSION

This is the first study where cell turnover of gastric epithelial cells is investigated in patients with CRF. We have shown that both *H pylori* infection and uremia cause increases in Bax and PCNA LI in gastric epithelial cells. Other studies in the literature that show *H pylori* increases the proliferation and apoptosis in gastric epithelial cells in cases with normal renal function support the results of our study. In addition, we also noted that both apoptosis and proliferation in gastric epithelial cells are more increased in patients with CRF.

Maintaining gastric mucosal integrity is a complex biological process[23]. This subject is provided with the balance between programmed cell death, which is also called apoptosis, and epithelial cell proliferation[23–26]. Apoptosis has been accepted as a physiological form of death and is a genetically programmed process where the cell commits suicide[27,28]. Unlike necrosis, dead cells do not cause inflammatory response in apoptosis[28]. Deranged apoptosis has been implicated in carcinogenesis, autoimmune diseases, and various infectious diseases including *H pylori* infection[5,23,28,29]. Regulation of apoptosis is a complex process. This process includes the activation of various apoptosis-related proteins such as the Bcl-2 family, p53, Fas and its ligand (FasL), and the interleukin-1b-related concerning enzyme (ICE) family[23,30].

There are several methods for evaluating cell division[31]. PCNA is a co-factor of DNA polymerase and mainly determined in late G_1 or S phase. There are several evidences that PCNA assessment is a useful tool to evaluate cell proliferation and previous studies have shown that PCNA index correlates with S phase fraction of tumor cells determined by DNA flow cytometry[32-35]. Furthermore, it has been found that PCNA immunostaining correlates with Ki67, the latter marking cells in G_1 and G_2 phases in addition to those in S phase and also with tymidine labeling index[36] and with bromodeoxyuridine uptake in cancer cell lines[20,37].

Many genes regulate the balance between apoptosis and cell proliferation. The pro-apoptotic protein, Bax, is a member of Bcl-2 gene family and is one of the genes that regulate apoptosis. Bax gene is a tumor suppressor gene and induces apoptosis via encoding Bax protein. It has been suggested that proliferation and apoptosis in the antral mucosa caused by *H pylori* is associated with the alterations in genes that regulate the process[8,22,38,39]. Konturek *et al*[23] showed that apoptosis induced by *H pylori* in gastric epithelial cells is associated with the upregulation

of proapoptotic Bax.

In many studies, it has been shown that the number of apoptotic cells in the stomach increase after *H pylori* colonization[4-6]. In addition, it has also been shown that the apoptotic cell number in stomach decreases to normal after *H pylori* eradication[5,8,9]. This increase in apoptotic rate causes compensatory hyperproliferative response in order to maintain gastric mucosa tissue mass[11].

In the literature, there are some data which suggest that apoptosis is associated with both bacterial and host factors[13-15,23]. However, the mechanism of apoptosis in *H pylori* infection is still not clear.

Some of the factors accused within the apoptosis are lipopolysaccharides, ammonia, and monochloramine (NH_2Cl), which is a highly toxic substance generated as a result of the reaction of ammonia with neutrophil-derived free radicals[13-15]. There are still debates on the role of cytotoxic agents such as *H pylori*-CagA and *H pylori*-VacA in apoptosis. In recent *in vivo* and *in vitro* studies, it has been found that *H pylori* strains can induce apoptosis without any dependency on Cag-A and Vac-A genotype[23]. In addition to the bacterial factors in infections of *H pylori*, characteristics of the host can also play important roles. Evidences are increasing about the inflammatory reactions that are induced by *H pylori* in gastric mucosa, especially cytokines such as nitric oxide and TNFα might assist to induce apoptosis[6].

One of the major factors that are responsible for *H pylori* derived apoptosis is ammonia. *H pylori* has a strong urease activity and the hydrolysis of urea causes production of high level of ammonia concentration in mucous gel layer[40]. *In vitro* studies have shown that *H pylori* derived ammonia causes lesions in insulated gastric epithelial cells. Ammonia concentrations, determined in *H pylori* infected subjects, cause gastric mucosal lesions[40-42], delay in mucosal improvement[43], and induce apoptosis in gastric epithelial cells[13,44].

Ammonia level, which is produced by *H pylori*, is controlled by the existence of urea in gastric juice. Patients with CRF have high intragastric urea concentrations and levels of ammonia produced by *H pylori* are significantly high[16]. Therefore, disorders associated with excessive ammonia production may be more prevalent in patients with uremia. In our cases, increased apoptosis and proliferation rate that are observed in uremia patients can be associated with excessive ammonia production by *H pylori* infection in uremia patients compared with cases that have normal renal functions.

In conclusion, in gastric epithelial cells, expression of both the pre-apoptotic protein Bax and the proliferation marker PCNA increase with *H pylori* infection. This increase is more evident in patients with uremia. These findings suggest that uremia accelerates apoptosis and proliferation in gastric epithelial cells.

Abstract

AIM: To evaluate whether the cytokine responses in liver and serum differ in chronic hepatitis C patients with normal and high alanine aminotransferase (ALT) levels.

METHODS: Thirty-three (16 with normal ALT level as group 1 and 17 with elevated ALT level as group 2) patients infected with genotype 1b hepatitis C virus (HCV) were examined. Liver infiltrating lymphomononuclear cells (LILMCs) were isolated from liver biopsy by collagenase type 1 and stimulated with phytohemagglutinin and interleukin 2 (IL-2). IL-10, IL-12, interferon gamma (IFN-γ) and tumor necrosis factor alpha (TNF-α) were determined in serum and LILMCs by ELISA.

RESULTS: Serum cytokine levels were similar in both groups (P>0.05). Stimulated IFN-γ and TNF-α levels in LILMCs were increased in both groups. IL-12 and IL-10 levels stimulated with IL-2 were higher in group 1 than in group 2 (P = 0.023). Histological activity index (HAI) and stage had a negative correlation with TNF-α and IFN-γ levels in group 2.

CONCLUSION: Increased T-helper type 2 (Th2) cytokine response may regress inflammatory and biochemical activity. Progression of histological abnormalities in persons with elevated ALT probably depends on insufficient Th2 cytokine response, which does not balance Th1 cytokine response.

Key words: Liver cytokines; HCV; ALT

INTRODUCTION

The liver is the primary site of hepatitis C virus (HCV) replication[1]. Clearance and control of HCV infection depend on immune responses. T lymphocytes and immunoregulatory cytokines play an important role in the host response to HCV infection[2]. Intrahepatic T-cell response to HCV may determine the hepatic injury of HCV infection[3,4]. T cells also play a role in HCV clearance[5]. Th1 cytokines such as IL-2 and IFN-γ are required for host antiviral immune response, while Th2 cytokine (IL-10) can inhibit the development of these responses[2]. TNF-α also triggers a partially overlapping set of antiviral defense mechanisms and serum level of TNF-α reflects the progression of inflammation[6,7].

The natural course of HCV infection is not clear. Also, the behavior of HCV infection cannot be estimated. Different immune responses in each patient may determine the clinical course. Approximately 30% of patients with chronic HCV infection show persistently normal ALT levels that are positive for HCV-RNA. Only a small number of these patients (0-20%) have normal histology. These people are referred as healthy HCV carriers[8]. Immunological differences between patients with normal and elevated ALT levels are not well known. Most patients with normal ALT levels have a certain degree of liver damage and show a slow progression[9].

This study aimed to evaluate whether the cytokine responses in liver and serum differ in chronic hepatitis C patients with normal and high ALT levels.

MATERIALS AND METHODS

Thirty-three patients infected with genotype 1b HCV were studied. Sixteen of them had persistently normal ALT levels (group 1), while 17 had high ALT levels (group 2) by at least four analyses in a year. Anti-HCV was determined by UBI EIA 4.0 (Organon Teknika, Holland). HCV-RNA was determined by polymerase chain reaction (COBAS Amplicor 2, Roche Diagnostics, Germany)

and HCV genotyping was carried out with INNO-LiPA HCV assay (Innogenetics NV, Belgium). Hepatitis B surface antigen (HBsAg) and anti-HIV were negative in all patients. HBsAg was detected by immunoenzymatic assay [Hepanostika HBsAg Uni-Form II (Organon Teknika, Holland)]. All patients were also negative for any other etiology of liver diseases. Blood was drawn from all patients and centrifuged at 2 500 r/min for 5 min and separated serum samples were stored at -85 ℃. Liver biopsy was performed in all the patients before the treatment. Histological changes (HAI and extent of fibrosis) were assessed according to the Knodell's scoring system[10].

LILMCs were isolated from liver biopsies as previously described by Bertoletti *et al*[11]. Biopsies were washed twice in RPMI 1640 medium to remove contaminated blood and digested with collagenase type-I (1 mg/mL CO130, Sigma Chemical Co., USA) and deoxyribonuclease I (25 mg/mL D4263, Sigma Chemical Co., USA) for 1 h at 37 ℃ on a shaking device. The liver specimen was then pipetted vigorously to disrupt the hepatic tissue and to release infiltrating lymphomononuclear cells. The mononuclear cell suspension was washed twice and the cells were recovered by centrifugation over a Ficoll-hypaque density gradient. Cells were then suspended in RPMI 1640 (GIBCO Lab) containing 10% heat inactivated fetal calf serum, 25 mmol/L HEPES, 2 mmol/L L-glutamine and 50μg/mL gentamycin. Viability was >95% by the trypan blue dye exclusion test. Cells were cultured in duplicate (1.0×10^5 viable cells/100 μL) in flat-bottomed 96-well plates at 37 ℃ in an atmosphere containing 50 mL/L CO_2 with medium alone (unstimulated culture) and stimulated with 10 μg/mL phytohemagglutinin (1:100 PHA, Sigma Chemical Co., USA) and recombinant IL-12 (20 U/mL, R&D Systems, USA). Restimulation was performed every 10 d. Supernatants were collected at the end of the proliferation assay and kept frozen at -70 ℃ for later analyses. Culture supernatants and sera were thawed and the serum level of cytokines was measured by ELISA.

The local ethic committee approved this study. Informed consent was obtained from each patient included in this study. Data were presented as mean±SD. Data analysis was made by the χ^2, Fisher's exact, Mann-Whitney *U* and Pearson's correlation tests using SPSS for Windows (Chicago, IL, USA) when appropriate. $P<0.05$ was considered statistically significant.

RESULTS

Age, gender and viral load were similar in groups 1 and 2 (Table 1). The results of biochemical analyses except for aspartate aminotransferase (AST) and ALT were also similar in both the groups. In group 1, five patients underwent liver biopsy before being enrolled in the study. Though liver histology was similar in three patients, histological progression from stage 1 to stage 3 was observed in two of them.

Serum levels of IFN-γ (1.2±1.8; 1.1±0.9 pg/mL), IL-12 (0.2±0.4; 0.11±0.26 pg/mL), IL-10 (17.7±55.6; 18.2±47.8 pg/mL) and TNF-α (0.9±1.2; 0.4±0.25 pg/mL) were similar in groups 1 and 2 ($P>0.05$). Both stimulated IFN-γ and TNF-α levels in LILMCs were increased in comparison to their serum levels in both groups.

In ALT normal patients, there was a positive correlation between TNF-α and IFN-γ levels (both serum and liver) ($P<0.05$, $r = 0.5$). IL-12 and IL-10 levels stimulated by IL-2

Table 1 Demographic and biochemical features of patients (mean±SD)

	Normal ALT	Elevated ALT	*P*
n	16	17

TNF-α			
IL-2	2.5±1.06	2.5±2.9	>0.05
PHA	3.3±1.4	3.8±3.2	>0.05

ALT: alanine aminotransferase; PHA: phytohemagglutinin; LILMCs: liver infiltrating lymphomononuclear cells.

were higher in group 1 than in group 2 ($P<0.05$, Table 2).

In elevated ALT patients, there was a negative correlation between serum IL-12 and IFN-γ levels ($P = 0.01$, $r = –0.6$). HAI and stage had a negative correlation with TNF-α ($P<0.05$, $r = –0.8$; $P<0.05$, $r = –0.6$, respectively) and IFN-γ ($P<0.05$, $r = –0.5$; $P<0.05$, $r = –0.4$, respectively) levels (Figure 1). IL-10 stimulated by IL-2 had a positive correlation with HAI ($P<0.05$, $r = 0.49$) and stage ($P<0.05$, $r = 0.59$) (Figure 2). TNF-α and IFN-γ levels in LILMCs were positively correlated ($P<0.05$, $r = 0.8$). Cytokine levels in serum and LILMCs were not correlated with serum HCV-RNA loads in both groups.

DISCUSSION

Factors involved in the progression to end-stage liver disease in HCV-infected patients are not well characterized. It is thought that cytotoxic T lymphocyte (CTL) response early in infection may be important for viral clearance, while continuous low-level anti-HCV CTL-dependent immune response may be responsible for accumulated liver damage[12]. Prezzi *et al*[13] showed that LILMCs have phenotypic and functional characteristics distinct from peripheral blood lymphocytes. All these immunological processes define natural progress of HCV infection. Patients with normal and elevated ALT levels show different clinical patterns[14]. Generally, HCV carriers with normal ALT have mild and stable diseases with a favorable prognosis[8]. Liver histology was normal in 20% of our cases with persistently normal ALT. Progression of liver fibrosis was observed in two of five patients (40%) who had a second liver biopsy in a period of 41.5±22.1 months.

Immunological studies concerning HCV infection generally focus on T lymphocytes. However, the serum cytokine levels have been found to be different in chronic hepatitis C patients[2,15,16]. Rico *et al*[1] showed that HCV specific CD4+ T-cell proliferation responses do not parallel in LILMCs and peripheral blood mononuclear cells. The magnitude of T-cell response is higher in the liver than in peripheral blood. In our study, serum levels of cytokines were similar in patients with persistently normal and elevated ALT, suggesting that liver cytokine levels are more important than serum levels in mediating T-cell responses.

IL-10 and IL-12 levels stimulated with IL-2 were higher in patients with normal ALT than in those with elevated ALT ($P<0.05$). While IL-10 showed Th2 response, IL-12 promoted Th1 cell induction and cell-mediated immunity. Interestingly both of them were high in patients with normal ALT, suggesting that strong Th2 response may be the cause of the mild biochemical and histological activity in patients with normal ALT.

Sobue *et al*[4] revealed that disease activity and progression correlate with dominant Th1 response in chronic hepatitis C patients. On the other hand, Tsai *et al*[17] showed that predominant Th1 response is stronger in patients with resolved infection than in those with chronic diseases. In our study, while histological stage and HAI were increased, TNF-α and IFN-γ levels were decreased in patients with elevated ALT (Figure 1). TNF-α and IFN-γ trigger antiviral defense mechanisms and have a principal effect on inflammation[6,7]. This means that the magnitude of antiviral immune response is decreased, while the histological activity and stage are increased. Though Th1 and Th2 responses were both strong in patients with normal ALT, Th1 response was not as high as that

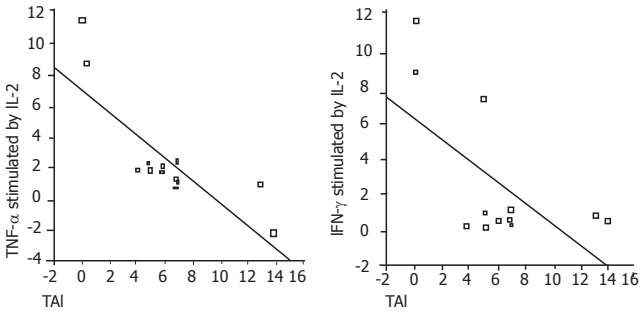

Figure 1 Negative correlations between histological activity index (HAI) and TNF-α and IFN-γ levels in LILMCs of patients with elevated ALT.

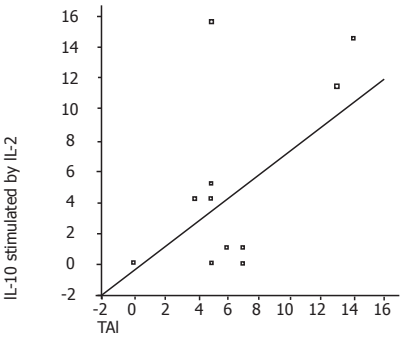

Figure 2 Positive correlation between IL-10 stimulated by IL-2 and HAI in patients with elevated ALT.

in patients with elevated ALT, suggesting that strong antiviral defense against HCV infection can normalize liver enzymes. On the other hand, histological abnormalities might be impaired by the increased Th2 response.

In conclusion, both Th1 and Th2 responses in liver are elevated in patients with normal ALT. Increased Th2 response may regress inflammatory activity. In patients with normal ALT, progression of histological findings may probably depend on insufficient Th2 response, which does not balance Th1 response. A differentiation between virus-specific and non-specific T-cell populations is the greatest challenge in future studies.

Abstract

AIM: To investigate the diagnostic accuracy of potent serum biochemical fibrosis markers in children with chronic hepatitis B evaluated by receiver operating characteristics (ROC) analysis.

METHODS: We determined the serum level of apolipoprotein A-I (APO A-I), haptoglobin (HPT) and a-2 macroglobulin (A2M) with an automatic nephelometer in 63 children (age range 4-17 years, mean 10 years) with biopsy-verified chronic HBeAg-positive hepatitis B. Fibrosis stage and inflammation grade were assessed in a blinded fashion according to Batts and Ludwig. We defined mild liver fibrosis as a score $\leqslant$2 and advanced fibrosis as a score equal to 3. ROC analysis was used to calculate the power of the assays to detect advanced liver fibrosis (AccuROC, Canada).

RESULTS: Serum concentrations of APO A-I, HPT and A2M were not significantly different in patients with chronic hepatitis B compared to controls. However, APO A-I level of 1.19 ng/L had a sensitivity of 85.7% and a specificity of 60.7% (AUC = 0.7117, P = 0.035) to predict advanced fibrosis. All other serum biochemical markers and their combination did not allow a useful prediction. None of these markers was a good predictor of histologic inflammation.

CONCLUSION: Apolipoprotein A-I may be a suitable serum marker to predict advanced liver fibrosis in children with chronic hepatitis B.

Key words: Chronic hepatitis B; Liver fibrosis; Children; Apolipoprotein A-I; Haptoglobin; a-2 macroglobulin

INTRODUCTION

Liver biopsy is regarded as the gold standard for the determination of the stage of liver fibrosis. However, in clinical practice, the use of invasive liver biopsy has several limitations such as complications, sampling variability, low reproducibility and it only provides static information about the fibrotic process[1-3]. There is a clinical need for noninvasive measurement of liver fibrosis both to diagnose significant hepatic fibrosis and to monitor the effects of antiviral or antifibrotic therapy.

Several matrix-derived surrogate markers of extracellular matrix (ECM) turnover have been studied in adults so far and some were found to be correlated with matrix deposition, while their role as predictors of ECM turnover remains unclear[4-6]. This applies particularly for children whose serum levels of ECM-derived parameters are usually influenced by body growth[7,8]. Therefore, there is an urgent need for noninvasive parameters that better define those children who should undergo liver biopsy in order to assess fibrosis stage, to decide whether they should receive antiviral therapy or not, to predict fibrosis progression or to monitor potential antifibrotic treatment. Serum levels of type IV collagen[9,10], hyaluronic acid[10-13], laminin[14], collagen VI[15], transforming growth factor beta 1 (TGF beta 1)[16] and metalloproteinases (MMPs) or tissue inhibitors of metalloproteinases (TIMPs)[10,17] have recently been studied in children, but almost exclusively in patients with secondary biliary fibrosis due to biliary atresia and cystic fibrosis.

To our knowledge, serum fibrosis markers predicting liver fibrosis have not been assessed before in children with chronic hepatitis B (HBV) except our previous studies[18-20]. From a broad panel of matrix-derived serum markers (collagen IV, collagen VI, PIIINP, laminin-2, hyaluronan, MMP-2, TIMP-1, MMP-9/TIMP1 complex, tenascin-C), the combination of serum hyaluronan and laminin-2 can accurately predict significant liver fibrosis[18].

In our previous studies, we have reported that serum TGF beta 1 and cystatin C level did not predict advanced liver fibrosis in children with chronic hepatitis B[19,20].

In the present study, the serum levels of apolipoprotein A-I (APO A-I), haptoglobin (HPT) and a-2 macroglobulin (A2M) were measured in children with chronic hepatitis B and compared to liver histological features to determine whether the measurement of these biochemical tests have any clinical usefulness as markers of liver fibrosis. Receiver operating characteristics (ROC) analysis was used to determine the sensitivity and specificity of the assays in detecting advanced liver fibrosis.

MATERIALS AND METHODS

Patients

The study was carried out in 63 children, including 41 boys and 22 girls (range 4-17 years, mean age 10 years) with biopsy-verified chronic HBeAg-positive hepatitis B prior to antiviral therapy. Other causes of chronic liver diseases, such as HCV coinfection, autoimmune hepatitis and metabolic liver disorders, were excluded. Children with diagnosed liver cirrhosis and evidence of other acute or chronic infections were also excluded from this study. Informed consent was obtained from all the parents of patients and the protocol used was approved by the Ethics Committee of the Medical University of Bialystok, Poland. As a control group, 16 children (mean age 10 years) were included without anamnestical, clinical or laboratory signs of liver or other systemic diseases.

Measurement of serum level of biochemical markers

APO A-I, HPT and A2M were measured in serum samples (obtained after an overnight fast) with an automatic nephelometer (BNII, Dade Behring; Marburg, Germany).

Histological analysis

All children underwent liver biopsy on the day after serum sampling. Liver specimens were fixed in buffered formalin and embedded in paraffin. Histological sections were stained using hematoxylin-eosin, Masson's-Goldner, Masson's trichrome and reticulin. Fibrosis stage and inflammation grade were assessed in a blinded fashion by a single pathologist who was without the knowledge of the patients' laboratory or clinical data. In order to determine specificity and sensitivity of the assay, we arbitrarily defined mild liver fibrosis or inflammation as a score $\leqslant$ 2 and advanced liver disease as fibrosis or inflammation score equal to 3 according to Batts and Ludwig[21].

Statistical analysis

Serum concentrations of biochemical tests were expressed as mean±SD. Statistical analysis was performed using the Mann-Whitney two-sample test for nonparametric data. The relationship between the enzymes and liver histology scores was analyzed by the Spearman's rank-correlation test for nonparametric data. Tests were considered statistically significant at $P<0.05$. Receiver operating characteristics (ROC) analysis (AccuROC, Montreal, Canada) was used to calculate the power of the assays to detect advanced liver fibrosis. The best cut-off points for the diagnosis of advanced fibrosis are those which maximize the sum of sensitivity and specificity. Sensitivity of the assays was plotted against the false positivity (1-specificity). Comparison of the area under the curve (AUC) was performed using a *P*-test, which compares the AUC to the diagonal line of no information (AUC 0.5)[22].

RESULTS

Characteristics of the patients

Selected biochemical and histological data are presented in Table 1.

Table 1 Initial characteristics of children with chronic hepatitis B

Parameters	Mean	SD	Minimum	Maximum
Age (yr)	10	3.41	4	17
ALT (IU/L)	84	57	12	312
AST (IU/L)	68	37	27	264
GGT (IU/L)	15	9	3	69
Bilirubin (μmol/L)	10.26	4.45	2.74	32.83
APO A-I (g/L)	1.14	0.3	0.5	1.77
HPT (g/L)	0.58	0.36	0.31	1.69
A2M (g/L)	2.27	0.57	1.0	3.59
Staging	1.9	0.56	1	3
Grading	1.49	0.56	1	3

Serum concentration of APO, HPT and A2M

Serum concentrations of APO A-I, HPT and A2M were not significantly different in patients with chronic hepatitis B as compared with the controls (1.14±0.3 *vs* 1.13±0.2; 0.58±0.36 *vs* 0.71±0.62, 2.27±0.57 *vs* 2.53±0.3, respectively). There were no significant correlations of examined markers with liver fibrosis and inflammation according to Batts and Ludwig[21].

Diagnostic value of biochemical markers for identification of patients with advanced liver fibrosis and inflammation

Seven children (11.1%) had advanced liver fibrosis. The ability of examined biochemical markers to differentiate the children with advanced liver fibrosis from those with mild fibrosis was not significant except APO A-I (Table 2 and Figure 1). Using the APO A-I and the Batts and Ludwig score, 34 and 6 out of 63 children could be correctly allocated either to the group with mild or advanced fibrosis, respectively, potentially avoiding biopsy in 40 (63.5%) of the examined children. HPT and A2M did not reach the predictive power of APO A-I (Table 2). None of the combination of examined markers resulted in a significant increase in sensitivity and specificity for the identification of patients with advanced liver fibrosis. None of these markers was a good predictor of histologic inflammation (Table 3).

Table 2 Diagnostic value of serum markers for predicting advanced fibrosis

Markers	Cut-off (g/L)	Se (%)	Sp (%)	PPV (%)	NPV (%)	AUC	*P* values
APO A-I	1.19	85.7	60.7	21.4	97.1	0.7117	0.035
HPT	1.01	14.3	87.5	12.5	89.1	0.3878	NS

Table 3 Diagnostic values of serum markers for predicting advanced inflammation

Markers	Cut-off (g/L)	Se (%)	Sp (%)	PPV (%)	NPV (%)	AUC	P values
APO A-I	0.87	89.7	20.6	49.1	70.0	0.3803	NS
HPT	0.59	34.5	70.6	50.0	55.8	0.4701	NS
A2M	1.6	96.6	14.7	49.1	83.3	0.3813	NS

Se: sensitivity; Sp: specificity; PPV: positive predictive value; NPV: negative predictive value; AUC: area under curve; NS: no statistical significance.

DISCUSSION

Infection with the hepatitis B virus remains one of the most important epidemiological problems all over the world. It was estimated that chronic HBV infection, which is the single most common cause of cirrhosis and hepatocellular carcinoma (HCC), affects more than 400 million people worldwide[23,24].

During the early phase of chronic hepatitis B, the underlying disease is usually subclinical and can be quite mild, particularly in children[25]. This is referred to as the immune-tolerant phase of infection[26]. While the natural history of chronic hepatitis B in children is usually marked by an indolent course, advanced disease with significant fibrosis can be found in up to one-third of the children, and decompensated cirrhosis and even HCC have been reported[27,28]. For this reason, noninvasive diagnosis and monitoring of liver fibrosis in children are urgently needed.

There are several features required for an ideal serum fibrosis marker. It should be liver-specific, independent of metabolic alterations, minimally influenced by impaired urinary and biliary excretion, easy to perform and it should measure either the dynamic processes of fibrogenesis or fibrolysis and reflect the degree of fibrosis. Unfortunately, no current assay fulfills enough of these criteria[5].

Recently, algorithms of non-ECM-derived serum markers have been proposed as the predictors of fibrosis stage in adult patients with chronic hepatitis C[29-31]. APO A-I, HPT and A2M are the components of FibroTest[32] and APO A-I and A2M are the components of PGAA index[33,34]; they have also been validated as single serum fibrosis markers[6,35-38].

In the present study, we did not find significantly different levels of examined serum fibrosis markers in children with chronic hepatitis B as compared with the controls. There were also no significant correlation of APO A-I, HPT, and A2M levels with histologically assessed stage of liver fibrosis and inflammation grade. Because liver biopsy is not necessarily a gold standard for assessing liver histology, noninvasive markers will not have complete concordance with histological staging. Only 11.1% children had advanced fibrosis according to Batts and Ludwig[21] and probably for this reason, we also did not observe statistically significant correlation between the examined markers and fibrosis stage.

These findings confirmed previous observation in children by Selimoglu *et al*[35,37] who also demonstrated that mean APO A-I level of the patients with chronic hepatitis B was not different from controls and did not correlate with fibrosis and inflammation scores. To our knowledge, A2M and HPT as potent serum fibrosis markers have not been assessed in children yet.

In adults with chronic hepatitis B, Oberti *et al*[6] and Huang and Gong[36] observed that APO A-I and A2M were significantly correlated with the staging of liver fibrosis. Lu *et al*[34] confirmed that A2M but not APO A-I was significantly correlated with fibrosis stage. However, HPT was negatively associated with fibrosis[38]. These opposing correlation of A2M and HPT with fibrosis staging could be explained by the different roles of hepatocyte growth factor (HGF) and TGF beta 1 in fibrogenesis and acute phase response[39-41]. As seen in experimental fibrosis, transduction with HGF gene suppresses increase of TGF beta 1[39] and the factor stimulates synthesis of A2M[40] and reduces synthesis of haptoglobin[40,41].

Recently, ROC analysis has been recommended to calculate the power of the assays to detect advanced liver fibrosis[42-46]. In this study, the ability of examined biochemical markers to differentiate children with advanced liver fibrosis from those with mild fibrosis was not significant except APO A-I. The high negative predictive value of this marker could potentially be useful in the selection of patients without significant fibrosis and in avoiding invasive liver biopsy in this group of children. Our study is not consistent with the findings of Selimoglu *et al*[35], because they did not find diagnostic performance of APO A-I for discriminating patients with advanced liver

disease. Usefulness of APO A-I as well as HPT and A2M as potent serum fibrosis markers in patients with chronic liver disease needs to be evaluated in large controlled studies.

Abstract

AIM: To evaluate the influence of L-carnitine on mental conditions and ammonia effects on patients with hepatic encephalopathy (HE).

METHODS: One hundred and fifty patients (10 patients with alcoholism, 41 patients with hepatitis virus B infection, 78 patients with hepatitis C virus infection, 21 patients with cryptogenetic cirrhosis) meeting the inclusion criteria were randomized into group A receiving a 90-d treatment with L-carnitine (2 g twice a day) or into group B receiving placebo in double blind.

RESULTS: At the end of the study period, a significant decrease in NH4 fasting serum levels was found in patients with hepatic encephalopathy ($P<0.05$) after the treatment with levocarnitine (LC). Significant differences were also found between symbol digit modalities test and block design in patients with hepatic encephalopathy ($P<0.05$).

CONCLUSION: Results of our study suggest an important protective effect of L-carnitine against ammonia-precipitated encephalopathy in cirrhotic patients.

Key words: Hepatic encephalopathy; Carnitine; Cirrhosis; Ammonia; Treatment

INTRODUCTION

Hepatic encephalopathy (HE) commonly occurs in patients with liver cirrhosis and is characterized by impaired mental function, neuromuscular disorders and altered states of consciousness. The pathogenesis of HE is controversial although ammonia has been found to induce alterations of cerebral neurotransmitter balance especially at the astrocyte-neuron interface.

Hyperammonemia induces abnormalities such as brain edema and intracranial hypertension in cirrhotic patients. In cirrhotic patients, the relation between blood levels of ammonia and brain events is also influenced by the changes in the permeability-surface area of the blood-brain barrier[1].

In hepatic encephalopathy, the Alzheimer type II astrocytes are the main neuropathological alteration, characterized by swollen cellular nuclei, with their chromatin displaced to the periphery.

The accumulation of glutamine, a product of ammonia detoxification generated within astrocytes expressing activity of glutamine synthetase, is a major factor for the swelling of astrocytes[2].

Previous studies have reported a significant protective effect of L-carnitine in mice, rats, and human beings. In fact L-carnitine treatment is associated with a significant reduction of blood and brain ammonia concentration[3-6]. Carnitine is a natural substance involved in regulating substrate flux and energy balance across cell membranes.

The pharmacological activity of L-carnitine presents various aspects. The carnitine acts by shuttling acetyl-CoA into mitochondria, enhances the metabolic flux in the tricarboxylic acid cycle by sparing free CoA and activating the transport of adenine nucleotides across the inner mitochondrial membrane and prevents adenylate translocase inhibition of the activity of pyruvate dehydrogenase by decreasing the acetyl-CoA/CoA ratio, thus enhancing the oxidative utilization of glucose.

Increased extra-intestinal ammonia production and reduced ammonia detoxification capacity in patients with cirrhosis[7-9] and HE, have not been studied[10].

L-carnitine, inducing ureagenesis, may decrease blood and brain ammonia levels[4,5]. In order to assess the clinical efficacy of L-carnitine in the treatment of HE, a randomized, double-blind, placebo-controlled study with oral administration in cirrhotic patients with hyperammonemia was carried out.

MATERIALS AND METHODS

Patients

One hundred and fifty patients (10 with alcoholism, 41 with hepatitis B virus infection, 78 with hepatitis C virus infection, 21 with cryptogenetic cirrhosis) meeting

the following inclusion criteria were enrolled in the study: chronic hepatitis with spontaneous manifest HE (mental state grade 1 or 2 according to the West Haven criteria) minimal HE (MHE) (mental status grade 0) and a number connection test performance time >30 s[11-13]; hyperammonemia (venous ammonia concentration >50 mmol/L); cooperative, hospitalized, adult patients with liver cirrhosis diagnosed by clinical, histological, and ultrasonographic findings.

Exclusion criteria included: major complications of portal hypertension, such as gastrointestinal blood loss, hepatorenal syndrome or bacterial peritonitis; acute superimposed liver injury; patients with other neurological disease and metabolic disorders, diabetes mellitus, unbalanced heart failure and/or respiratory failure or end-stage renal disease; severe HE (mental state grade 3-4); administration of anti-HE medications such as neomycin, lactulose, lactitol, branched-chain aminoacids; any additional precipitating factors such as high protein intake (additional high-protein meals), constipation or intake of psychostimulants, sedatives, antidepressants, benzodiazepines, or benzodiazepines-antagonists (flumazenil); patients with fever, sepsis or shock were also excluded to avoid variations caused by body temperature.

Study design

Patients meeting the inclusion criteria were randomized either into group receiving a 90-d treatment with L-carnitine (2 g twice daily) or into group receiving placebo in double-blind. Concomitant medications throughout the study included diuretics and beta-blockers.

Patients were visited weekly throughout the treatment period for the assessment of adherence to the study protocol, blood pressure and cognitive functions, as well as recording of adverse events. Throughout the trial, levo-carnitine was supplied as 2 g vials for oral use.

All administered drugs were identical in appearance, and neither investigators nor patients were informed of the selected agents at the end of the study. Administration instructions were provided with each patient pack. All patients were instructed to take the trial medication as prescribed. Patients were considered compliant, if the number of returned vials was between 80% and 120% of the planned treatment regimen. For the duration of the trial, concomitant drugs were administered at the lowest possible therapeutic dosage, and unchanged as far as possible.

Study series

A total of 150 cirrhotic hepatopathic patients met the criteria for inclusion in this study performed between January 2000 and December 2001. They were randomly assigned to receive placebo (75 patients) or L-carnitine (75 patients). The two groups had similar demographic characteristics, etiology, course of disease and Child-Pugh grade. All study series were subdivided into groups of MHE or HE 1 or HE 2 according to the initial HE grade (West-Haven criteria). Group A consisted of patients with MHE (21 patients receiving LC, 19 patients receiving placebo). Group B consisted of patients with initial HE 1 (30 patients receiving LC, 30 patients receiving placebo). Group C consisted of patients with initial HE 2 (25 patients receiving LC, 25 patients receiving placebo). The effectiveness of therapy was compared and evaluated separately in the different subgroups.

The groups were homogeneous with regard to anamnestic and diagnostic criteria. Differences in composition of the two groups with respect to precipitant factors might be minimized, because the patient population was well defined by inclusion and exclusion criteria.

Diagnosis of minimal hepatic encephalopathy

Psychometric tests and automated EEG analysis were performed for all the patients.

Minimal hepatic encephalopathy was defined as the presence of at least one of the abnormal psychometric tests.

Trail making test: The trail making test was used to evaluate abstract reasoning, tactile performance, tactile-visual and spatial memory, rhythm perception and memory, speech-sound perception, primary motor speed, intelligence, psychomotor speed, sequencing abilities, language function, sensory function, grip strength, and personality functioning.

Time was recorded in seconds. This test included part A and B.

In part A, patients were asked to serially connect digits that were scattered on a page as quickly as possible. In part B, patients were asked to sequentially alternate numbers and letters (i.e. 1-A-2-B-3-C) as quickly as possible. A decrease in the time indicated an improvement in neuropsycological function.

Wechsler adult intelligence scale-revised: Block design test and symbol digit modalities test. The Wechsler adult intelligence scale-revised (WAIS-R) could provide information on global intellectual functioning.

Cognitive functions assessed in the block design test (BDT) were construction, praxis, spatial reasoning motor function, and processing speed. The symbol digit modalities test (SDMT) was used to assess attention, concentration executive function, motor function, and processing speed.

An increase in the number of points in the BDT and SDMT indicated an improvement in neurological function.

Diagnosis of hepatic encephalopathy

Hepatic encephalopathy grade was diagnosed on the basis of the evaluation of consciousness, intellectual functions, behavior and neuromuscular functions according to West Haven criteria introduced by Conn and Liebertahl[11].

Neurophysiological assessment

The EEG was recorded using standardized techniques. Five electrodes were attached to the skin at the positions T3, T4, O1, O2, and Cz according to the international "10-20 system". Electrode impedance was kept lower than 5 KQ. After applying the usual handpass filters (0.53-35 Hz), 2 runs of 100 s each were recorded and

compared for reproducibility. Artefact-free recordings were selected and fed into a computer after digital conversion (sample frequency 102.4 Hz). Ten epochs of 10 s each were analyzed by applying fast Fourier transformation, and the mean power spectrum was calculated.

Patients were graded into different studies of hepatic encephalopathy according to their mean dominant frequency (MDF) and the relative powers of delta and theta activity[14].

Liver function assessment

The Child-Pugh[15] score was determined to assess the severity of cirrhosis, including three biochemical variables (serum albumin, bilirubin, and prothrombin time) and two clinical characteristics (presence or absence of ascites and clinical hepatic encephalopathy).

A patient had a Child-Pugh score A cirrhosis if the score was ≤6 points, a Child-Pugh B cirrhosis if the score was 7-9 points and a Child-Pugh C cirrhosis if the score was >9 points. Patients without signs of ascites were scored as two points for ascites[15].

Venous ammonia concentration

The ammonia was determined according to the enzymatic determination of ammonia with glutamate dehydrogenase in a rapid and interference-free photometric determination (340 nm) of NH4+ in native blood plasma as previously described[16].

Due to reasons of safety, blood was immediately sent to the laboratory for determination of NH4+.

Safety parameters

Safety parameters included blood tests (hemoglobin, hematocritus, white blood cell count, and thrombocytes) and liver function tests (alanine amino transferase, aspartate amino transferase, gamma glutamyl-transpeptidase, cholinesterase activity, serum bilirubin concentrations, prothrombin time and partial thromboplastin time) on d 0, 30, 60 and 90.

Statistical analysis

Descriptive statistics was proposed from the study sample and results were expressed as mean±SD.

Statistical analyses were performed by two-way analysis of variance (ANOVA), as well as by controlling for multiple correction of Bonferroni.

All *P* values were two-sided, using $\alpha = 0.05$ as the reference standard for determining the significance of the principal outcomes.

Statistical Analysis System (Cari, NC, USA) software version 6.11 was used for all analyses.

The primary population for statistical analysis was to intent to treat population of all randomized patients (I.T.T.).

RESULTS

Baseline values

The two groups had similar general characteristics. Serum NH4+ fasting concentrations were not significantly different before the treatment.

Comparison with baseline

In MHE, ammonia serum levels were significantly decreased to 13.10 μmol/L (CI-24.3 to-1.8; $P<0.05$), to 19.10 μmol/L (CI-30.2 to-8.0; $P<0.001$), to 28.1 μmol/L (CI-38.5 to 17.6; $P<0.001$) after 30, 60, and 90 d of treatment, respectively.

The trial making test-A and trial making test-B were significantly decreased to 13.80 s (CI-19.87 to-7.73; $P<0.05$), to 25.00 s (CI-29.09 to –20.91; $P<0.05$), to 18.00 s (CI-23.50 to-12.50; $P<0.05$) and to 26.00 s (CI-29.61 to-22.39; $P<0.05$), to 21.50 s (CI-26.62 to-16.38; $P<0.05$), and to 28.9 (CI-32 to-25; $P<0.05$) respectively, after 30, 60 and 90 d of treatment.

The symbol digit modalities test was significantly increased from 4.00 points (CI 3.51 to 4.49; $P<0.05$), after 30 d of treatment, to 8.00 points (CI 7.56 to 8.44; $P<0.05$), and 8.00 points (CI 7.53 to 8.47; $P<0.05$) after 60 and 90 d of treatment, respectively.

The block design in MHE were significantly increased from 4.10 points (CI 3.59 to 4.61; $P<0.05$), to 7.90 points (CI 7.35 to 8.45; $P<0.05$), and to 12.90 points (CI 12.53 to 13.27; $P<0.05$) respectively after 30, 60, and 90 d of treatment.

In HE1, ammonia serum levels were significantly decreased to 12.0 μmol/L (CI-22.57 to-3.65; $P<0.05$), to 23.90 μmol/L (CI-33.23 to-14.57; $P<0.05$) and to 41.00 (CI -50.23 to 31.77; $P<0.05$) respectively after 30, 60, 90 d of treatment.

The TMT A and B were significantly decreased to 11.60 s (CI-18.08 to-5.12; $P<0.05$) and to 9.20 s (CI-12.62 to-5.78; $P<0.05$), to 21.60 s (-27.73 to-15.47; $P<0.05$) and to 19.10 s (CI-22.70 to-15.50; $P<0.05$), to 28.80 s (CI-34.87 to-22.73; $P<0.05$) and to 23.80 s (CI-27.06 to 20.54; $P<0.05$) respectively after 30, 60, 90 d of treatment.

The SDMT were significantly increased from 5.10 (CI 4.45 to 5.75; $P<0.05$) to 8.00 (CI 7.30 to 8.70; $P<0.05$) and to 14.00 (CI 13.39 to 14.10; $P<0.05$) respectively after 30, 60, 90 d of treatment.

The BDT were significantly increased from 3.00 points (CI 2.40 to 3.60; $P<0.05$) from 6.10 points (CI 5.47 to 6.73; $P<0.05$) and from 12.10 points (CI 11.62 to 12.58; $P<0.05$) respectively after 30, 60 and 90 d of treatment.

In HE2, ammonia serum levels were significantly decreased to 15.10 μmol/L (CI-23.44 to-6.76; $P<0.05$) and to 36.00 μmol/L (CI-44.84 to-27.16; $P<0.05$) respectively after 60 and 90 d of treatment.

The TMT A and B were significantly decreased to 10.50 s (CI-16.97 to-4.03; $P<0.05$) and to 9.50 s (CI-13.31 to-5.60; $P<0.05$), to 26.20 s (CI 32.97 to-22.39; $P<0.05$) and 21.79 s (CI-25.70 to 17.88; $P<0.05$), to 30.20 s (CI-36.48 to 23.92; $P<0.05$) and 35.00 s (CI 39.13 to 30.87; $P<0.05$) respectively after 30, 60, and 90 d of treatment.

The SDMT were significantly increased to 3.10 points (CI 2.56 to 3.64; $P<0.05$), to 7.00 points (CI 4.15 to 9.85; $P<0.05$) and to 12.90 points (CI 12.27 to 13.53; $P<0.05$) respectively after 30, 60, and 90 d of treatment.

The BDT were significantly increased from 4.10 points (CI 3.5 to 4.7; $P<0.05$) to 8.10 points (CI 7.60 to 8.60; $P<0.05$) and to 13.00 points (CI 12.40 to 13.60; $P<0.05$) respectively after 30, 60, and 90 d of treatment.

No significant differences were observed in the patients treated with placebo compared to baseline (Table1).

Table 1 Baseline data of patients

Parameter	Carnitine group, *n* = 75	Placebo group, *n* = 75

Comparison between treatments

At the end of the study period, fasting serum levels of NH4, TMT-A, TMT-B were significantly decreased in patients with hepatic encephalopathy compared to controls ($P<0.05$) after treatment with LC and placebo respectively. MHE-28.10 *vs* -2.00, $P < 0.05$; HE1-41.00 *vs* -1.50, $P<0.05$; HE2-36.00 *vs* 3.90, $P < 0.05$; TMT-A MHE -21.50 *vs* -7.30, $P < 0.05$, HE1 -28.8 *vs*-7.30, $P<0.05$; HE2 -30.20 *vs* -2.90, $P < 0.05$; TMT-B MHE-28.9 *vs* 1.0, $P < 0.05$; HE1-23.8 *vs*-4.00, $P < 0.05$; HE2-12.29 *vs* 0.90, $P < 0.05$.

Significant differences were also found between symbol digit modalities test and block design.

The SDMT was increased to 4.00 *vs* 0.20, 2.90 *vs* 0.80, 3.90 *vs* 0.20, respectively in MHE, HE1, and HE2 ($P<0.05$). The block design was increased to 3.80 *vs* 0.40, 3.10 *vs* 0.40, 4.00 *vs* 1.00, respectively in MHE, HE1, and HE2 ($P<0.05$) (Table 2).

DISCUSSION

The pathogenetic mechanisms underlying the development of hepatic encephalopathy are complex.

Symptoms of hepatic encephalopathy are generally reversible, suggesting a metabolic cause. Among the possible neurotoxins implicated in hepatic encephalopathy, ammonia is considered as a leading candidate[17,18].

The majority of blood ammonia results from muscle protein catabolism at the intestinal level. The remnant is produced by the action of colic bacteria on the nitrium present in digested foods. Ammonia is vehicled to the liver throughout the portal flux and normally eliminated as urea. The liver damage or the presence of porto-systemic shunts increases its serum levels[19-21]. The excess ammonia is eliminated from the blood by transforming glutamate into glutamine in skeletal muscle and central nervous system. Neurotoxicity of ammonia is probably due to a direct action on neurons, because the reduction of glutamate and the increase of glutamine may induce swelling of the astrocytes[22,23].

O'Connor *et al*[19] observed that mice treated with L-carnitine experience a continuous rise in blood urea N until a plateau is reached 1 h after injection, whereas mice not treated with L-carnitine experience a rise in blood urea N, but one died within 15 min after ammonium acetate administration.

Intravenous L-carnitine significantly can lower plasma ammonia N levels in ewes after an oral urea challenge even though the concentration of ruminal free, non-ionized ammonia N is similar to those in ewes treated only with the urea solution, suggesting that L-carnitine administration may prevent hyperammonemia in ruminants[24].

Carnitine has been shown to be efficacious in valproic acid hyperammonemia[25]. Preventive supplementations with L-carnitine might afford some benefits. Ohtani *et al*[26] have showed that oral administration of carnitine for 4 wk corrects hyperammonemia in patients treated with valproic acid. Studies in valproate-treated rats indicate that L-carnitine supplementation can correct hyperammonemia, hypocarnitinemia and protect rat liver against mitochondrial swelling[27].

Results of our study showed a protective effect of L-carnitine against ammonia-precipitated encephalopathy in cirrhotic patients[6].

In patients with MHE, HE 1, or 2, we observed a significant reduction of ammonia serum levels after 30 d of treatment. After 60 and 90 d of treatment, we observed a persistent trend of decreased ammonia serum levels.

A significant therapeutic effect of carnitine was also observed in the NCT-A, which is an accepted and reliable psychometric test for the assessment of mental function in cirrhotic patients with HE[12,28]. L-carnitine crosses the hemato-encephalic barrier slowly (brain uptake index 5.5%) but its amount in brain is relatively large[29]. The protective effect of L-carnitine is accompanied with a significant attenuation of the increased cerebrospinal fluid and brain alanine as well as cerebrospinal fluid lactate content, caused by ammonium acetate administration[30], suggesting that mitochondrial respiration is at least partially restored in L-carnitine-treated animals. The possible beneficial effect of carnitine may be related to an improved pyruvate oxidation, Krebs cycle and flux through

glutamate dehydrogenase. The latter could then explain the lowering of blood ammonia levels that follows L-carnitine administration .

The best-known function on L-carnitine is the facilitation of b-oxidation by transforming activated long-chain fatty acids into mitochondria. High concentration of fatty acids has numerous deleterious effects upon mitochondrial metabolism.

Acyl-CoA derivates competitively inhibit the activation of the gluconeogenetic enzyme pyruvate carboxylase with acetyl-CoA[31]. Thus when mitochondrial b-oxidation is inhibited, not only is acetyl-CoA, but also the activating effect of acetyl-CoA is further inhibited by non-esterified acyl-CoA esters, an effect that further decreases gluconeogenesis.

High levels of acyl-CoA derivates also may inhibit ureagenesis (resulting in hyperammonemia and the tricarboxylic acid cycle)[32].

Treatment with levocarnitine decreases the serum levels of ammonia and improves the mental functions in cirrhotic patients, and has been proven effective with small adverse events.

Abstract

AIM: To assess the synergistic action of famotidine (FMD) and chlorpheniramine (CPA) on acetic acid-induced chronic gastric ulcer in rats.

METHODS: Chronic gastric lesions were induced in male Sprague-Dawley (SD) rats by serosal application of the acetic acid. Forty SD rats were randomly divided into blank group (n = 8), control group (n = 8), FMD group (n = 8), CPA group (n = 8), and FMD+CPA group (n = 8). Each group was given intraperitoneally (i.p.) 0.5 mL/100 g distilled water, 9 g/L NaCl saline, 4 mg/kg FMD, 10 mg/kg CPA, 4 mg/kg FMD+10 mg/kg CPA, respectively, daily for 10 d. On d 10, ulcer area was determined by planimetry. The level of myeloperoxidase (MPO) in the liver homogenation was determined by biochemical methods and the plasma levels of 6-ketoprostaglandin F1 alpha (6-keto-PGF_{1a}) and IL-8 were determined by radioimmunoassay.

RESULTS: The synergistic effects of FMD+CPA group on the lesion, IL-8, 6-keto-PGF_{1a} and MPO were confirmed. The effect of FMD+CPA group was significantly different as compared to the control and FMD groups. The lesion (mm^2) was reduced from 40.18±2.6 in control group to 6.83±2.97 in PMD+CPA group, P<0.01, and from 32.9 ±3.27 in FMD group to 6.83±2.97 in PMD+CPA group, P<0.01. The plasma levels of IL-8 decreased from 0.69± 0.11 ng/L in control group to 0.4±0.04 ng/L in PMD+CPA group, P<0.01, and from 0.51±0.08 ng/L in FMD group to 0.4±0.04 ng/L in PMD+CPA group, P<0.05. The level of 6-keto-PGF_{1a} increased from 7.55±1.65 ng/L in control group to 16.62±0.97 ng/L in PMD+CPA group, P<0.01, and from 13.15±1.48 ng/L in FMD group to 16.62±0.97 ng/L in PMD+CPA group, P<0.05. The levels of MPO in the liver homogenate decreased from 9.12±2.05 u/L in control group to 4.33±0.95 u/L in PMD+CPA group, P<0.01, and from 8.3±1.29 u/L in FMD group to 4.33± 0.95 u/L, P<0.01.

CONCLUSION: The synergistic action of FMD and CPA on acetic acid-induced chronic gastric ulcer in rats decreases the incidence of ulcer and also enhances the healing of ulcer.

Key words: Gastric ulcer; Acetic acid; Famotidine; Chlorpheniramine; Interleukin-8; 6-Ketoprostaglandin F1 alpha; Myeloperoxidase

INTRODUCTION

Peptic ulcer is a common disorder of the gastrointestinal system and the pathogenesis of peptic ulcer disease is multifactorial, including *Helicobacter pylori*, gastric acid, pepsin, gastroduodenal motility, smoking, use of nicotine, and complex interaction between so-called aggressive and protective factors[1]. Mast cells are initiators and regulators of inflammation. After mast cell degranulation, histamine causes the secretion of gastric acid by triggering H_2-receptors, marked infiltration of inflammatory cells into the gastric mucosa, and expression of cytokines by triggering the H_1-receptors. Consequently, mast cells are considered as important effector cells in the pathogenesis of gastritis, especially in *H pylori*-associated peptic ulcer[2]. Histamine H_2-receptor antagonists that possess a potent antisecretory activity can greatly enhance the healing rate of peptic ulcers. However, after H_2-receptor antagonist therapy peptic ulcer recurs rapidly and frequently. The possible reasons why the recurrence rate is high after H_2-antagonist therapy are acid rebound after the cessation of treatment, deficiency in gastric defensive factors such as gastric prostaglandin levels, and low maturity of regenerated mucosa. Recently, H_1-receptor antagonists are potent anti-inflammatory compounds. Erwin[3] reported that H_1-receptor antagonists have anti-inflammatory activity, including their effects on eicosanoid production

and cytokine release and their influence on the release rate of proinflammatory mediators. Cetirizine reduces the attraction of inflammatory cells to the inflammatory focus after the antigen challenge and inhibits the expression of the intercellular adhesion molecule 1 (ICAM-1) on the surface of epithelial cells[4]. It also might be able to block the antigen-induced production of leukotrienes (LTC4)[5]. Loratadine and its metabolite decarboethoxyloratadine inhibit the release of tryptase and amacroglobulin[6], interleukins (IL) 6 and 8[7], leukotrienes and prostaglandin D2 (PGD2)[8], and suppress the expression of ICAM-1 and of HLA-II antigens on the surface of epithelial cells[9]. Therefore, H_1 and H_2 blockers have not only antisecretory activity but also anti-inflammatory activity when they are used in the treatment of gastric ulcer. The aim of the present study was to assess the synergistic action of famotidine (FMD) and chlorpheniramine (CPA) on acetic acid-induced chronic gastric ulcer in rats.

MATERIALS AND METHODS

Materials

IL-8 and 6-ketoprostaglandin F1 alpha (6-keto-PGF_{1a}) kits were obtained from Beijing North Institute of Biological Technology. Myeloperoxidase (MPO) kit was obtained from Nanjing Jiancheng Bioengineering Institute.

Animals

Male Sprague-Dawley (SD) rats (180-220 g) were provided by the Medical Experimental Animal Center, Tongji Medical College, Huazhong University of Science and Technology (No: TJLA-2004-159). Animals were fed with standard laboratory chow and tap water, and kept in a room with constant humidity and temperature (25 °C) in a 12-h light-dark cycle for 1 wk before the experiments.

Induction of gastric ulcer

Gastric ulcers were induced using the method described by Takagi *et al*[10] with some modifications. Gastric ulcers were produced by the application of round filter paper (diameter: 5 mm) immersed in a 100% acetic acid on the serosal surface of anterior wall of the stomach approximately at the center of the corpus for 30 s and the process was repeated twice. This produced an immediate necrosis of the entire mucosa and submucosa (but not serosa) within the area (20 mm^2), where the acetic acid was applied. The excess of acetic acid was then removed and the serosa was gently washed with saline. Control animals received no surgery. The abdomen was then sutured, and the animals were allowed to recover and returned to their cages with free access to food and water.

Experimental groups

Two days after the ulcer induction, 40 male SD rats, weighing 180-220 g, were randomly divided into blank group (n = 8), control group (n = 8), FMD group (n = 8), CPA group (n = 8), FMD+CPA group (n = 8). Rats were given intraperitoneally (i.p.) 0.5 mL/100 g distilled water, 0.5 mL/100 g, 9 g/L NaCl saline, 4 mg/kg FMD, 10 mg/kg CPA, 4 mg/kg FMD+10 mg/kg CPA for 10 d. On d 8, the rats were deprived of food for 48 h prior to the experiment but allowed free access to water. After the last dose, each animal was anesthetized with 10 g/L sodium thiopental. Five milliliters of blood was collected by intracardiac puncture. Each sample contained 0.22 mL 6-keto EDTA, and was centrifuged for 15 min at 5 500 r/min. The plasma from each sample was stored at -80 °C for the determination of the level of interleukin IL-8 and 6-keto-PGF1a by RIA using IL-8 and 6-keto PGF1a kits, respectively. Subsequently, the abdomen was opened and the stomach was exposed after the esophagus and pyloric were ligated, and then 5 mL 40 g/L neutral buffered formalin was instilled into the stomach via the incision for pathological examination.

Ulcerated area (mm^2) determination

After being fixed in formalin overnight, the stomach was opened along the greater curvature and spread out with pins on a cork board, and then photographed. The ulcerated area (mm^2)[11] was computed using the following equation: $S = \pi(d_1/2)\times(d_2/2)$, where S represents the ulcerated area (mm^2), d_1 and d_2 represent the longest longitudinal and transverse diameters of the ulcer respectively.

Light microscopy

After fixation, the stomach was divided into two parts and each part was subdivided into four tissue strips by cutting along the whole width of the half stomach. The blocks were embedded in paraffin wax. Five micrometer thick sections were cut in a standard fashion and stained with hematoxylin and eosin.

Radioimmunoassay (RIA) for IL-8 and 6-keto-PGF1a

All the blood samples for IL-8 and 6-keto-PGF_{1a} determination were stored in the tubes. Serum level of IL-8 and 6-keto-PGF_{1a} was determined by RIA with the IL-8 and 6-keto-PGF_{1a} RIA kits according to their manufacturer's instructions.

MPO activity

The level of MPO in the liver homogenate was determined by biochemical methods with the MPO kits according to its manufacturer's instructions.

Statistical analysis

All the values were expressed as mean±SD. One-way ANOVA was used to analyze the differences among them. Student's t-test was applied to comparisons between the two groups. $P<0.05$ was considered statistically significant. Software SPSS10.0 was used in all statistical analyses.

RESULTS

Ulcerated area (mm^2)

The lesion (mm^2) decreased from 40.18±2.6 in control

Table 1 Effects of combined famotidine (FMD) and chlorpheniramine (CPA) on the ulcerated area in different groups (mean±SD)

Group	Dose (mg/kg)	Area of ulcer (mm^2)	6-keto-PGF_{1a} (ng/L)	IL-8 (ng/L)	MPO (μ/L)

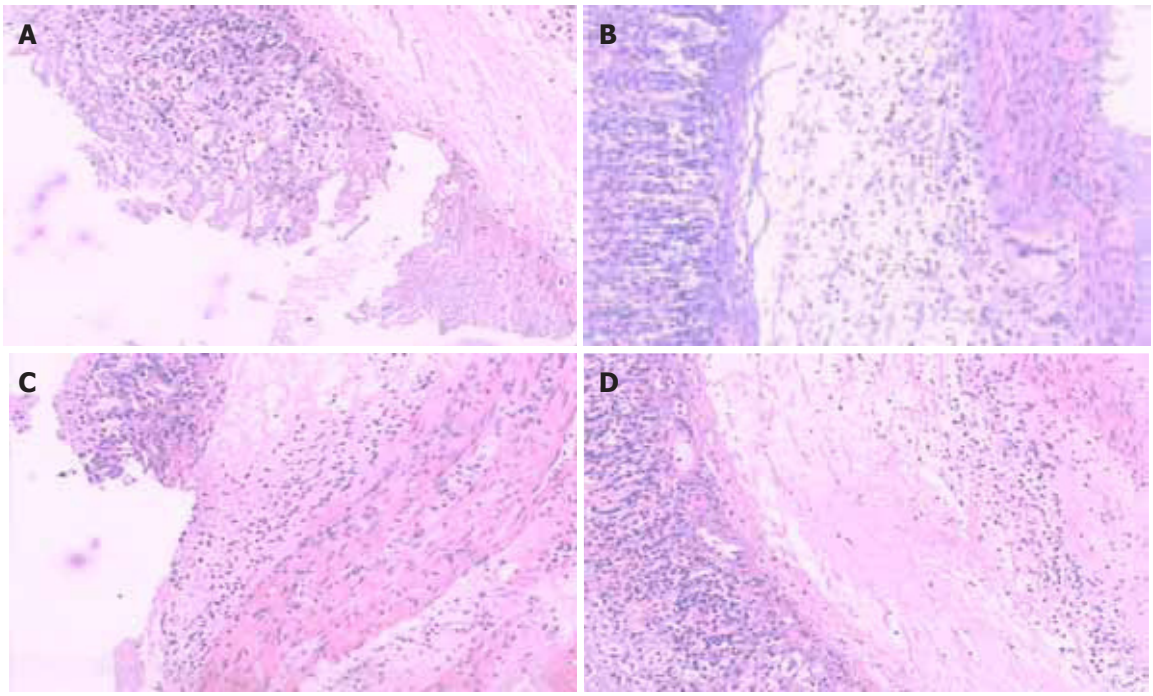

Figure 1 Pathological feature of gastric mucosa in the control group (**A**), FMD group (**B**), CPA group (**C**), and FMD+CPA group (**D**) under light microscope, HE ×200.

group to 0 in the blank group. The lesion (mm^2) was reduced from 40.18±2.6 in the control group to 6.83±2.97 in the PMD+CPA group (P<0. 01), and from 32.9 ±3.27 in FMD group to 6.83±2.97 in PMD+CPA group (P<0.01) (Table 1).

Light microscopy

Microscopic findings on the gastric mucosal scar showed that the mucosal architecture of the scar healed by FMD+CPA group (Figure 1D) was better restored than that of the scar in the control group or in the case of treatment with FMD alone which exhibited much lymphocyte infiltration, and surface epithelial lesions (Figures 1A and B).

Plasma level of 6-keto-PGF_{1a}

The level of 6-keto-PGF_{1a} in the FMD+CPA group was significantly different from that in the control and the FMD groups, which increased from 7.55±1.65 ng/L in the control group to 16.62±0.97 ng/L in the PMD+CPA group (P<0.01) ng/L, and from 13.15±1.48 ng/L in the FMD group to 16.62±0.97 ng/L in the PMD+CPA group, P<0.05 (Table 1).

MPO level in liver homogenate

In the liver homogenate, the level of MPO activity decreased from 9.12±2.05 μ/L in the control group to 4.33 ±0.95 μ/L in the PMD+CPA group, P<0.01, and from 8.3 ±1.29 μ/L in the FMD group to 4.33±0.95 μ/L (P<0.01) (Table 1).

The plasma levels of IL-8

The plasma level of IL-8 decreased from 0.69±0.11 ng/L in the control group to 0.4±0.04 ng/L, P<0.01, and from 0.51±0.08 ng/L in the FMD group to 0.4±0.04 ng/L in the PMD+CPA group (P<0.05) (Table 1).

DISCUSSION

The acetic acid injection-induced ulcer model is a mature classical model. The drawback of the model is that the dose of injection is not rigorous. We used a round filter paper (diameter: 5 mm) immersed in a 100% acetic acid

on the serosal surface to establish the model, which is characterized by high success rate, small coefficient of variation, low rate of perforation.

Prostaglandins (PGs) are well-known mucosal defense factors, protecting the gastric mucosa against injury caused by a variety of toxic stimuli[12,13]. PGE2 stimulates the secretion of gastric mucus and bicarbonate, increases mucosal blood flow, inhibits acid secretion, and reduces gastric motility. In addition, downregulation of proinflammatory cytokine expression by PGs is also likely to be important for mucosal protection against *H pylori* infection. 6-Keto PGF_{1a} is a PGI2 metabolite, and PGI2 plays an important role in gastric cytoprotection. This study also approved that the ulcerated area decreased with the increase in the level of 6-Keto PGF_{1a} and this supports that prostaglandins possess gastric cytoprotection function.

Gastric mucosal integrity is maintained by an interplay of some aggressive and defensive factors controlling cell apoptosis and proliferation. Disturbing this balance leads to ulcer. Proinflammatory cytokines play an important role. IL-8 is an important cytokine in the host inflammatory response to *H pylori*[14-16], which correlates with its induction in gastric epithelial cells co-cultured with *H pylori in vitro*[17-19]. Upregulation of IL-8 by *H pylori* may lead to free radical generation and the release of proteolytic enzymes from activated neutrophils, affecting mucosal integrity[20]. Eradication of *H pylori* in ulcer patients results in a reduction in antral IL-8 mRNA expression, neutrophil infiltration, and surface epithelial lesions[16], suggesting that inflammatory cytokines may play an important role in mucosal damage due to *H pylori* infection. Leukocyte infiltration in gastric mucosa is assessed by determining tissue activity of MPO[21], an enzyme used as a marker for leukocyte infiltration in a variety of tissues including the rat gastric mucosa. Recently, experimental data on H_1 receptor antagonists demonstrate potentially anti-inflammatory effects in addition to their anti-allergic effects on histamine production, the histamine-induced response. Cook *et al*[22] reported that human conjunctival mast cells can be purified (>95%) from cadaveric tissues and that olopatadine inhibits anti-IgE antibody-mediated release of TNF-α from human conjunctival mast cells. Bakker[23] showed that the histamine H_1 receptor, which is also an important player in allergic and inflammatory conditions, activates NF-κB in a constitutive- and agonist-dependent manner and that the observed constitutive NF-κB activation is inhibited by various H_1-receptor antagonists, suggesting that inverse agonism may account, at least in part, for their ascribed antiallergic properties. Miki *et al*[24] showed that histamine concentration-dependently enhances the TNF-α-induced expression of E-selectin and intercellular adhesion molecule-1 (ICAM-1) in vascular endothelial cells. Arnold[25] suggested that cetirizine reduced the release of IL-8 from A549 cells stimulated with PMA and TNF-α, by lowering IL-8 gene expression. Modlin *et al*[26] reported that histamine may also act as an autocrine growth factor for ECL hyperplasia via H_1 receptors. Therefore, histamine may be an important regulator of all gastric endocrine cells. It was reported that a high dose FMD administration significantly increases serum gastrin concentration and proliferates G and ECL cells[27] indicating that the synergistic action of histamine H_1 receptor antagonists and histamine H_2 receptor antagonists may reduce the incidence rate of carcinoids.

The present experimental study demonstrated that FMD, a H_2 receptor antagonist, afforded against gastric ulcers. Chlorpheniramine, a H_1 receptor antagonist could give partial protection. When both H_1 and H_2 blockers were given, they decreased the incidence of ulcer and also enhanced the healing of ulcers. At the same time, this study showed that H_1-antagonists reduced the release of proinflammatory mediators (IL-8 and MPO) from mast cells in comparison with the controls. The synergistic effect indicates that H_1 receptors play a role in gastric ulceration as the H_2 receptors.

Abstract

AIM: To explore the effects of liniment levamisole on cellular immune functions of patients with chronic hepatitis B.

METHODS: The levels of T lymphocyte subsets and mIL-2R in peripheral blood mononuclear cells (PBMCs) were measured by biotin-streptavidin (BSA) technique in patients with chronic hepatitis B before and after the treatment with liniment levamisole.

RESULTS: After one course of treatment with liniment levamisole, the levels of $CD3^+$, $CD4^+$, and the ratio of $CD4^+/CD8^+$ increased as compared to those before the treatment but the level of $CD8^+$ decreased. The total expression level of mIL-2R in PBMCs increased before and after the treatment with liniment levamisole.

CONCLUSION: Liniment levamisole may reinforce cellular immune functions of patients with chronic hepatitis B.

Key words: Liniment levamisole; Chronic hepatitis B; Cellular immune function; T lymphocyte subsets; mIL-2R

INTRODUCTION

It has been reported that cellular immune functions are abnormal in patients with hepatitis B[1]. To explore the effects of liniment levamisole on cellular immune functions of patients with chronic hepatitis B, we measured the levels of $CD3^+$, $CD4^+$, $CD8^+$ and the ratio of $CD4^+/CD8^+$ cells as well as the expression level of mIL-2R in PBMC in patients with chronic hepatitis B before and after the treatment with liniment levamisole. The results support that levamisole can improve cellular immune functions of patients with chronic hepatitis B.

MATERIALS AND METHODS

Patients

According to the diagnostic criteria modified during the 10th National Conference on Viral Hepatitis and Hepatopathy 2 000, 76 patients with chronic hepatitis B (45 males and 21 females) aged 25-64 years (average 48.25 years) were enrolled in this study and randomly divided into treatment group (n = 38, 27 males and 11 females, aged 32-64 years and averaged 51.8 years) and control group (n = 38, 18 males and 10 females, aged 25-58 years and averaged 44.7 years).

Treatment methods

Vitamins B and C, silymarin compound and other liver-protecting drugs were used in the 76 patients. The treatment group was primed with liniment levamisole at a dose of 500 mg twice a week for 3 mo (a course of treatment). Five milliliters of liniment levamisole was smeared on the surface of skin inside the four limbs near the body. The area of the skin should be as large as possible and the smeared skin was washed within 24 h to assure absorption of the drug. No antiviral agent or immunomodulator was used in the two groups.

Samples

Five milliliters of peripheral vein blood was collected at 8:00 a.m. from each patient with hepatitis B and 2.5 mL was put into a sterile test tube and 2.5 mL into an anticoagulant test tube with heparin.

Separation of PBMC and detection of T cell subsets, mIL-2R

After the heparinized blood was mixed with an equal

volume of Hanks' liquid without Ca^{2+} and Mg^{2+}, PBMCs were harvested from heparinized whole blood by centrifugation on Ficoll-Hypaque sedimentation gradient and diluted to (1-3)×10^6/L cell suspension with RPMI 1 640 culture liquid. Ten microliter suspension of PBMCs was smeared on sheet glass pores so that the cells with $CD3^+$, $CD4^+$, $CD8^+$ and the rest phrase of mIL-2R could be detected. Of the PBMC suspension, 0.5 mL was mixed with RPMI 1640 culture liquid. The cells were grown in continuous culture (37 ℃, 50 mL/L CO_2 in atmosphere) for 72 h and mIL-2R could be measured by antibodies against the membrane of T cells[1].

Immunocytochemical BSA technique

Different monoclonal antibodies (mAb) against $CD3^+$, $CD4^+$, $CD8^+$ and Tac with biotin and SA-HRP were smeared on different sheet glasses. The smears were left to dry naturally and fixed with acetone for 15-20 min. The cells were incubated in continuous culture (37 ℃, 50 mL/L CO_2 in atmosphere) for 30 min. The immune sheet glass pores were measured after being stained with color-developing agents and washed with Tris buffer solution (TBS). The total number of PBMCs was counted and the positive cells were analyzed with the help of high power lens.

Reagents and instruments

Antibodies against T-lymphocyte subsets were provided by Shanghai Jing'an Medical Institute; Ficoll-Hypaque sedimentation gradients were offered by Shanghai Second Reagent Factory. Carbon dioxide incubator (MDF-135) was from Japan.

Statistical analysis

Statistical analysis was performed using *t* test to determine the difference between the two groups.

RESULTS

Before the treatment, there was no significant difference in the levels of $CD3^+$, $CD4^+$, $CD8^+$, mIL-2R and the ratio of $CD4^+/CD8^+$ between the two groups. After one course of treatment, the levels of $CD3^+$, $CD4^+$ and the ratio of $CD4^+/CD8^+$ increased, while the level of $CD8^+$ decreased. The total expression level of mIL-2R in PBMCs increased before and after the treatment with liniment levamisole.

DISCUSSION

This study demonstrated that levamisole could exert its immunopotentiating activity in patients with chronic hepatitis B. As an immune stimulant, levamisole could be connected with receptors of thymopentin on the surfaces of immunologic cells and induces inhibited T lymphocytes into immunologically competent cells, which take part in cell-mediated immune, induce interferon production and prime the lymphocytes and macrophages[2-11]. According to clinical experiments, levamisole has therapeutic effectiveness and boosts immunity in a variety of infectious diseases and some cancers[11-24]. Krastev *et al*[25] treated 25 viremic patients with chronic HBV infection with LMS and found that LMS may benefit some patients with chronic ongoing viral replication including patients who are contraindicated for TNF-α. It was reported that LMS acts by resetting the immune balance toward a type 1 response via the induction of IL-18[26].

We have previously shown that decreased $CD3^+$ and $CD4^+$ levels and $CD4^+/CD8^+$ ratio as well as increased $CD8^+$ level occur in patients with chronic hepatitis B[1]. We have also shown that the level of mIL-2R in PBMCs is lower than that in normal controls[1]. In the present study, all these parameters including the levels of $CD3^+$, $CD4^+$, $CD8^+$, mIL-2R and the $CD4^+/CD8^+$ ratio became normal in the levamisole-treated patients. This reversion of aberrant cellular immunity may improve symptoms of chronic hepatitis B patients.

Liniment levamisole is made from levamisole, which is applied on the surface of skin and can penetrate into the liver, spleen, lungs, kidneys and other internal organs through the skin. We suggest that liniment levamisole should be used in the treatment of patients with chronic hepatitis B.

Abstract

AIM: To explore the correlation between the expressions of gastrin (GAS), somatostatin (SS) and cyclin, cyclin-dependent kinase (CDK) in colorectal cancer, and to detect the specific regulatory sites where gastrointestinal hormone regulates cell proliferation.

METHODS: Seventy-nine resected large intestine carcinomatous specimens were randomly selected. Immunohistochemical staining for GAS, SS, cyclin D1, cyclin E, cyclin A, cyclin B1, CDK2 and CDK4 was performed according to the standard streptavidin-biotin-peroxidase (S-P) method. According to the semi-quantitative integral evaluation, SS and GAS were divided into high, middle and low groups. Cyclin D1, cyclin E, cyclin A, cyclin B1, CDK2, CDK4 expressions in the three GAS and SS groups were assessed.

RESULTS: The positive expression rate of cyclin D1 was significantly higher in high (78.6%, 11/14) and middle GAS groups (73.9%, 17/23) than in low GAS group (45.2%, 19/42) ($P<0.05$, $\chi^2_{\text{high } vs \text{ low}} = 4.691$; $P<0.05$, $\chi^2_{\text{middle } vs \text{ low}} = 4.945$). The positive expression rate of cyclin A was significantly higher in high (100%, 14/14) and middle GAS groups (82.6%, 19/23) than in low GAS group (54.8%, 23/42) ($P<0.01$, $\chi^2_{\text{high } vs \text{ low}} = 9.586$; $P<0.05$, $\chi^2_{\text{middle } vs \text{ low}} = 5.040$). The positive expression rate of CDK2 was significantly higher in high (92.9%, 13/14) and middle GAS groups (87.0%, 20/23) than in low GAS group (50.0%, 21/42) ($P<0.01$, $\chi^2_{\text{high } vs \text{ low}} = 8.086$; $P<0.01$, $\chi^2_{\text{middle } vs \text{ low}} = 8.715$). The positive expression rate of CDK4 was significantly higher in high (78.6%, 11/14) and middle GAS groups (78.3%, 18/23) than in low GAS group (42.9%, 18/42) ($P<0.05$, $\chi^2_{\text{high } vs \text{ low}} = 5.364$; $P<0.01$, $\chi^2_{\text{middle } vs \text{ low}} = 7.539$). The positive expression rate of cyclin E was prominently higher in low SS group (53.3%, 24/45) than in high (9.1%, 1/11) and middle (21.7%, 5/23) SS groups ($P<0.05$, $\chi^2_{\text{high } vs \text{ low}} = 5.325$; $P<0.05$, $\chi^2_{\text{middle } vs \text{ low}} = 6.212$). The positive expression rate of CDK2 was significantly higher in low SS group (77.8%, 35/45) than in high SS group (27.3%, 3/11) ($P<0.01$, $\chi^2_{\text{high } vs \text{ low}} = 8.151$). There was a significant positive correlation between the integral ratio of GAS to SS and the semi-quantitative integral of cyclin D1, cyclin E, cyclin A, CDK2, CDK4 ($P<0.05$, ${}^{D1}r_s = 0.252$; $P<0.01$, ${}^{E}r_s = 0.387$; $P<0.01$, ${}^{A}r_s = 0.466$; $P<0.01$, ${}^{K2}r_s = 0.519$; $P<0.01$, ${}^{K4}r_s = 0.434$).

CONCLUSION: The regulation and control of gastrin, SS in colorectal cancer cell growth may be directly related to the abnormal expressions of cyclins D1, A, E, and CDK2, CDK4. The regulatory site of GAS in the cell cycle of colorectal carcinoma may be at the G_1, S and G_2 phases. The regulatory site of SS may be at the entrance of S phase.

Key words: Colorectal cancer; Gastrin; Somatostatin; Cyclin; CDK

INTRODUCTION

Colorectal cancer is one of the most common human malignant tumors in the world, with a high incidence rate in North America, Western Europe, Australia, New Zealand and France, and is the second leading cause of gastrointestinal cancer-related mortality worldwide[1–3]. Although great progress has been made in understanding the molecular aspects of colorectal cancer and several therapeutic agents have been developed, it still poses a serious threat to public health and remains as the major killer among the Chinese. The general survival rate of colorectal cancer patients does not exceed

40%[4,5]. Studies demonstrate that the occurrence of colorectal cancer is directly related to the abnormal expression of gastrointestinal hormones such as gastrin, somatostatin, etc[6]. At the same time, some studies found that somatostatin is able to induce apoptosis of large intestinal cancer cells and inhibit cell proliferation, but the role of GAS (gastrin) is opposite[7-9]. However, the detailed molecule mechanism by which gastrin and somatostatin regulate and control the growth of large intestinal carcinoma is not fully known. We have used immunohistochemical staining standard streptavidin-biotin-peroxidase (S-P) method to detect the expressions of GAS, somatostatin (SS), cyclin D1, cyclin E, cyclin A, cyclin B1, CDK2, CDK4 proteins in large intestinal cancer tissue. The aim of our study was to explore the correlation between the expressions of SS, GAS and cyclins, cyclin-dependent kinase (CDKs) and to further confirm whether GAS, SS could regulate and control large intestinal cancer cell growth by affecting the expression of cyclins and CDKs.

MATERIALS AND METHODS

Seventy-nine cancer tissue samples were randomly selected from patients with large intestinal carcinoma hospitalized in the Department of Pathology of the First Affiliated Yijishan Hospital of Wannan Medical College from June 2001 to June 2003. All patients were confirmed to have colorectal carcinoma by clinical pathology. Among them, 37 were cases of rectum cancer, 42 were cases of colorectal carcinoma. Thirty-five were females and 44 were males. The median age was 52.9±14.3 years, with a range of 27-78 years. Ulcerative type was found in 44 patients, protruded type in 33, infiltrating type in 2, papillary adenocarcinoma in 7, glandular adenocarcinoma in 40, mucoid carcinoma in 14, signet-ring cell carcinoma in 11, and undifferentiated carcinoma in 7. The clinical stage was determined according to the Dukes' stage. Dukes' stages A and B were found in 38 patients, Dukes' stages C and D in 41 patients.

The polyclonal rabbit antibodies against human SS and GAS, monoclonal mouse antibodies against human cyclins D1, E, A, B1, and CDK2, CDK4, and immunohistochemical staining kits were all purchased from Beijing Zhongshan Biological Technology Co., Ltd.

Specimens obtained during surgery were routinely fixed in 10% neutral formalin and embedded in paraffin. Serial 4-μm-thick sections were cut. Immunohistochemical staining for cyclins D1, E, A, B1, and CDK2, CDK4, GAS, SS was performed according to the S-P method. The detailed manipulation was conducted according to the introduction for users. Positive pancreatic tissue, stomach antrum mucous membrane, healthy amygdalae tissue, breast cancer tissue, reactive lymph node tissue, healthy skin tissue were used as a positive control for GAS, SS, cyclins A, B1, D1, E, and CDK2, CDK4, respectively. PBS (0.01mol/L) as a negative control replaced the primary antibody.

Positive SS and GAS were stained brown-yellow mainly in cell plasma, partly in cell membranes. When SS and GAS protein expression were scored, both the extent and intensity of immunopositivity were considered. The intensity of staining was scored as follows: 0 as no staining, 1 as weak-yellow, 2 as brown-yellow, and 3 as brown-black. The extent of positive cells was scored as follows (100 cells were counted by two independent observers, who did not know the clinicopathological features of these large intestinal cancers): 1 = positively stained cells <5%, 2 = positively stained cells being 5-10%, 3 = positively stained cells being 10-20%, 4 = positively stained cells >20%. The final score was determined by multiplying the intensity and extent of positivity scores, yielding a range from 1 to 12. According to the semi-quantitative integral evaluation, SS and GAS were divided into three groups as follows: scores 1-3 were defined as the low group, 4-6 as the middle group, and 7-12 as the high group.

Positive cyclin B1 was stained brown-yellow mainly in the cell plasma. Positive cyclins D1, E, A, and CDK2, CDK4 were stained brown-yellow mainly in karyons. The degree of their staining was estimated by semiquantitative evaluation and categorized by the extent and intensity of staining as follows[10]. The intensity of staining was scored as follows: 0 as negative, 1 as weak-yellow, 2 as brown-yellow, and 3 as brown-black. The extent of positively stained cells was scored as follows: 0=positively stained cells being 0-5%, 1 = positively stained cells being 6-25%, 2 = positively stained cells being 26-50%, 3 = positively stained cells being 51-75%, 4 = positively stained cells>75%. Combined staining score was used to evaluate the staining of cyclins D1, E, A, B1, and CDK2, CDK4. The final score was determined by adding the intensity and extent of staining scores, yielding a range from 0 to 7. Scores1-2 were defined as negative staining (-), 3 as weak staining (+), 4 as moderate staining (++), ⩾5 as strong staining (+++).

Statistical analysis was performed using chi-square test to differentiate the positive rates of different groups and using Spearman's test to analyze the correlation between the ratio of GAS to SS and the integral of cyclins D1, E, A, B1, and CDK2, CDK4. All data were analyzed with SPSS version 10.0. $P<0.05$ was considered statistically significant.

RESULTS

The positive expression rate of cyclin D1 was significantly higher in high (78.6%, 11/14) and middle GAS groups (73.9%, 17/23) than in low GAS group (45.2%, 19/42) ($P<0.05$, $\chi^2_{\text{high } vs \text{ low}} = 4.691$; $P<0.05$, $\chi^2_{\text{middle } vs \text{ low}} = 4.945$). The positive expression rate of cyclin A was significantly higher in high (100%, 14/14) and middle GAS groups (82.6%, 19/23) than in low GAS group (54.8%, 23/42) ($P<0.01$, $\chi^2_{\text{high } vs \text{ low}} = 9.586$; $P<0.05$, $\chi^2_{\text{middle } vs \text{ low}} = 5.040$). The positive expression rate of CDK2 was significantly higher in high (92.9%, 13/14) and middle GAS groups (87.0%, 20/23) than in low group (50.0%, 21/42) ($P<0.01$, $\chi^2_{\text{high } vs \text{ low}} = 8.086$; $P<0.01$, $\chi^2_{\text{middle } vs \text{ low}} = 8.715$). The positive

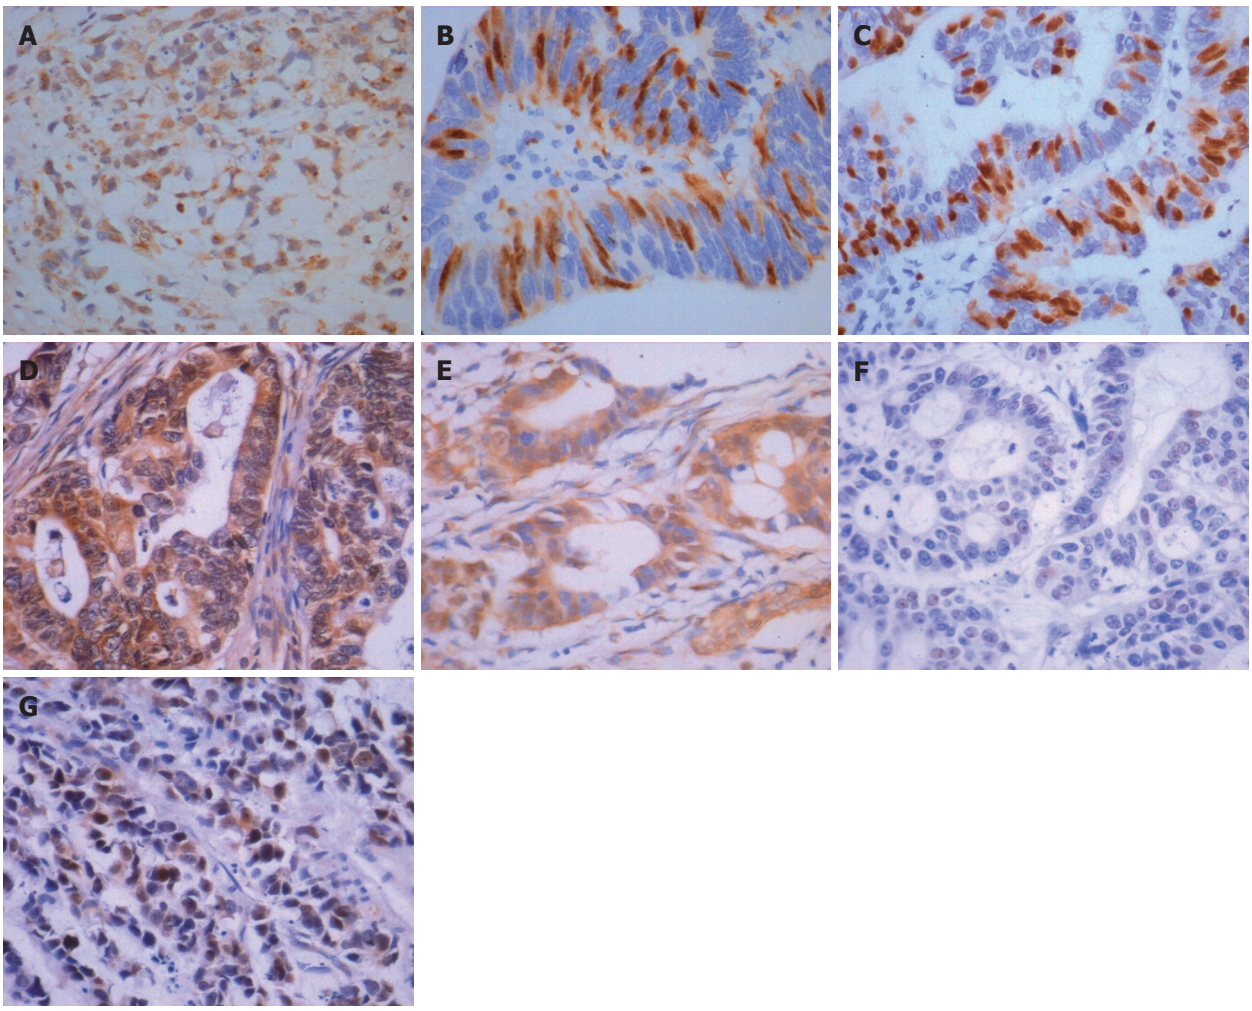

Figure 1 Strong expressions of GAS (**A**), cyclin D1 (**B**), cyclin A (**C**), CDK4 (**D**), SS (**E**), cyclin E (**F**) and CDK2 (**G**) in colorectal carcinoma tissue, S-P×400.

expression rate of CDK4 was significantly higher in high (78.6%, 11/14) and middle GAS groups (78.3%, 18/23) than in low group (42.9%, 18/42) (P<0.05, $\chi^2_{\text{high vs. low}}$ = 5.364; P<0.01, $\chi^2_{\text{middle vs. low}}$ = 7.539). However, the positive expression rate of cyclins E and B1 was significantly higher in high (57.1%, 8/14; 92.9%, 13/14) and middle GAS groups (47.8%, 11/23; 73.9%, 17/23) than in low GAS group (26.2%, 11/42; 66.9%, 28/42), but there was no statistically significant difference among the three groups when compared to three groups to each other (P>0.05, χ^2 = 5.608; P>0.05, χ^2 = 4.417) (Table 1, Figure 1 A-D).

The positive expression rate of cyclin E was prominently higher in low SS group (53.3%, 24/45) than in high (9.1%, 1/11) and middle (21.7%, 5/23) SS groups (P<0.05, $\chi^2_{\text{high vs low}}$ = 5.325; P<0.05, $\chi^2_{\text{middle vs low}}$ = 6.212). The positive expression rate of CDK2 was significantly higher in low SS group (77.8%, 35/45) than in high SS

group (27.3%, 3/11) ($P<0.01$, $\chi^2_{\text{high vs low}} = 8.151$). However, the positive expression rate of CDK4, cyclin D1 was significantly higher in low SS group (64.4%, 29/45; 62.2%, 28/45) than in high SS group (36.4%, 4/11; 45.5%, 5/11), it was not statistically significant ($P>0.05$, $\chi^2 = 2.868$; $P>0.05$, $\chi^2 = 1.038$). There was no statistically significant difference in the positive expression rate of cyclins A and B1 in high (72.2%, 8/11; 81.8%, 9/11), middle (69.6%, 16/23; 73.9%, 17/23) and low SS groups (71.0%, 32/45; 71.1%, 32/45) when compared to each other ($P>0.05$, $\chi^2 = 0.039$; $P>0.05$, $\chi^2 = 0.554$) (Table 1, Figure 1 E-G).

There was a significant positive correlation between the integral ratio of GAS to SS and the semiquantitative integral of cyclins D1, E, A, and CDK2, CDK4 ($P<0.05$, ${}^{D1}r_s = 0.252$; $P<0.01$, ${}^{E}r_s = 0.387$; $P<0.01$, ${}^{A}r_s = 0.466$; $P<0.01$, ${}^{K2}r_s = 0.519$; $P<0.01$, ${}^{K4}r_s = 0.434$). But there was no correlation between the integral ratio of GAS to SS and cyclin B1 integral ($P>0.05$, $r = -0.108$).

DISCUSSION

Cancer arises mainly from mutations in the somatic cells. However, conversion of normal cells to cancer cells is not the result of a single mutation; it is achieved through a multi-step process that is closely associated with the accumulation of multiple gene changes including both oncogenes and tumor suppressor genes[11-13]. Uncontrolled cell proliferation is one of the main hallmarks of cancer, and tumor cells have acquired damage to genes that are directly involved in regulating the cell cycle. The cell cycling process is carefully regulated. The switch or transition between phases is a hallmark of the cell cycle, with an extremely accurate timing and order of molecular events. However, if something goes wrong, the cells have several systems for interrupting the cell cycle[12,14,15].

In order to ensure the cell cycling process, CDK timing-activity is a critical step in the regulation and control mechanism of cell cycle. At least nine different CDKs are known today. However, only some of them seem to be involved in cell cycle regulation. CDKs that are required for cell cycle regulation contain an active kinase subunit in complex with a regulatory subunit, or activator, commonly called cyclin[16,17]. Cyclins are important mediators of CDKs activity, and their level fluctuates throughout the cell cycle, some being more abundant in specific cell phases than others[18]. These cyclins have been divided into three classes: G_1-S cyclin, S cyclin, and M cyclin. Cyclins response to mitogenic signals and unscheduled expression, leading to uncontrolled proliferation, has been implicated in different human cancers[19], such as colon cancer[20] and breast cancer[21]. The CDK/cyclin complex is subjected to several kinds of regulation factors, both positive and negative.

Cell cycle progression is positively regulated by multiple cyclins and CDKs and cyclin/CDK complexes are negatively regulated by a number of CDK inhibitors including p27[22,23]. P27 is a CDK inhibitor and plays an important role in the negative regulation of the cell cycle during G_0 and G_1 phases[12,13,24,25]. Proliferating cells pass through several cell cycle checkpoints, mainly the G_1 to S and G_2 to M transitions. The former checkpoint is considered as the most important one in the replication of DNA and mitosis. The G_1-S transition is a highly regulated and important transition in the cell cycle. At this stage, the cell cycle passes a point between G_1 and S phases (restriction point) with an irreversible commitment to a new cycle. The underlying molecular mechanisms are the induced expression of CDKs and cyclins required for the cells to progress from early G_1 phase into late G_1 phase of the cell cycle, reaching the restriction point. This is a critical point in the late G_1 phase where the mammalian cells become committed to entering the S phase and to complete the cell cycle, even in the absence of growth factors[23,26,27]. The main CDKs involved in the progression from mid- to late G_1 are CDK4 and CDK6, driven by three G_1-specific cyclins, D1, D2 and D3[15]. Cycle progression from G_1 to S phase is usually accompanied with Rb phosphorylation induced by cyclin D_1-CDK_4 and cyclin E-CDK_2 complexes in the late G_1 phase[28]. Cyclin-dependent kinase 2 (CDK2) activity is critical for S phase entry. CDK2 activation is apparently cyclin E-dependent. Late G_1 phase CDK2/cyclin E activity depends on early G_1 phase CDK2/cyclin E function[29,30].

Previous studies have shown that some tissue growth is regulated by hormones, and these tissues that have turned into tumors are still controlled by hormones[31]. Gastrointestinal hormones such as gastrin and somatostatin regulate the secretion, motility, absorption, blood flow and cell nutrition of the digestive tract. Abnormality of their secretion often affects the normal functions of the digestive tract, even causes clinical symptoms or syndromes[32,33]. Some studies demonstrated that there is a high correlation between the abnormal expressions of GAS, SS and the occurrence and development of colorectal cancer[34-36]. Recently, great progress has been made in understanding the cell cycle mechanisms of GAS and SS. Some studies showed that the abnormal expressions of GAS and SS are closely related to cell apoptosis and proliferation of colorectal cancer, and that the expression of gastrin protein and the proliferation index are higher in colorectal cancer tissue, while the action of somatostatin is opposite in colorectal carcinoma[9,37,38]. Though there is abundant evidence that gastrin plays an important role in promoting tumor growth in the stomach, as well as malignancies in the GI tract, the precise mechanisms governing the gastrin-induced and somatostatin-restrained proliferation are still largely unknown. To elucidate the mechanisms of gastrin and somatostatin in regulating mitogenesis, we have analyzed their effects on the expression of cyclins and CDKs in human colorectal cancer tissue.

Gastrin is a gastrointestinal (GI) peptide that possesses potent trophic effects on most normal and neoplastic mucosae of the GI tract. Gastrin is mainly secreted from gastrin secreting cells (G cells) in the antrum mucosa or upper small intestine, large intestine. Medulla oblongata and dorsal nuclei of vagus nerves in central nervous system also secrete gastrin[39,40]. Studies indicate that

chronic hypergastrinemia increases the risk of colorectal cancer and cancer growth, and that interruption of the effects of gastrin may be a potential target in the treatment of colorectal cancer[41]. Shen *et al*[42] showed that gastrin is able to promote DNA and protein synthesis in colorectal cancer tissue. However, gastrin-released peptide receptor antagonist proglumide could block these effects of gastrin, and restrain colorectal cancer cells from G_0/G_1 phase into S and G_2, M phase transitions. It was recently reported that gastrin (G-17) is able to induce a significant increase in G_1-specific marker cyclin D1 transcripts, protein, and promoter activity via the activation of beta-catenin and CRE-binding protein pathways in gastric adenocarcinoma cells, which promote transition of tumor cells from G_1 phase into S phase, and lead to uncontrolled proliferation of tumor cells[43]. Lefranc *et al*[44] studies found that gastrin is able to significantly modify the growth of a number of experimental gliomas. This effect seems to occur via a cytostatic effect, that is, an accumulation of tumor astrocytes occurs in the G_1 cell cycle phase. The cytostatic effect relates to a gastrin-induced decrease in the level of cyclin D3-CDK4 complex. In this study, we have found that the level of gastrin protein expression was higher and the positive expression rate of cyclins D1, A, and CDK2, CDK4 was higher in large intestinal carcinoma tissue, indicating that mechanism of gastrin in promoting colorectal cancer cell proliferation is via inducing the overexpression of cyclins D1, A, and CDK2, CDK4, thus leading to the rise of the level of cyclin D1-CDK4 and cyclin A-CDK2 complexes, which influence cell cycle progress and promote cell proliferation.

Somatostatin is a widely distributed inhibitory hormone that plays an important role in several biological processes including neurotransmission, inhibition of exocrine and endocrine secretions, and cell proliferation. Somatostatin acts as an inhibitory peptide of various secretory and proliferative responses. Somatostatin is secreted from somatostatin secreting cells (D cells). D cells are distributed mainly in intestinal nerve plexus, stomach and pancreas. The diverse biological effects of somatostatin are mediated by a family of five somatostatin receptors (sst1-sst5) that belong to the family of G-protein-coupled receptors and regulate diverse signal transduction pathways including adenylate cyclase, phospholipase C-β phospholipase A_2, guanylate cyclase, ionic conductance channels, and tyrosine phosphatase[45-48]. The mechanisms underlying the inhibition are the combined interaction of somtostatin and its analogs to SST1-5R in tumor tissues, either directly inhibiting division and proliferation of tumor cells or the activities of growth factors such as vascular endothelial growth factor, insulin-like growth factor, etc[49-51], thus counteracting tumorigenesis and tumor cell proliferation[52]. The ability of somatostatin and its stable analogs to inhibit normal and tumor cell growth has been demonstrated in various cell types including mammary, prostatic, gastric, pancreatic, colorectal, and small cell lung cancer cells. However, the mechanisms of somatostatin underlying cell growth arrest are still poorly understood. Pages *et al*[53] showed that activation of sst2 promotes cell growth arrest through the ability of somatostatin to maintain high levels of $p27^{Kip1}$ and inactivates cyclin E-CDK2 complexes, leading to hypophosphorylation of pRb, restraining transition of tumor cells from G_1 phase into S phase. Charland *et al*[54] reported that somatostatin is able to inhibit cyclin E expression in pancreatic cells and cyclin E-associated CDK2 activity, as well as pRb phosphorylation, and to restrain transition of cells from G_1 phase into S phase, thus inhibiting cell proliferation. Zhao *et al*[55] demonstrated that somatostatin analog, octreotide, inhibits the proliferation of cholangiocarcinoma cells through G_0/G_1 cell cycle arrest rather than through the process of apoptosis. These effects are partially mediated by enhancing the expression of p27kipl, and decreasing the level of cyclin E-CDK2 complex. In this study, the higher the integral of SS, the lower the positive expression rate of cyclin E and CDK2. Our data indicate that the mechanism of somatostatin in inhibiting colorectal cancer cell proliferation is via restraining the expression of cyclin E and CDK2, and decreasing the level of cyclin E-CDK2 complex, which inhibits transition of cells from G_1 phase into S phase and induces cell cycle arrest, thus restraining cell proliferation.

In the present study, we have found that the ratio of GAS to SS had an effect on the biological characteristics of large intestinal cancer[56]. The increased ratio of GAS to SS is an event of significance in large intestinal cancer occurrence and development[31]. Our results indicate that there is a positive correlation between the ratio of GAS to SS and the semi-quantitative integral expression of cyclins D1, A, E, and CDK2, CDK4. Furthermore, the expression of GAS and SS has a direct relation with the expression of cyclins D1, A, E, and CDK2, CDK4 in colorectal cancer.

In conclusion, the regulation and control of gastrin, somatostatin in colorectal cancer cell growth may be directly related to the abnormal expressions of cyclins D1, A, E, and CDK2, CDK4. The regulatory site of GAS in the cell cycle of colorectal carcinoma may be at the G_1, S and G_2 phases. The regulatory site of SS may be at the entrance of S phase.

Abstract

A 42-year-old Japanese man with liver cirrhosis by hepatitis C virus (HCV) had successful interferon therapy in May 1991. Since then, serum HCV-RNA and liver function tests had been negative. He had continued to drink more than 100 g/d of alcohol as before. In June 2003, a 5-cm tumor was found in the posterior segment of the liver. The tumor was curatively resected and the surgical specimen showed a well-differentiated hepatocellular carcinoma (HCC). Non-cancerous lesions of the liver revealed fibrosis at stage F3 with minimal to mild inflammation of grade A1. Heavy drinking may retard the dissolution of fibrosis and accelerate HCC development in patients with sustained virological response.

Key words: Hepatocellular carcinoma; Interferon; HCV; Eradication

INTRODUCTION

Hepatocellular carcinoma (HCC) is the third leading cause of death in Japan. Hepatitis C virus (HCV) infection is apparently a major cause of HCC[1-6]. Patients with chronic HCV infection seem destined for progression from milder forms of hepatitis to cirrhosis and, eventually, to HCC. The more advanced is the fibrosis of the liver, the higher is the risk of HCC development. This risk is surprisingly high in cirrhotic patients, the incident rate being about 7% per year[7]. Previously, those patients had no choice but to pass uneasy days in fear of HCC development. It was believed that liver fibrosis is an irreversible change and liver cirrhosis is an incurable disease. Recently, however, it has been shown that the risk of HCC is reduced in HCV-infected patients by interferon therapy, even in cirrhotic patients[8-13]. Interferon therapy can not only improve inflammation, but also ameliorate fibrosis and reduce the risk of HCC. More recently, it has been considered that HCC rarely develops long after HCV eradication[14,15].

Although interferon therapy has been employed for more than a decade, it is not clear how long the risk of HCC lasts among patients who have achieved sustained virological response (SVR). Recently, we had a case with HCC developing 12 years after HCV eradication. This case seems worthy of noting the details, and the data might be helpful for managing patients after HCV eradication.

CASE REPORT

A 42-year-old Japanese man had abnormal liver function tests at a health check-up in 1987. Serum ALT and AST were moderately elevated, 80 and 79 IU/L, respectively. He had no history of blood transfusion or drug abuse, but had been consuming more than 100 g/d of alcohol for 20 years. The liver biopsy specimen showed liver cirrhosis, diagnosed later as A1F4 according to the Classification by Desmet[17]. Alcohol hyaline was not found in the specimen (Figure 1).

In May 1991, he underwent successful interferon therapy after a diagnosis of HCV infection using a total dose of 390 MU of natural interferon-alpha (Sumiferon®, Sumitomo Pharmaceuticals Co., Ltd., Osaka, Japan). Serum HCV-RNA had been negative ever since, and liver function tests, including ALT and AST, had also been normalized. He had continued to drink alcohol heavily as before.

His follow-up had included blood tests and ultrasound examinations every 4-6 mo. In June 2003, ultrasonography

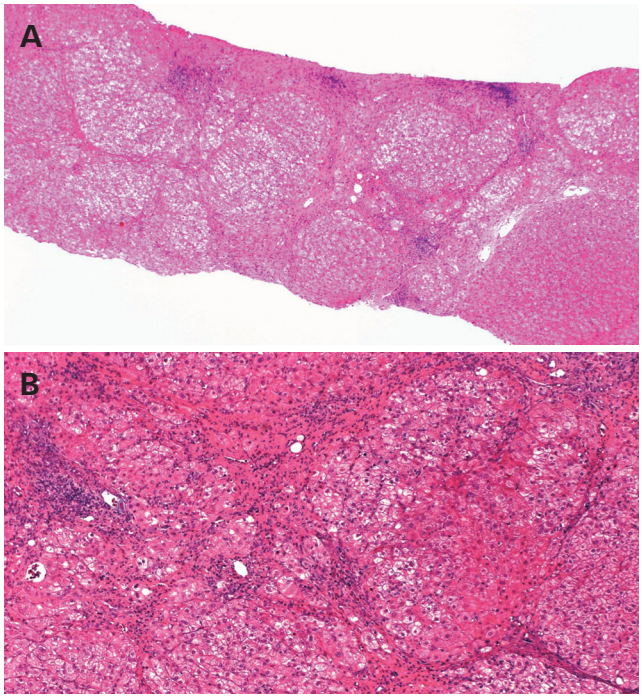

Figure 1 (**A** and **B**) Liver biopsy specimen before interferon therapy revealed liver cirrhosis with mild inflammation. It was graded as A1F4 according to the Classification by Desmet. Alcohol hyaline was not found (H&E stain, original magnifications A: ×4, B: ×200).

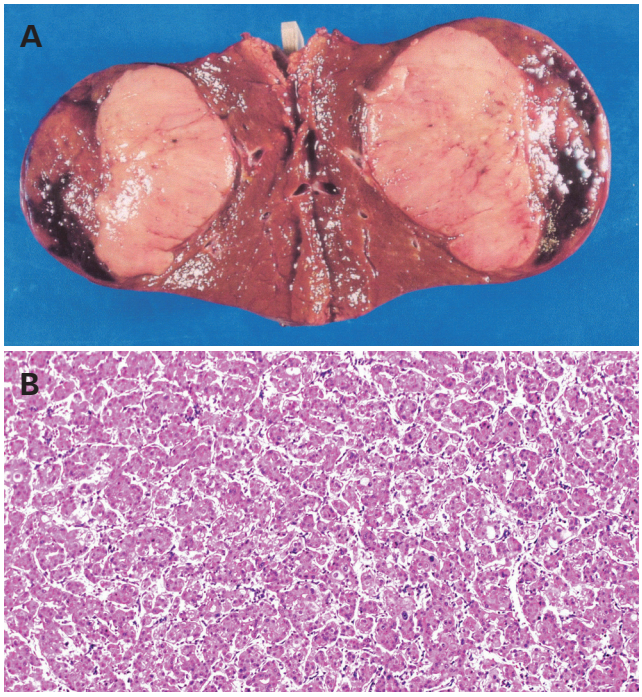

Figure 3 (**A**) Surgical specimen showing an 8-cm tumor. (**B**) Histological examination revealing a well-differentiated hepatocellular carcinoma (H&E stain, original magnification ×200).

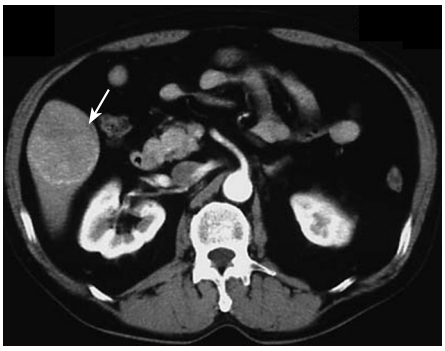

Figure 2 Contrast medium-enhanced CT image of the liver tumor of the right inferior segment (a white arrow).

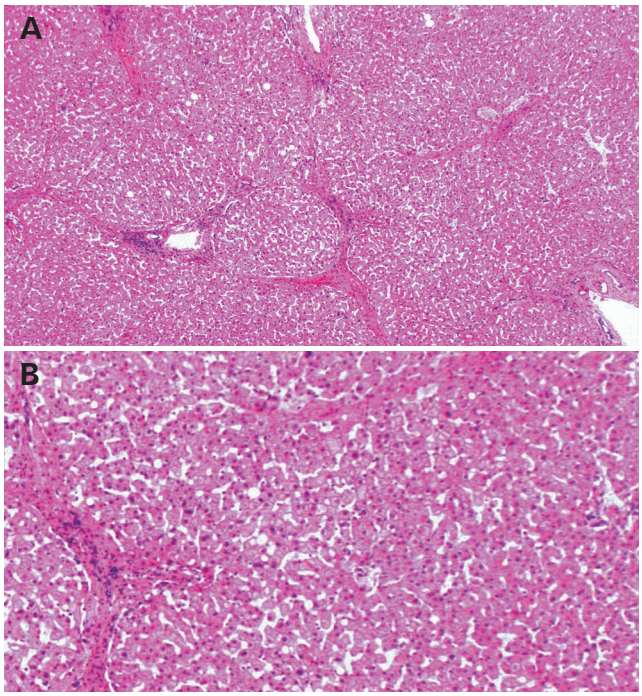

Figure 4 (**A** and **B**) Surgical specimen of non-cancerous lesion showing improvement of fibrosis and inflammation. However, great amounts of septa were observed, although fibrous bundles apparently decreased. Fibrosis resolved, revealing liver cirrhosis with mild inflammation. It was graded as A1F3 (H&E stain, original magnifications A: ×4, B: ×200).

and CT scan demonstrated a tumor of 5 cm in diameter in the posterior segment of the liver (Figure 2). Blood tests were normal except for elevated desgamma carboxy prothrombin (DCP, 44 mAu/mL, normal <40 mAu/mL). Angiography confirmed a hypervascular nodule, suggesting HCC.

The tumor was curatively resected and the surgical specimen showed a well-differentiated HCC (Figure 3). Non-cancerous lesions revealed minimal to mild inflammation and severe fibrosis of A1F3 (Figure 4).

The patient had recurrence of multiple HCCs, 12 mo after the surgery. Chemoembolization was performed repeatedly, and he was in remission up to September 2004.

DISCUSSION

Interferon therapy has been shown to reduce the risk of HCC development among the patients with chronic HCV infection. Their risk is decreased to one-third and their

survival is also significantly improved when they obtain SVR[17,18].

In patients achieving SVR, fibrosis is gradually dissolved and the risk for HCC development is reduced. Our concern is how long their risk of HCC lasts. There have been few documented cases of HCC development for more than 10 years after the interferon therapy, with more than 10 years having passed since its introduction. At that point, the possibility of HCC development is also believed to be notably decreased.

The present case developed HCC, 12 years after HCV eradication, perhaps the latest developed HCC case on record. It may be helpful for the management of post-eradication patients to review the details of this case in terms of the potential of HCC development.

The present patient had been showing normal aminotransferase values, including ALT and AST, and negative results for serum HVC RNA for 12 years after receiving interferon treatment. Although the histological findings of the liver were improved, great amounts of septa were still observed in the surgical specimen, suggesting F3. In patients with this status, the HCC risk is appraised at 5% per year. The dissolution of fibrosis may have been retarded in the present case. Shiratori *et al*[19] reported that the *F* values regress at a rate of -0.282/year among patients with SVR that is based on the method of Poynard[20]. The regression rate in the present case was from F4 to F3 for over the course of 12 years, a meager -0.083/year compared to the reported rate.

The patient had been consuming alcohol since the successful interferon therapy, perhaps accounting for the fact that the hepatic fibrosis had not been dissolved as expected. Alternatively, a long time after eradication, the regression rate in patients may not be as high as in those previously reported. As little data is available regarding regression or HCC development in patients with more than 10 years of follow-up, further studies will be needed.

In addition, alcohol itself may accelerate HCC development. Alcohol intake of 41-80 g/d and over 80 g/d is reported to increase the risk of HCC in HCV-infected patients by two- and four-fold, respectively[21]. Alcohol may also facilitate the growth of HCC, as the doubling time of tumor volume was reported as 148 d in abstemious patients and 78 d in imbibing patients[22].

The degree of liver fibrosis, male gender, higher age, and alcohol intake are well-known risk factors for HCC in chronic HCV-infected patients. The present patient met all these conditions, although little is known as to whether they serve as risk factors in patients with SVR. However, alcohol may have played a role in the development of HCC in this case. If he had stopped consuming alcohol, his liver fibrosis would likely have been improved to a greater extent, and he might have escaped from HCC entirely.

In conclusion, heavy drinking may retard the dissolution of fibrosis and accelerate HCC development in patients with SVR. A larger population of similar cases needs to be studied.

Abstract

Inflammatory bowel diseases (IBD) can be really considered to be systemic diseases since they are often associated with extraintestinal manifestations, complications, and other autoimmune disorders. Indeed, physicians who care for patients with ulcerative colitis and Crohn's disease, the two major forms of IBD, face a new clinical challenge every day, worsened by the very frequent rate of extraintestinal complications. The goal of this review is to provide an overview and an update on the extraintestinal complications occurring in IBD. Indeed, this paper highlights how virtually almost every organ system can be involved, principally eyes, skin, joints, kidneys, liver and biliary tracts, and vasculature (or vascular system) are the most common sites of systemic IBD and their involvement is dependent on different mechanisms.

Key words: Crohn's disease; Ulcerative colitis; Inflammatory bowel disease

INTRODUCTION

Inflammatory bowel diseases (IBD) can be really considered to be systemic diseases since they are often associated with extraintestinal manifestations, complications, and other autoimmune disorders. Indeed, physicians who care for patients with ulcerative colitis (UC) and Crohn's disease (CD), the two major forms of IBD, face a new clinical challenge every day, worsened by the very frequent rate of extraintestinal complications. Virtually almost every system can be involved, principally eyes, skin, joints, kidneys, liver and biliary tracts, and vasculature (or vascular system) are the most common sites of systemic IBD and their involvement is dependent on different mechanisms.

Extraintestinal IBD-related immune disease can be classified into two major groups: the first one includes reactive manifestations often associated with intestinal inflammatory activity and therefore reflecting a pathogenic mechanism common with intestinal disease (arthritis, erythema nodosum, pyoderma gangrenosum, aphthous stomatitis, iritis/uveitis)[1,2] (Table 1); the second one includes many autoimmune diseases independent of the bowel disease that reflect only a major susceptibility to autoimmunity. They are not considered (apart for primary sclerosing cholangitis) as specific IBD features but only as autoimmune associated diseases such as ankylosing spondilitis, primary biliary cirrhosis, alopecia areata, and thyroid autoimmune disease and others[1] (Table 2).

Moreover, many extraintestinal complications due to metabolic or anatomical abnormalities caused directly by

Table 1 Major extraintestinal immune-related manifestations of IBD

Wegener's granulomatosis
Takayasu's arteritis

Table 3 Extraintestinal complications in IBD and principal pathogenetic mechanisms of arthritis

Extraintestinal complications in IBD	Principal pathogenetic mechanisms of arthritis
Anemia	Iron deficiency, inflammation
Thromboembolic events	Hypercoagulopathies, platelet activation
Osteopathy	Steroid therapy, vitamin D deficiency inflammation
Growth failure	Malnutrition
Nephrolithiasis	Dehydration, hyperoxaluria, low urinary PH
Cholelithiasis	Intestinal loss of bile acids
Amyloidosis	Acute phase reaction, chronic inflammation
Fatty liver	Malnutrition

IBD have been reported frequently and include osteoporosis, biliary and urinary lithiasis, and anemia (Table 3).

Aim of this paper is to review the pathogenic mechanisms, frequency, features, and therapy of the major IBD-associated extraintestinal manifestations.

Pathogenesis of immune-related extraintestinal manifestation in IBD

Extraintestinal immune-related manifestations in IBD are directly dependent on intestinal disease, often coexist in the same patients and have probably the same, even if not completely clarified, pathogenesis[2]. Evidence coming from many studies in genetically susceptible animal models of colitis suggests the crucial role of enteric flora in activating the immune system against bacterial antigens and contemporary against colonic mucosa on the basis of an antigenic cross-reactivity ("antigen mimicry")[3]. The sharing of these colonic antigens by extraintestinal organs, associated with a genetic susceptibility, would finally lead to an immune attack to these organs[2]. One of the best example is represented by primary sclerosing cholangitis occurring in UC: in a subset of patients, the presence (in sera and colonic mucosa) of anti-colonic mucosa auto-antibodies that cross react with biliary epithelium has been identified[4]. Furthermore, recently a colonic epithelial protein (CEP) and the human tropomyosin isoform 5 (hTM5), which are not only expressed in the colon but also in the biliary tract, skin, eyes, and joints, have been suspected to be the major common targets of autoimmune attack in extraintestinal organs of IBD patients being IgG1 specific auto-antibodies identified in UC patients presenting multiple extraintestinal manifestations[5].

It remains unclear why the extraintestinal organs are not always involved at the same time and why these auto-antibodies are absent in colonic CD. A partial explanation is that genetic factors or local co-existent damage factors (infections, trauma) could regulate the display of cryptic antigens and the susceptibility to autoimmune attack[2].

According to the previously explained mechanism, we can identify an immune induction site, where T cells are primed, represented by the colon and the effectors sites that are the extraintestinal organs. Immune cells infiltrate the effectors sites (where they will proliferate) with the help of adhesion molecules (α4β7 integrin, vascular adhesion protein 1) that have a cytokine-mediated overexpression in specific tissues[6].

It is interesting how autoimmune attack can happen many years after the removal of the colon. In the case of primary sclerosing cholangitis (PSC), probably memory lymphocytes that have been primed in the bowel can recirculate for many years also even after the removal of the colon without causing damage until the occurrence of a stimulus in the liver that activates inflammation with the overexpression of adhesion molecules (MAdCAM and CCL 25) and consequent persistent lymphocytes recruitment[7]. Interference with adhesion molecules could be useful in the treatment of extraintestinal manifestation as it has already been shown for the intestinal inflammatory activity[8].

Genetic susceptibility

Extraintestinal manifestations have certainly a familial predisposition (83% of concordance between siblings)[9] and this suggests the existence of a strong genetic influence leading to the identification of many suspected predisposal genes.

HLA system is considered as one of the major genetic markers associated with IBD and extraintestinal manifestations, probably a specific and appropriate antigen presentation that leads to autoimmune reaction in particular predisposing conditions.

It has been reported that UC patients who display HLA-B8, DR3 phenotype have a 10-fold higher risk of primary sclerosing cholangitis[10].

Moreover, UC patients who have HLA DRB1*0103 (DR103) have a higher risk of ocular and articular manifestations[11] and patients with HLA-B*27 and B*58 have a higher risk of uveitis (Orchard TR 2002). HLA-B*27 is strongly associated with ankylosing spondylitis (AS) being present in 90% of these patients but it seems not to be significantly associated with IBD; anyway IBD patients with HLA-B*27 positiveness have a higher risk to develop AS and IBD patients with axial articular involvement are HLA-B*27 positive from 25% to 75%[12]. The polymorphism -1031 C TNF-α has been associated with erythema nodosum in IBD patients[13]. It is possible that HLA genes interfere actively in the pathogenesis of IBD-extraintestinal manifestations or that are in linkage disequilibrium with other really responsible unknown genes. Moreover, caspase-activation recruitment domain containing protein 15 (CARD15), a gene found in association with ileocecal CD with a potential role in the bacterial handling, has been recently associated with sacroiliitis even if previous results did not agree[14].

Joint involvement in IBD

Inflammatory arthropathies are the most common extraintestinal manifestations in IBD patients with a prevalence ranging between 7% and 25%[1,12]. Articular and musculoskeletal manifestations are included in the spondyloarthropathies (SpAs) that are a group of seronegative autoimmune related disorders with common characteristics including: ankylosing spondylitis, reactive arthritis, psoriatic arthritis, inflammatory bowel disease,

some forms of juvenile arthritis and acute anterior uveitis[15].

Articular involvement (peripheral or axial) can precede, be synchronous or begin afterward the diagnosis of IBD, it is characteristically pauciarticular, asymmetrical, transitory, migrating, prevalently non deforming. The axial involvement can vary from asymptomatic sacroiliitis to inflammatory lower back pain to ankylosing spondylitis (that occurs in 3% of IBD patients)[1].

It is interesting that the high incidence of asymptomatic sacroiliitis (varying from 10% to 52%)[16,17,18] and on the other hand the equally high incidence (about 50%) of characteristic inflammatory low back pain in the absence of radiological findings in IBD patients[12] indicating how history and physical examination should be the diagnostic tools. Peripheral arthritis, different from axial involvement, has a significant positive association with the skin, mouth, and ocular manifestation; it happens more frequently in CD (and particularly in colonic localization), often accompanies intestinal activity ameliorating with IBD pharmacological or surgical treatment[1]. In some patients, despite the amelioration of gut inflammatory activity, articular disease persists[19].

Arthritis is often associated with enthesitis, tenosynovitis, dactylitis that can also appear in the absence of arthritis[20]; typically they do not alter inflammatory markers and can compromise deeply the quality of life.

Conventional treatment of inflamed joints include nonsteroidal anti-inflammatory drugs and cyclooxygenase-2-inhibitor that should be used for short-term period because of gastrointestinal side effect and IBD reactivation risk[21,22] nevertheless at drug suspension articular relapse can occur. Also local intra-articular steroid treatment can be useful.

The majority of interventional studies included undifferentiated spondyloarthropathies- or ankylosing spondilytis patients and no IBD patients, so that the results can only be extrapolated. Sulfasalazine has been shown to be effective in peripheral joint disease in SpAs patients[23,24] and positive but limited results have been obtained with methotrexate[25].

Interesting results have been obtained with anti TNF-α inhibitors in resistant SpAs with IBD. In uncontrolled studies, infliximab has shown efficacy in the treatment of SpAs in CD patients as induction and maintenance therapy[26-28], also in the absence of acute phase reactants and intestinal activity; there is also a reported case of positive results in SpA associated with ulcerative colitis[29]. In limited reports (two cases) etanercept, that is ineffective in IBD treatment[30], has given good results in the treatment of SpAs associated to CD[31]. It is not clear at the moment the effect of anti TNF-α therapies on articular damage evolution, certainly the early recognition and appropriate treatment can help to limit the patient's inability.

Hepatobiliary disease

Hepatobiliary diseases are common in IBD patients; they can or cannot be immuno-mediated and can also depend on side effects of medications (see Table 4). Elevation of liver function tests have been observed from 11% to 49% in IBD patients in observational studies[32-34]. The most common immuno-mediated hepatobiliary disease is primary sclerosing cholangitis (PSC) that is a chronic cholestatic disorder characterized by inflammation and fibrosis of the intrahepatic and extrahepatic bile ducts. It is more frequent in male individuals, and the prevalence of IBD (mostly UC) in PSC is about 70-80%[35]. Conversely about 2-7% of UC patients[35,1] and 0.7-3.4% of MC patients have a diagnosis of PSC[36,1]. Suggestive symptoms of PSC are fatigue, pruritus, jaundice, and abdominal discomfort but it is not rare that the isolate finding of abnormalities in liver biochemical markers (first of all alkaline phosphatase); in fact 15-70% of PSC patients are asymptomatic[37,1]. There are no specific auto-antibodies and so biopsy or cholangiography is often necessary for the diagnosis. In PSC patients, IBD frequently present some specific features: pancolonic extension with rectal sparing, backwash ileitis, low intestinal activity, and high pouchitis incidence after colectomy. These distinguishing features have suggested the existence of an IBD-PSC specific clinical phenotype[38]. It is well-known that the increased risk of colonic dysplasia/carcinoma in PSC patients compared to the general population (10-fold risk)[39] and to other UC patients[35] it could depend on the long-lasting and asymptomatic colitis (consequently often underestimated) and by alterations in bile salts pool or folate deficiency. Similarly it has significantly increased the risk of bile duct cancer[40] and metabolic bone disease[41,38]. PSC has a median survival time of 9-12 years from the time of diagnosis; it seems that neither concomitant IBD presence nor colectomy (in UC patients) alter its natural history. Moreover, the colorectal cancer risk does not seem to be decreased after liver transplantation[42].

The therapeutic possibilities in PSC are limited; the best results have been obtained with UDCA at a high dose (until 20 mg/kg)[43-45] and the combined use of corticosteroids showed only a little additive benefit[46,47].

The best clinical approaches to PSC include colonoscopic examination with a biopsy to identify a possible asymptomatic UC and/or cancer and a prevention colonoscopy program in patients identified to have had UC. Association between primary biliary cirrhosis (PBC) and UC is rare but possible and it has been reported in 15 cases; similarly to the CSP it seems that colectomy does not alter the progression of the hepatic disease[48].

Apart from classical immunological liver diseases in IBD patients, they are often observed for other abnormalities. Liver enlargement is the most common reported finding and is strictly related to steatosis grade. Steatosis has been described in more than 30% of patients and it does not seem to be related to the kind of IBD and sex. Data about the influence of disease activity and pharmacological treatment on steatosis are contradictory[49].

Also cholelithiasis is more frequent in IBD patients (about 10%) than in the general population (7%) and mainly in CD (first of all in ileal localization); it seems

to correlate with female sex, previous surgery (mainly ileal resection), and old age. In limited series, it has been shown to be less often symptomatic than in the general population[49]. Probably cholelithiasis is caused by bile salt pool alteration for malabsorption.

Rare complications reported in literature are liver abscesses; it is thought that in most cases portal bacteremia, favorite by mucosal barrier alterations, can be the principal mechanism; rarely an ascending acute cholangitis in PSC has been suspected to be the cause[50]. Portal vein thrombosis and suppurative pylephlebitis has also been described in rare cases[49].

Cutaneous manifestations

Cutaneous manifestations of IBD are relatively common. The incidence varies from about 10% at the time of IBD diagnosis to more than 20% in the course of the disease[1]. Skin lesions can be classified into three principal classes: granulomatous, reactive, and secondary to nutritional deficiency.

Granulomatous cutaneous lesions have the same histological features of the bowel disease and include: perianal and peristomal ulcers and fistulas, metastatic CD, oral granulomatous ulcers.

Perianal disease is very frequent occurring in about 50% of CD patients during their clinical history, and it varies from perianal erythema to abscesses and perianal complex fistulae[51].

Other fistulae can be internal or entero-cutaneous; rarely develop on the abdominal scar of laparotomy or at the umbilicus. Many efforts have been made to treat fistulizing disease, and the classical surgical approach has been supported recently by a larger use of drugs. Antibiotics, azathioprine/mercaptopurine, tacrolimus, thalidomide showed efficacy in uncontrolled studies[52] but at the moment only infliximab showed effectiveness as induction[53] and maintenance therapy[54] in phase III controlled trials; consequently it has been approved as first line therapy in perianal and enterocutaneous fistulizing CD by the United States Food and Drug Administration (FDA) and the European Agency for the Evaluation of Medicinal Products in Europe. Surgical procedures as colostomy in the more severe cases of perianal fistulas, fistulotomy, abscesses drainage, and non-cutting setons placement seem to be very useful, and the combined medical and surgical approach is probably the best one[55].

Metastatic CD is a rare complication defined as the occurrence of specific granulomatous cutaneous lesions remote from the intestinal disease[56]. It manifests as subcutaneous nodules or ulcers mainly at the lower extremities with rare case of genital (testicular and vulvar) localizations. It seems unrelated to the bowel activity. Corticosteroids, antibiotics, azathioprine, methotrexate[57], and more recently infliximab[58,59] have been used successfully.

The group of reactive skin manifestations of IBD includes aphthous stomatitis, erythema nodosum, pyoderma gangrenosum, and the rare Sweet's syndrome.

Aphthous stomatitis is observed in about 10% of patients: it occurs generally during active intestinal disease, often recurs and shows a good response to intestinal treatment.

The prevalence of erythema nodosum in IBD is 3-8%. It appears more often in women, in the colonic localization, in concomitance with arthritis and active intestinal disease[1]; furthermore, there is a positive response to proctocolectomy[42].

Histological examination shows lympho-histiocytic infiltrate of the lower derma. On the basis of uncontrolled data, corticosteroids are generally an effective therapy; also immunosuppressive therapy is used[56]. Resistant cases have been treated effectively with infliximab[60].

Pyoderma gangrenosum is a very debilitating ulcerating chronic skin disorder occurring in about 1-2% of IBD patients. It occurs often on the extensor surface of the legs, particularly in coincidence with exacerbation of intestinal disease and in association with other extraintestinal manifestations (arthritis and erythema nodosum)[1,61]. Moreover, it is often associated with colonic involvement and in UC patients it seems to benefit lesser than erythema nodosum from colectomy[42].

According to disease severity, the treatment (based on non-controlled evidence) can be local or systemic and includes a high dose of oral or intralesional corticosteroids, immunosuppressive/immunomodulatory therapy (cyclosporine, tacrolimus, mycophenolate mofetil, azathioprine, dapsone)[61]. Infliximab has shown to be very effective in the refractory disease and can be used as first choice therapy[59,62,63]; also etanercept has been reported to be effective in a refractory case of pyoderma gangrenosum[64].

Another rare cutaneous manifestation associated with IBD is the Sweet's syndrome. It is a neutrophilic dermatosis probably related to pyoderma gangrenosum consistent with painful erythematous plaques or nodules often associated with fever and leukocytosis that usually responds to corticosteroids[65].

The more frequent nutritional-deficient cutaneous manifestation is the acrodermatitis enteropathica; it is caused by zinc deficiency and manifests as a psoriasis form erythema[61].

Furthermore, an association between autoimmune cutaneous disease and IBD has been reported. The most frequent disease is psoriasis (7-11% of IBD population *vs* 1-2% of general population) than vitiligo and more rarely are polimyositis, lupus erythematosus and scleroderma[66].

Ocular manifestations of IBD

Ocular manifestations occur in about 10% of IBD patients. They can be immune-related (episcleritis, scleritis, uveitis, corneal disease) or related to drug exposure (cataract, glaucoma).

Episcleritis manifests as acute redness, irritation, burning, tender to palpation; if there is also an impairment of vision, the presence of a scleritis is possible. In this case, a referral to an ophthalmologist is mandatory for risk of vision loss. Uveitis can be anterior and posterior and is often associated with joints and skin manifestations.

Anterior uveitis is the most common and presents painful eye, visual blurring, and photophobia but can be also asymptomatic and sometimes precedes the diagnosis of IBD. Concomitance with IBD activity is typical for episcleritis and uveitis[1,67].

Corneal disease (potential cause of perforation) has also been reported; conjunctivitis is frequent in IBD population but probably does not differ in frequency and etiologic factors from the general population. Anyway it is important that the clinician is aware that serious ocular disease can mimic conjunctivitis in IBD patients[67].

Ocular manifestations can benefit first of all by the treatment of the underlying IBD (particularly for anterior uveitis and episcleritis).

Treatment of ocular disease can prevent complications such as retinal detachment or optic nerve swelling in scleritis and secondary glaucoma and cataracts in uveitis.

Cycloplegics, NSAIDs, topical and systemic steroids are useful. Immunosuppression can be necessary in case of scleritis; sulfasalazine/mesalazine seems to prevent anterior uveitis recurrence[67]. Recently infliximab has shown efficacy in acute uveitis, in episcleritis, and scleritis[68,69]. Other rare reported ocular manifestations of IBD are: retinitis, orbital IBD, retinal arterial and venal occlusion, optic neuritis, retinal vasculitis, marginal corneal disease, lid margin ulcers[70,67].

Metabolic osteopathy

IBD is also associated with an increased risk of osteoporosis and osteopenia. The prevalence rates ranges from 2% to 30% for osteoporosis and from 40% to 50% for osteopenia[71]. The risk of fractures in IBD patients varies widely in different studies[72-74] (from an OR of 1.41 to 2.5) the real impact being completely clear on the IBD population; because of contrasting results, it is also uncertain if the risk is comparable for UC and MC and for men and women.

Osteoporosis occurrence is often underestimated as shown in an observational study conducted in the UK[74] in which women aged 65 years with severe IBD have shown a 10-years probability of hip fracture of 7%; nevertheless only 13% of patients who had already sustained a fracture were in bone-sparing therapy.

Furthermore, a significant number of fractures in IBD patients (as in the general osteoporotic population) are asymptomatic (14.2% in a study of Stockbrugger) and many fractures will be underreported[75].

Bone loss and consequent fractures are certainly multifactorial processes. They are significantly dependent on the age (above 60 years), the use of corticosteroids[74-76] and the grade of systemic inflammation (intestinal disease activity correlates with the risk of fracture)[74].

Recently the role of the inflammatory-induced osteopenia has been revaluated and a surface receptor (RANK) localized on osteoclasts that induces osteoclastogenesis has been identified. Its ligand (RANKL) is induced by proinflammatory cytokines; its decoy receptor that prevents ligation of RANKL to RANK is called osteoprotegerin (OPG), and is produced by osteoblasts and prevents bone loss. Its production is inhibited by corticosteroids and increased by bisphosphonates. So OPG-RANKL-RANK system is certainly a pivot in inflammatory-induced bone loss[77,78]. Initial therapeutical use of recombinant OPG in inflammation-induced osteoporosis seems to be promising[79].

On the basis of these findings, the role of nutritional deficiency could be smaller than previously thought, as also shown in a preliminary recent observational study that found low intake of calcium (<1 000 mg/die) and vitamin D (<200 IU/die) in premenopausal IBD women not to be a predictor of bone loss[80].

Other factors that could favor osteoporosis are the use of corticosteroids, the hypogonadism, and the immobility. Also genetic markers have been proposed as determinants of bone loss in IBD patients. In the future, they could contribute to identify high-risk patients and support clinical behavior[81].

Definition of a correct clinical approach is difficult because therapeutic trials on IBD patients with the specific end-point of fractures prevention are lacking and an extrapolation by the major clinical trials on osteoporosis is difficult, since these studies involve postmenopausal patients, certainly older than IBD patients with osteoporosis.

A small randomized, placebo-controlled trial showed that alendronate significantly ameliorates spine bone density compared with the control group after 1-year-long therapy in IBD patients[82]. Also azathioprine, effective on intestinal activity, seems to have positive effect on bone loss retardation[83].

The expert recommendations on therapy, in the absence of more specific evidence, do not significantly differ from that of the general population. Supplementation of vitamin D for patients above 60 years, therapy with bisphosphonates in case of osteoporosis (identified with densitometry), osteoporotic fractures and chronically steroid treatment, use of minimum dosage of corticosteroids (preferentially non-systemic), correction of early menopause or male hypogonadism by hormone therapy have also been reported[84,85]. Recently apart from OPG use, another osteoanabolic substance, the parathyroid hormone 1-34, is under evaluation for the steroid-induced osteoporosis[86]; in the future they could show effectiveness in IBD osteoporosis. More efforts are yet to be taken in the identification of high-risk patients and in the definition of the most cost-effective clinical behavior in IBD patients.

Thromboembolism and IBD

Patients with IBD have a well-known increased risk (threefold higher than in controls) of thromboembolism (TE), which is an important cause of morbidity and mortality. The incidence ranges from 1.2% to 6.1% according to different studies and in necropsy studies it reaches 39%[87].

Thrombosis accidents occur prevalently as deep vein thrombosis and pulmonary thromboembolism; they happen in earlier age than in non-IBD patients and are more frequent in active or complicated IBD; the type of

IBD and the sex seems not to influence thromboembolic risk[87,88]. Using the logistic regression model, it has been found that IBD is an independent risk factor for thrombosis that is a specific IBD feature. In fact, other inflammatory chronic condition as rheumatoid arthritis or chronic intestinal malabsorptive conditions as celiac disease do not show an increased risk of TE[87].

IBD patients have a frequent exposure to classical thrombosis risk factors: immobility, surgery, steroid therapy, central venous catheter, contraceptives/hormone substitution, smoke; nevertheless, these risk factors do not explain the TE risk increase completely[87].

It is well-known that in IBD patients there is not a completely explained imbalance between coagulation and fibrinolysis in favor of coagulation.

Active intestinal inflammation is not probably the unique risk determinant since about 30-40%[87,89] of thrombosis occurs during quiescence of the IBD and proctocolectomy has not shown a very clear protective effect on recurrent venous thrombosis[90].

Also other factors have been claimed; hyperhomocysteinemia, a well-known risk factor for venous and arterial thrombosis, occurs more often in IBD patients than in the general population and seems to be directly dependent by folate and vitamin B12 deficiency even if there is not a complete concordance in literature[91-93].

The role of the inherited thrombophilia has been recently reviewed[94]. The analysis has shown that the most frequent prothrombotic genetic mutations (factor V Leiden mutation, G20210A mutation in the gene of prothrombin, homozygous in the gene of methylenetetrahydrofolate reductase) are not significantly associated with IBD.

At the same time with the limit of a small number of subjects participating in the studies, it seems that there is no difference in the prevalence of genetic mutations in IBD patients with thrombosis compared with non-IBD subjects with thrombosis. Anyway a recent study comparing IBD patients with thrombosis and IBD controls has revaluated the role of genetic factors finding a significant higher prevalence of factor V Leiden in the thrombosis group (20% *vs* 0%)[95].

The data regarding the prevalence of antiphospholipid antibodies in IBD are conflicting, but seem to suggest an increase frequency in IBD. In limited series, the level of lipoprotein (A) has been found to be higher than in controls[87]. No evidence exists about treating thrombotic events differently than in non-IBD patients[87].

Conclusively many factors are suspected to play a role in the thromboembolic increased risk of IBD patients but further studies are necessary to identify their specific contribution.

At the moment in IBD patients the elimination of removable risk factors is recommendable; in case of thrombosis probably is useful to evaluate the thrombotic risk performing coagulation laboratory parameters and genetic tests.

Anemia
