## Abstract

Animal models have allowed detailed study of hemodynamic alterations typical of portal hypertension and the molecular mechanisms involved in abnormalities in splanchnic and systemic circulation associated with this syndrome. Models of prehepatic portal hypertension can be used to study alterations in the splanchnic circulation and the pathophysiology of the hyperdynamic circulation. Models of cirrhosis allow study of the alterations in intrahepatic microcirculation that lead to increased resistance to portal flow. This review summarizes the currently available literature on animal models of portal hypertension and analyzes their relative utility. The criteria for choosing a particular model, depending on the specific objectives of the study, are also discussed.

**Key words:** Cirrhosis; Nitric oxide; Portal vein

## INTRODUCTION

As for all pathologic conditions, the use of animal models is of enormous importance for the study of pathophysiological disturbances of portal hypertension, since they allow comprehensive study of questions that cannot be addressed in human studies. The historical evolution of the knowledge of portal hypertension clearly illustrates this. The concept that portal hypertension is not only the consequence of an increased resistance to portal blood flow, but also of an increase in portal inflow could not be definitely demonstrated until the development of an adequate methodology to conduct detailed hemodynamic studies in experimental animals[1,2]. Later, the isolation and *ex vivo* study of the two vascular beds implicated in the syndrome, the mesenteric bed and the liver vasculature, allowed the physiological characterization of the vasoactive mediators involved in mesenteric vasodilation and in the increased vascular tone of the cirrhotic liver. The next step was the introduction of introduction of molecular biology tools to molecular biology to identify the alterations in the signaling pathways responsible for the dysregulation of these mediators[3]. This allowed the development and validation of therapeutic targets that have been ultimately tested in patients with cirrhosis and portal hypertension.

This review will cover the most commonly used animal models of portal hypertension and their relative utility for the study of different aspects of this syndrome. In the selection of an animal model for the study of portal hypertension some general concepts, which apply to every animal model, must be considered[4] (Table 1). The final choice will largely depend on the specific alteration of the pathophysiology of portal hypertension to be studied, because not all models express all disturbances characteristic of the portal hypertension syndrome. The first step is species choice. Rat and rabbit are the species used most often. More recently, the methodology for hemodynamic studies in rat and rabbit have been implemented to mice[5-7]. This advance has enormously widened the research possibilities due to the availability of *knock out* and transgenic mice. The use of animals like dogs or pigs[8] offers an advantage for the instrumentation and dissection of vascular structures due to their size, but this practice has been abandoned due to high cost. This review will focus on commonly used models at present.

## MODELS OF PORTAL HYPERTENSION

The portal pressure gradient is the result of the interaction between portal blood flow and the vascular resistance that opposes that flow. This relationship is defined by Ohm's law in the equation:

$$\Delta P = Q \times R$$

where $\Delta P$ is the portal pressure gradient (the difference between portal pressure and inferior vena cava pressure), Q is blood flow within the entire portal venous system (which in portal hypertension includes also the portal-systemic collaterals), and R is the vascular resistance of the entire portal venous system. It follows that portal pressure may increase because of an increase in portal blood flow,

**Table 1 General considerations in choosing animal models (modified from Mullen & McCullough[4])**

| |
|---|
| **Reproducibility:** % of animals reaching the desired state. Consistent time frame to attain desired state. |
| **Specificity:** The model should have the desired abnormality without other complicating problems. |
| **Costs:** Consider not only the direct costs, but also indirect costs such as animal housing (and, therefore, the time to achieve the desired state). An expensive but reliable model could be cheaper than a cheap but inconsistent model. |
| **Safety:** Animal and induction method should not be a risk for the personal. |
| **Size:** Blood volume sample requirements or need for vascular access may determine the size of the animal. The size also determines drug spending. |
| **Ethics:** Different ethics committees can have different opinions about the acceptability of one model. |
| Feasibility: Whether the laboratory has the expertise, manpower facilities, *etc*, to generate or handle the model. |

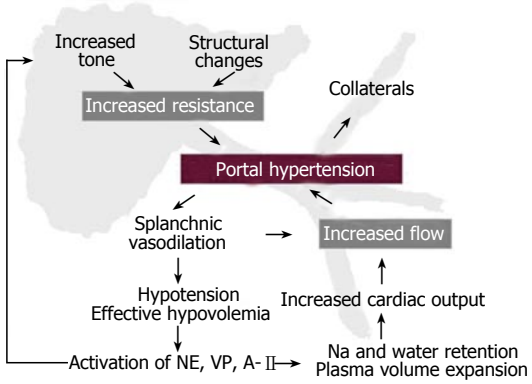

**Figure 1** Summary of the pathophysiology of portal hypertension. The increase in hepatic resistance leads to an increase in portal pressure. This leads to a cascade of disturbances in the splanchnic and systemic circulation characterized by vasodilation, sodium and water retention and plasma volume expansion, that are major players in the pathogenesis of ascites and hepato-renal syndrome. Additionally, these alterations lead to an increase in portal blood inflow that contributes to maintain and aggravates portal hypertension. Another characteristic feature is the development of porto-systemic collaterals that are resposible for complications such as variceal bleeding and hepatic encephalopathy.

an increase in vascular resistance, or by a combination of both[3]. It is well established that the primary factor leading to portal hypertension is an increased resistance to portal blood flow[9-11]. This increased resistance can be prehepatic (portal vein thrombosis), intrahepatic (liver cirrhosis) or posthepatic (Budd-Chiari syndrome). Independently of the cause, portal hypertension is associated with severe disturbances in the systemic and splanchnic circulation, characterized by vasodilation, hypotension, activation of vasoactive systems, plasma volume expansion and increased cardiac output[12]. This is known as the hyperdynamic circulatory syndrome, and it leads to an increase in portal blood inflow that contributes to maintain or worsen portal hypertension despite the development of portal-systemic collaterals (Figure 1). This means that for the study of hyperdynamic circulation both models of pre-hepatic and intra-hepatic portal hypertension are useful. For the study of the intrahepatic circulation specific models of disease are needed.

### *Models of pre-hepatic portal hypertension*

**Partial portal vein ligation:** Partial portal vein ligation model (PVL) has been widely used in the study of the pathophysiology of portal hypertension. This model has been developed in rats[1,13,14], mice[6,7] and rabbits[15]. The portal vein is freed from surrounding tissue after a midline abdominal incision. A ligature (silk 3-0) is placed around a blunt-tipped needle lying along the portal vein. Subsequent removal of the needle yields a calibrated stenosis of the portal vein that has the diameter of the needle. In the conventional rat PVL model a 20G needle is used (0.889 mm diameter)[1,13,14]. By using needles of greater caliber, less severe stenosis and thus less severe degrees of portal hypertension are induced[16,17]. The diameters of the needles and resulting levels of stenosis are as follows: 16G: 1.651mm, 18G: 1.270 mm, 20G: 0.889 mm. The conventional needles for mice and rabbits are 27G[6,7] and 18G[15], respectively. Surgery must be conducted in aseptic conditions. Numerous websites provide information on surgical techniques and pre- and post-operative care of the animals, including information on anesthesia, analgesia and antibiotic prophylaxis (http://info.med.yale.edu/yarc/vcs/). For portal vein ligation no antibiotic prophylaxis is needed.

PVL model has been extensively used because the procedures are easy to perform, inexpensive, reproducible and portal hypertension develops very fast. One week after portal vein ligation rats develop the complete portal hypertensive syndrome, with hyperdynamic circulation and portal-systemic shunting. Portal-systemic shunting is already detectable at two days. The percentage of portal-systemic shunting; i.e. the amount of portal blood inflow diverted to collaterals, approaches 100% after the 7$^{th}$ day[10]. Mesenteric vasodilation and increased cardiac output are detectable at 4 d[10,13]. The main drawback of the model is that portal hypertension developes acutely. Thus, contrary to the majority of situations found in clinical practice, the degree of portal hypertension is maximal at 24 h, and decreases afterwards due to the development of portal-systemic collaterals[10].

### *Models of intrahepatic portal hypertension*

Intrahepatic portal hypertension can be classified as presinusoidal, sinusoidal and postsinusoidal. Models of cirrhosis, the most common cause of portal hypertension in western countries, have a double component, which are the pre- and post-sinusoidal components, but for practical purposes they will be discussed with the models of sinusoidal portal hypertension.

**Presinusoidal intrahepatic portal hypertension:** (1)Schistosomiasis Experimental infection with Schistosoma mansoni has been characterized in mice and hamsters. This model is achieved by injecting cercariae of the parasite in the abdominal wall. Portal hypertension develops 5 to 7 wk after inoculation[18,19]. An important feature of this model is that portal hypertension develops progressively. In the hamster Schistosoma infection does not induce the development of portal-systemic shunting despite the presence of portal hypertension[20]. On the contrary, mice infected with Schistosoma mansoni develop portal

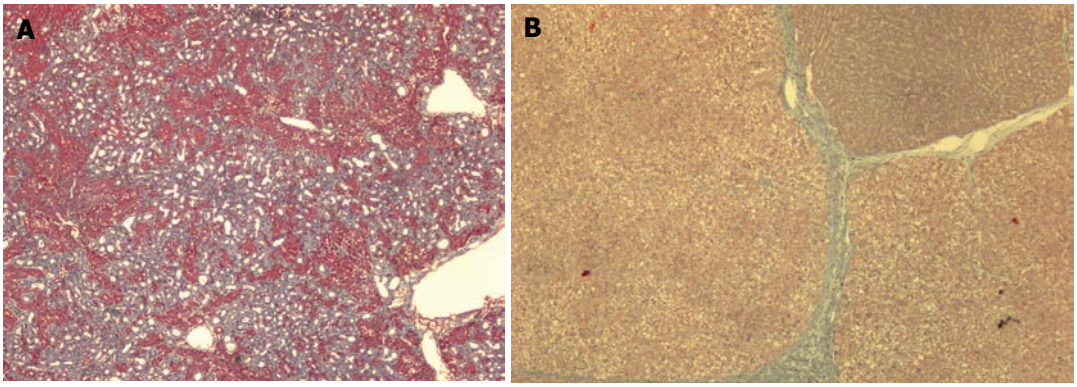

**Figure 2** A comparison of microscopic aspect of a liver 6 wk after CBDL (**A**) and 12 wk after TAA (**B**) administration.

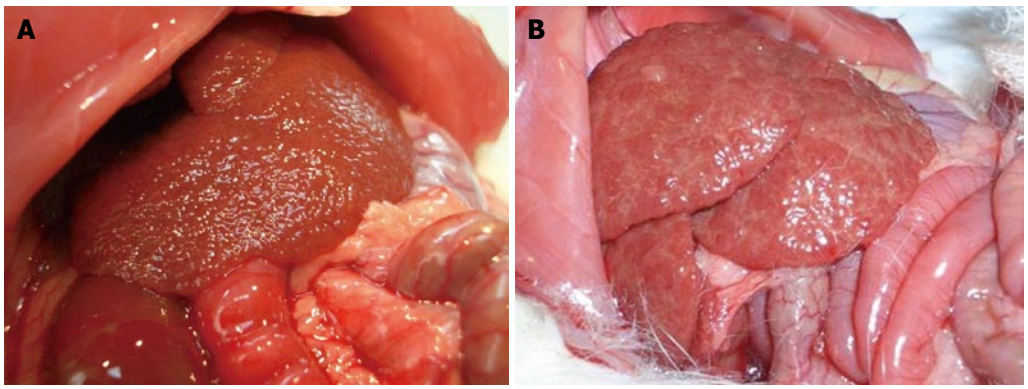

**Figure 3** Macroscopical images of livers from $CCl_4$ (**A**) and TAA (**B**) models.

hypertension with portal-systemic shunting. Shunting is detectable from wk 9 and reaches 15% at wk 11[18,19]. Currently this model is seldom used, and no studies have been published in the last decade.

**Sinusoidal portal hypertension:** A number of models of cirrhosis have been described. We will limit our discussion to those that have been used for the study of portal hypertension.

(1) Common bile duct ligation (CBDL) CBDL is a model of secondary biliary cirrhosis. It has been mainly developed in rats[21], which are especially appropriate due to the lack of a gallbladder, but it has also been developed in rabbits[22] and mice[23]. Mice, however, develop a marked dilation of the gallbladder after bile duct ligation, which may lead to perforation and choleperitoneum. The intervention consists of the isolation of the common bile duct followed by a double ligature. The first ligature is made below the junction of the hepatic ducts. The second is made above the entrance of the pancreatic ducts. The portion of the bile duct between the two ligatures is resected to avoid repermeabilization. Mortality is high after the 5$^{th}$ wk (20%). The use of prophylactic antibiotics (Ampicilin 100 mg/Kg s.c. or similars) before surgery and weekly administration of vit K (50 mcg s.c.)[24] notably improve the survival of CBDL rats. One of the drawbacks of this model is the potential formation of a biliary cyst, which may compress the portal vein at the hilum. This problem can be solved by gently injecting 10% formalin (120 μL/100 g) through a P10 catheter in the bile duct before ligation[14,25]. Other authors have prevented cyst formation by injecting Ethibloc®[26], a substance developed for vessel embolization, or by ligating the biliary duct of each lobule[27,28].

This model develops biliary fibrosis-cirrhosis in 4-6 wk. Histology shows marked cholangiolar proliferation and expansive portal fibrosis (Figure 2A), but the architectural disturbances typical of cirrhosis are seldom found[29]. At 2 wk rats develop mild portal hypertension[30] and at 4 wk severe portal hypertension, hyperdynamic circulation and portal-systemic shunting of 30%-60%[21,31,32]. Approximately, 60% of the rats develop ascites. Portal hypertension in this model has a presinusoidal component[30]. A major drawback of this model is that it is not adequate for pharmacological studies with drugs that are eliminated through the biliary route.

(2) Carbon tetrachloride induced cirrhosis ($CCl_4$) Acute administration of carbon tetrachloride induces acute hepatitis of primary perivenular localization. Continuous administration induces chronic liver injury that leads to cirrhosis. This methodology to induce cirrhosis has been used in rats[33,34], mice[35] and rabbits[22]. Route of administration varies among laboratories, but the most effective are oral[36,37], intraperitoneal[38,39] or inhalatory[34,40,41]. Subcutaneous route is not recommended due to its low yield of cirrhosis. The use of different administration schedules, even using the same route of administration, could explain the variability in the yield and time to cirrhosis in different laboratories. In our unit, Phenobarbital (0.3 g/L) is added to drinking water to increase the yield of cirrhosis, starting one week before first $CCl_4$ administration. Hemodynamic studies are performed 5-7 d after stopping $CCl_4$ and Phenobarbital.

Twelve to 15 wk after $CCl_4$ administration the rats develop micronodular cirrhosis (Figure 3A), portal

hypertension, portal-systemic shunting (30%-60%) and hyperdynamic circulation[2]. If maintained for 12 to 20 wk, most rats develop ascites. A major complexity of this model is the different sensitivity of the rats to $CCl_4$, which makes it difficult to obtain a homogeneous group of cirrhotic rats. Proctor *et al*[36] proposed a solution that consists of the individualization of the dose according to weight gain/loss of the animal in response to the previous dose.

(3) Cirrhosis induced by thioacetamide (TAA) This is another widely used model of toxic cirrhosis. The toxin affects both perivenular and periportal areas. It has been used in rats[42] and mice[43]. TAA can be administered in drinking water[42] or by i.p. injection[44,45]. I.p. injection offers much more consistent results[45].

This model develops macronodular cirrhosis with portal hypertension in 12 wk (Figures 2B and 3B)[42,45,46]. Longer periods of induction might be required for the instauration of overt hyperdynamic circulation[46]. Approximately 40% develop ascites[42]. One particular feature of this model is that, contrary to what occurs with the $CCl_4$ model, fibrosis remains stable for weeks after TAA withdrawal[45]. After 18 wk of TAA administration the rats might develop cholangiocarcinoma[47].

(4) Dimethylnitrosamine induced cirrhosis (DMNA) DMNA is another hepatotoxin that induces hepatocellular necrosis. After continuous administration (generally i.p.) the rats develop fibrosis with portal hypertension, already present at 5 wk, but at this time the animals do not have cirrhosis nor features of hyperdynamic circulation[48]. Overt cirrhosis with ascites develops in 13 wk[49,50]. This model has been seldom used for the study of the pathophysiology of portal hypertension, probably due to restrictions in the use of DMNA due to its high carcinogenetic potential.

(5) Diet induced cirrhosis A diet deficient in choline and methionin, or a diet with low protein and choline and enriched with fat, induces liver steatosis associated with marked oxidative stress that induces inflammation and fibrosis[49,51]. Cirrhosis is developed after 12-24 wk. These models have not been well-characterized from the hemodynamic point of view and have not been used for the study of portal hypertension.

**Postsinusoidal portal hypertension:** Recently, a model that reproduces the pathological and clinical characteristics of veno-occlusive disease has been developed[52]. This is achieved by the administration of monocrotalin by oral gavage. Rats develop hyperbilirrubinemia, hepatomegaly and ascites at 4-5 d. This model is useful for the study of the pathophysiology of veno-occlusive disease, but has not been characterized from the hemodynamic point of view.

### *Posthepatic portal hypertension*

The aim of these models is to reproduce the features of the Budd-Chiari syndrome; i.e. liver injury derived from hepatic venous outflow obstruction. This has been achieved by placing an ameroid, which is a stainless steel device that allows slow expansion inside upon contact with the wet tissue, in the hepatic veins inducing a progressive occlusion of hepatic venous outflow. This model has been developed in dogs[53]. However, in the rat it is almost impossible to dissect the hepatic veins, so hepatic venous outflow occlusion has been induced by occluding the inferior vena cava cranially to the hepatic veins[54]. This is not a pure model of Budd-Chiari. These models have been very seldom used, and therefore it is uncertain whether they have any utility in the study of the hemodynamics of Budd-Chiari syndrome.

**Table 2 Utility of the most commonly used animal models of portal hipertensión**

| Type of study | PVL | CBDL | $CCl_4$ | TAA |
|---|---|---|---|---|
| Abnormalities of the intrahepatic microcirculation in cirrhosis | - | ** | *** | *** |
| Pathophysiology of the hyperdynamic circulation | *** | *** | *** | *** |
| Temporary sequence of alterations leading to the hyperdynamic circulation | *** | ** | * | * |
| Pathophysiology of ascites | ** | ** | *** | *** |
| Mesenteric circulation | *** | ** | *** | ? No experience |

| Hepato-pulmonary syndrome | - | *** | - | - |
| Portal hypertension-related bleeding models | *** | *** | ? No experience | ? No experience |

Utility of the most commonly used animal models of portal hypertension for the study of the different manifestations of the syndrome. $CCl_4$ model has been the most widely used model for the study of the intrahepatic circulation. In the study of the splanchnic and systemic circulation the PVL model is particulary useful for hypothesis generation, that might be later confirmed in the cirrhosis models. Only the CBDL model develops features of hepatopulmonary syndrome (-: Not useful; *: Low utility; **: Moderately useful; ***: Very useful).

## SELECTION OF A MODEL FOR THE STUDY OF THE PATHOPHYSIOLOGY OF PORTAL HYPERTENSION AND ITS COMPLICATIONS (TABLE 2)

### *Abnormalities in the intrahepatic circulation in cirrhosis*

The most frequent cause of portal hypertension in western countries is liver cirrhosis. The primary factor leading to portal hypertension is an increased resistance to portal blood flow. This is not only the result of the disruption of the liver architecture, but is also due to an increased hepatic vascular tone. This concept has been demonstrated in isolated liver perfusion[55], which allows evaluation of the hepatic vascular tone and its response to vasoconstrictors and vasodilators. This is problematic in *in vivo* studies because it is very difficult to discern the effects of a particular vasoactive substance that depend on changes in systemic, splanchnic and collateral circulation

from those derived from changes on hepatic resistance. Another way of evaluating intrahepatic microcirculation is by intravital microscopy[56].

The model most frequently used for isolated perfusion has been $CCl_4$ induced cirrhosis. In these livers, it has been demonstrated that there is an increased hepatic vascular tone, hyperresponse to vasoconstrictors and hyporresponse to vasodilators. The main mechanism mediating these abnormal vascular responses is endothelial dysfunction with insufficient NO production and an increased production of vasoconstrictive eicosanoids[57,58]. Vascular responses have also been studied in other models of cirrhosis, such as CBDL[59,60] and TAA[46,61], but data are still scarce and less consistent than that obtained with the $CCl_4$ model. Moreover, it must be stressed that the CBDL model has an important presinusoidal component in the increase in hepatic resistance[30].

### Abnormalities in the systemic, mesenteric and collateral circulation in portal hypertension

These studies include *in vivo* hemodynamic studies and *ex vivo* perfusion of the mesenteric vascular bed and the portal-systemic collaterals.

The *in vivo* studies are very useful for the study of the pathophysiology of the hyperdynamic circulation associated with portal hypertension. The hyperdynamic circulation has been described in the PVL model[1,13] and in the models of cirrhosis induced by $CCl_4$[2], CBDL[21] and TAA[46,62]. The *in vivo* studies, on the other hand, globally evaluate the effects of a drug on portal pressure, which is the result of the integrated effects of the drug on portal blood inflow, collateral resistance and hepatic resistance.

Any model of portal hypertension is valid, in theory, for the study of mesenteric circulation. This has been evaluated by the isolated perfusion of the mesenteric vascular bed (McGregor's preparation[63]), by the study of vascular responses in isolated mesenteric vessels[64] or by the perfusion of intestinal microvasculature[65]. The characteristic hyporesponse to vasoconstrictors of the mesenteric circulation has only been demonstrated so far in the PVL and the $CCl_4$ models[40,64-66].

Collateral circulation has been studied with different methodologies. The most common has been the evaluation of portal-systemic shunting by the injection of radioactive, colored or fluorescent microspheres[67,68]. If different isotopes or colored or fluorescent markers are used, changes in portal-systemic shunting after different interventions can be evaluated in the same animal[9]. Another way of studying the collateral circulation is the measurement, with transit-time flow probes, of the blood flow of the spontaneous splenorenal shunt, a major collateral developed after portal hypertension[48]. Mosca et al developed a system for *ex vivo* perfusion of collaterals[69], in which the vascular responses of the collateral vascular bed to different vasoactive substances can be tested. The interpretation of the results obtained with this methodology might differ among models, because in the PVL model shunting is about 100%, while in the cirrhosis models shunting does not go beyond 60%.

The availability of the PVL model has shown great advantage for the study of the abnormalities of systemic, mesenteric and collateral circulation, because it is a very rapid model and much less expensive than models of cirrhosis. In the last 20 years, most investigators have chosen to generate and test hypothesis first in the PVL model, and subsequently confirm those hypothesis in the more laborious and expensive models of cirrhosis.

### Ascites and renal dysfunction

The vast majority of studies in this field have been performed using the $CCl_4$ cirrhosis model[70-72]. $CCl_4$ administration is maintained until the animal develops ascites at physical examination, which occurs between 12-20 wk. The PVL model, akin to what happens in patients with prehepatic portal hypertension, does not develop ascites. Even though, since this model is ideal for sequential studies, it has been instrumental in the description of hyperdynamic circulation[13] and in the validation of the peripheral arterial vasodilation hypothesis as the trigger for sodium and water retention in cirrhosis[13,73-75]. CBDL and $CCl_4$ models have been also used for longitudinal studies aimed at demonstrating the sequence vasodilation-sodium retention-ascites[76-78], but the temporal evolution of these models (especially for $CCl_4$) is less consistent.

### Portal hypertensive gastropathy

Several studies have demonstrated that PVL and cirrhotic rats show abnormalities of the gastric microvasculature comparable to those observed in portal hypertensive gastropathy in humans. Studies in these models have been useful to test therapeutic interventions that subsequently showed some efficacy in patients bleeding from portal hypertensive gastropathy[79,80].

### Hepatopulmonary syndrome

CBDL rats develop alterations analogous to those of hepatopulmonary syndrome seen in humans, such as intrapulmonary vascular dilatations and an increased alveolar to arterial oxygen gradient[81]. These alterations are obvious from the 2nd wk after bile duct ligation[44]. Other models of portal hypertension, such as the PVL and the TAA, do not develop hepatopulmonary syndrome[44,81].

### Models of portal hypertension-related bleeding

Our laboratory has recently described a portal hypertension-related bleeding model that has been useful in evaluating therapeutic interventions in acute variceal bleeding, such as for determining the best policy for volume replacement and the effects of vasoactive drugs on the outcome of bleeding[14,25,82]. This model consists of the isolation and section of a branch of the ileocolic vein (Figure 4). The severity of hemorrhage depends on the degree of portal hypertension and the size of the sectioned branch[14]. This model has been characterized in PVL and CBDL rats[14,25,82]. A section of the first order branch of the ileocolic vein results in 50% mortality in CBDL rats, whereas mortality is 0% in PVL rats. Subsequently, a modification of the model was developed, in which 2 successive sections of a first order branch of ileocolic

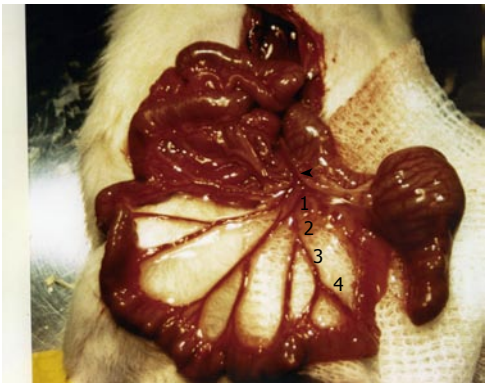

**Figure 4** Model of portal hypertension-related bleeding. In these model a section of a first (1), second (2), third (3) or fourth order branch of the ileocolic vein is isolated and sectioned[14,25,82].

vein are performed in PVL rats. In this way the second bleeding is induced when the rat is already hypovolemic. This modification increases mortality to 50%, and allows testing of the vasoactive drugs in hypovolemic conditions, a situation that better reproduces the clinical context in which these drugs are applied[82].

## Abstract

Celiac disease (CD) is a common autoimmune disorder, induced by the intake of gluten proteins present in wheat, barley and rye. Contrary to common belief, this disorder is a protean systemic disease, rather than merely a pure digestive alteration. CD is closely associated with genes that code HLA-II antigens, mainly of DQ2 and DQ8 classes. Previously, it was considered to be a rare childhood disorder, but is actually considered a frequent condition, present at any age, which may have multiple complications. Tissue transglutaminase-2 (tTG), appears to be an important component of this disease, both, in its pathogenesis and diagnosis. Active CD is characterized by intestinal and/or extra-intestinal symptoms, villous atrophy and crypt hyperplasia, and strongly positive tTG auto-antibodies. The duodenal biopsy is considered to be the "gold standard" for diagnosis, but its practice has significant limitations in its interpretation, especially in adults. Occasionally, it results in a false-negative because of patchy mucosal changes and the presence of mucosal villous atrophy is often more severe in the proximal jejunum, usually not reached by endoscopic biopsies. CD is associated with increased rates of several diseases, such as iron deficiency anemia, osteoporosis, dermatitis herpetiformis, several neurologic and endocrine diseases, persistent chronic hypertransami-nasemia of unknown origin, various types of cancer and other autoimmune disorders. Treatment of CD dictates a strict, life-long gluten-free diet, which results in remission for most individuals, although its effect on some associated extraintestinal manifestations remains to be established.

## INTRODUCTION

Celiac disease (CD) is an immune-mediated disorder, the only one with a well-established origin, resulting from a permanent gluten intolerance, which primarily involves the gastrointestinal tract.

It is characterized by the presence of chronic inflammation of the small bowel's mucosa and submucosa, and is clinically characterized by the presence of diverse systemic manifestations.

It may start at any age, both during childhood and adolescence, and is also relatively common in adulthood. It is being increasingly diagnosed even in elderly patients (up to 20% of patients are older than 60 years, at the time of diagnosis)[1-3].

The causal agent, gluten, is well established; a mixture of proteins present exclusively in cereals –mainly wheat, barley, rye and oats- but not corn. It affects only predisposed individuals, whose most susceptible genetic features are related to human leukocytes antigens from class two (HLA-Ⅱ), predominantly HLA-DQ2 (90%), while much less frequency HLA-DQ8 (5%-10%). However, these genetic markers are a necessary, but not a sufficient condition, since a significant frequency of CD patients (5%-10%) are DQ2 and DQ8-negative. This means that other, still not well-established, genotypes may exist that probably correspond to the class one HLA system (HLA-Ⅰ), including MICA, MICB and others[4].

A strong genetic susceptibility is present with about 75% concordance rate, among monozygotic twins. Certain populations have an increased prevalence of CD. For instance, the first-degree relatives of individuals with biopsy-proven CD, have a prevalence between 4%-12% of those suffering from this disease. Second-degree relatives also appear to have an increased prevalence. Patients with type 1 diabetes mellitus (IDDM) have a prevalence of CD ranging to 3%-8%. In Down´s syndrome, the presence of CD is found between 5%-12%. Also, CD is associated with Turner's and William's syndromes, IgA deficiency and several autoimmune disorders[5-7]. Most affected individuals show sustained clinical remission when they are put strictly on a gluten-free diet (GFD), which must be maintained indefinitely due to this illness' genetic background.

## EPIDEMIOLOGY

Until the last decade, CD was considered to be a rare disease, but today it is known to be universally distributed, to involve all races, and it is one of the most commonly known genetic diseases, with a mean prevalence of 1%-2% in the general population, being clearly underestimated and

underdiagnosed worldwide.

This would represent an estimated 3 million people affected in Europe and at least another 3 million in the United States. Selected ethnic groups may have a lower prevalence than that suggested for the Caucasian race, but not far from them, as the worldwide distribution of CD is pretty homogeneous, the only exception being the Saharawui population, which lives in refugee camps. This population in North Africa has a mean estimate of 5%, the highest found all over the world[8-10].

In Southern Asia there are still no data available of CD prevalence in the general population. This fact may be due to partly, because in past decades the reports of gluten intolerance were only of sporadic cases. Nowadays, several recent studies suggest that CD is also common in South Asia. For instance, 26%-49% of Indian children presenting with chronic diarrhea, are diagnosed with CD in tertiary care hospitals[11,12].

If we assume that China has approximately 1 billion inhabitants, we can extrapolate the same world proportion of CD (around 1% of the general population), then the approximate number of possible celiac patients in this country would be around ten million people. There are few reports of CD in Far East countries, yet recently, three adult cases have been reported in Canada among descendents of Japanese and Chinese immigrants[13].

These findings suggest that genetic susceptibility for CD also exists among people of the Far East, where the real incidence of the disease is clearly underestimated because their dietary habits are different (more rice than wheat, in the staple diet), and possibly for the interest of doctors to recognize CD. These concerns pose important issues, which require further studies of CD in the different countries of this important and extensive area of the world.

CD is also very prevalent in people from the Middle East and these data are not surprising as they inhabit countries included in the "Fertile Crescent" such as Anatolia (South of Turkey), Lebanon, Syria, Palestine and Iraq, where some 10000 years ago, some tribes changed from a nomadic lifestyle, to one of stable settlement, started the agriculture and probably propagated the spread of this disease throughout the world[14].

Thus, gluten intolerance appears to be a widespread public health problem and an increased level of awareness and clinical suspicion are needed to diagnose CD all over the world. Moreover, the GFD possess a big problem in developing countries, since commercial gluten-free products are not available, while in others they are very expensive and are difficult to acquire.

## CLINICAL PRESENTATIONS

The clinical presentation of CD varies greatly, ranging from asymptomatic to severely malnourished patients. The most common clinical manifestations of CD include abdominal cramping pain with moderate to severe abdominal distension, frequently associated with relapsing or permanent dyspepsia, presence of gastro-esophageal reflux (GERD) and recurrent episodes of altered bowel habits (diarrhea and/or constipation), weight loss, bone disease, anemia and weakness.

While diarrhea was almost considered a persistent symptom, this is not the case in adults, and up to 50% of patients predominantly have constipation, which on many occasions becomes refractory to all types of therapy. It should be noted, that up to 30% of celiac patients have increased body mass index (BMI) and obvious obesity at diagnosis.

CD is sometimes divided into clinical subtypes. The terms "symptomatic or classic" apply to cases that meet the typical features described above. By contrast, in the "atypical forms" of the disease, the gastrointestinal symptoms may be absent or less pronounced, and in this case the extra-intestinal features predominate, such as chronic iron deficiency anemia, osteoporosis, short stature or failure to thrive, infertility and increased number of abortions.

Since atypical presentations are found more frequently in later decades, CD is now considered to be a multisystemic disorder, rather than a sole gastrointestinal process (Table 1).

## PATHOGENESIS

The triggers for CD are specific immunogenic peptides that are present only and exclusively in the dietary gluten proteins, from wheat and similar structural cereals such as rye and barley. These peptides are resistant to digestion by gastric and pancreatic enzymes and find their way into the lamina propria of the small bowel, presumably after some changes occur in the intercellular tight junctions with an increase in the intestinal permeability. One such peptide is a 33-amino acid sequence, which is a potent activator of specific T-cell lines from patients with CD[15].

The subsequent infiltration by CD4 (+) T lymphocytes into the lamina propria and CD8 (+) into the intestinal epithelium, are a hallmark of active CD. The recognition of HLA-bound gluten peptides by T cells, leads to their activation and clonal expansion of B cells that produce antibodies. Other cytokines released by activated CD4 T cells that involve the adaptive immune response, promote various inflammatory mechanisms and produce the intestinal lesion.

Less information is available on the activation and mode of action of intraepithelial T cells, which are mediated by the innate immune system. The expression of the interleukin-15 cytokine appears to play a central role in driving various processes that lead to the increased number of intraepithelial lymphocytes (IELs) as well as in the destruction process of the epithelial cells and the mucosal damage[16].

Tissue transglutaminase 2 (tTG), plays an important role in the immune response and is present in several tissues in the body. The cross-linking activity of tTG is involved in several functions, such as wound healing, formation of cell envelopes in apoptosis and stabilization of the extra-cellular matrix. In addition, this enzyme can deaminate glutamine residues. Glutamine-rich gluten peptides are, therefore, excellent substrates for tTG. The resulting deaminated and thus, negatively-charged peptides, have much higher affinity for the HLA-DQ2 and DQ8

**Table 1 Risk groups and associated disorders**

  - Chronic asthenia

molecules, and have a key step in the immune response in CD[17].

In summary, we must say that CD is a complex disorder that results from an interplay of several genetic, immunological and environmental factors, with many aspects for which the final pathogenetic mechanisms remains to be solved.

## SEROLOGICAL TESTS

Among the serological tests needed to diagnose CD, the measurement of anti-gliadin IgA antibodies (AGA), has completely fallen into disuse and probably justifiably abandoned, as its sensitivity and specificity is very low (around 50%). In 1997, tTG was established by Dieterich *et al* to be the auto-antigen for anti-endomysial antibodies[18] and since then, is preferred for clinical use, because it show good sensitivity, greater than 90%, and a high specificity, around 95%, although it displays small variations between the different commercial kits employed[19].

The presence of these antibodies correlates with the degree of villous atrophy and various studies have clearly shown that the sensitivity of testing tTG is decreased in patients with normal duodenal biopsies or with mild histological changes[20].

Measurement of tTG antibodies of the IgA isotype is usually determined in the clinical practice. Nevertheless, IgA deficiency occurs in 1.7%-2.6% of CD patients, which represents 10-15 times increase, over that in the general population. If IgA deficiency is found, measuring the IgG class tTG is recommended[21]. Diagnosis of CD based solely on serologic markers is not accepted and the identification of the characteristics changes at the duodenal mucosa is required before starting on a GFD.

In conclusion, in clinical practice, serologic tests for CD are frequently used to identify both symptomatic and asymptomatic at-risk individuals who require an intestinal biopsy examination to confirm the diagnosis.

## HISTOLOGICAL FINDINGS

The findings on a duodenal biopsy must be interpreted in detail by a pathologist experienced and interested in this condition and according to Marsh's criteria (modified), which stratify this disease into four types or stages. Biopsy samples are usually collected during an upper GI endoscopy in the second portion of the duodenum close to the Vater ampulla; at least 4-6 well-oriented samples should be submitted, as the CD lesions are often irregular and patchily distributed[22].

CD may be diagnosed with a normal duodenal biopsy (Stage 0), with an increased percentage of intraepithelial lymphocytes (IELs) above 30% (Stage 1), the presence of crypt hyperplasia and inflammatory infiltrates in the lamina propria (Stage 2), and all of them with well-preserved villi. It is not until Stage 3, that villous atrophy develops, which is divided into three different categories: Mild (A), Moderate (B), and Total or Subtotal (C). Finally, Stage 4, or total hypoplasia of the mucosa, is now rarely seen.

Routine use of Marsh's classification in the study of duodenal biopsies, is of great help, when recognizing occult, doubtful cases, and must always be used when performing a diagnostic upper endoscopy in patients belonging to so-called "at risk groups" regarding CD, including those with chronic diarrhea, refractory ferropenic anemia, or both[23].

Duodenal biopsy is still considered by most authors the "gold standard" in the diagnostic process, albeit its usefulness in the adult is still slightly controversial. If results of the histological study are negative but serologic tests are positive and CD is strongly suspected, the results of the biopsy should be reviewed with an expert gastrointestinal pathologist before additional biopsies are considered. In addition, if the histological exam yields equivocal results, it is useful to proceed with HLA typing. Although almost 40% of the general population has the HLA-DQ2 or HLA-DQ8 markers, nearly 90%-95% of CD patients have them[24].

## CLINICAL DIAGNOSIS

The main diagnostic criteria still rest on duodenal biopsy findings while the patient is following a normal diet and whether significant clinical and analytical improvement is seen while the patient is on a strict GFD. Patients usually undergo hematological and biochemical tests along with the determination of serological CD markers (usually

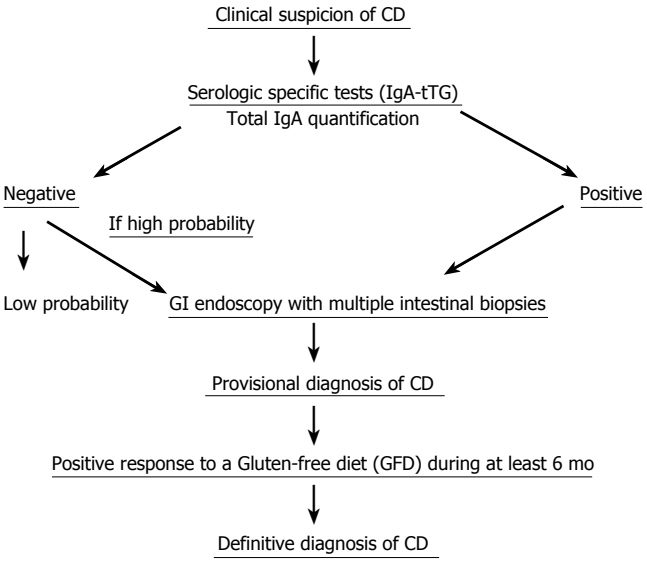

**Figure 1** Algorithm for evaluation of patients suspected of CD.

tTG-IgA class) by ELISA, when this disease is suspected. If serology results are negative, but clinical suspicion is high, intestinal biopsy should be performed. These biopsies must be oriented correctly in order to determine the degree of villous atrophy and to assess the presence and quantify the number of IELs, epithelial disarray, crypts hyperplasia and the degree of chronic inflammation present at the lamina propria.

A clear clinical improvement while the patient is following the GFD yields a definitive diagnosis. The serum antibodies generally disappear by 6 to 12 mo, although they are not necessarily a reliable indication of the mucosal response[25].

When patients do not present with the classic clinical symptoms of CD, a second biopsy that shows histologic improvement will confirm the diagnosis. An algorithm for a possible diagnosis of celiac disease, consisting of several consecutive steps, is shown (Figure 1).

For diagnostic confirmation in uncertain cases, several potential strategies may be agreed upon according to patient and family preferences. Amongst them, we shall quote the following: (a) repeat serology and laboratory tests periodically (b) perform a full family exploration, searching the presence of new potential cases (c) perform a new endoscopy with biopsy samples (less accepted) (d) try a GFD for 6 mo, monitoring the clinical response as well as the serologic and analytical changes. Gluten challenge is not considered necessary for diagnosis, except in patients for whom no initial diagnostic biopsy was done, or results of biopsy are unclear or uncharacteristic of CD. Patients should be informed that they may have a severe reaction with the gluten challenge.

## TREATMENT

The mainstay of treatment is a strict lifelong adherence to a GFD, in which the patient must avoid permanently all kinds of food products containing some wheat, rye, barley and oat. Commonly substituted grains, including rice and corn taken directly, or in the form of flour derived from them.

GFD is a very healthy and complete diet, very well balanced in all the immediate principles and rich enough in all kind of vitamins and minerals; it is the only type of treatment required for these patients. Compliance is a difficult task, at any age, because the wheat flour is present in a great part of foods or as an additive product. Patients whose disease does not respond to dietary treatment should undergo a systematic review[26,27].

The only gluten-free cereal is corn and is, therefore, allowed in the celiac patient's diet whether raw or roasted, in salads, *etc*. Corn flour, if pure in its composition (100%) regarding preparation, processing and manufacture, may be used for bread, cookies, baby food and sweets, which may render a celiac patient's diet more bearable.

Dairy products must be avoided when starting on a GFD, as secondary lactase deficiency is often associated with celiac disease. After 1-2 mo on a GFD, milk derivatives may be gradually reintroduced as long as the patient has no complaints following ingestion, since lactose intolerance is secondary to gluten, and usually regresses within three months with strict GFD adherence. On the other hand, dietary calcium and proteins are essential to correct existing mineral deficiencies, given the high prevalence of osteoporosis seen in celiac patients[28].

Beer must be completely avoided, even from alcohol-free brands, as its manufacture involves the fermentation of various gluten-containing cereals, including barley and rye. The same can be said of all kinds of whisky, obtained from malt distillation procedures. Approximately 70% of patients experience symptoms improvement after 2 wk on a GFD.

The rapidity and extent of histological regression are unpredictable, but there is invariably a delay against clinical improvement, which may not be apparent in repeated biopsies until after three to six months. While histological findings usually regress in children, one half of adults only achieve a partial histological resolution.

When there is severe iron-deficiency anemia, the administration of iron preparations through the intravenous or intramuscular route is recommended for a few months (2 or 3), in order to shorten the recovery time. The two most important questions to answer are if the patient truly has CD and whether he/she is following a strict GFD. The evaluation requires a review of the original biopsies and a complete assessment by an expert dietician. Several associated conditions must be ruled out including the concomitant presence of pancreatic insufficiency, bacterial overgrowth, lymphocytic colitis and true refractory sprue with a clonal T-cell population[29,30].

## DERMATITIS HERPETIFORMIS

Gluten sensitivity is relatively associated with several skin alterations but the most common presentation is in a form of chronic pruritic disease characterized by the presence of several symmetrical papulo-vesicular rash that evolves to crusting lesions broadly distributed over the body, but especially on the forearms, knees, buttocks, wrists and

scalp. It is well known as dermatitis herpetiformis (DH) and the skin biopsy shows the characteristic lineal, granular deposits of IgA in the dermal papillae. This condition affects about 15%-25% of patients with CD and its presence is known as the "card presentation" of some CD patients[31].

A GFD is the treatment of choice, although at the start of the diet, drug therapy may be added, usually dapsone, to effectively and quickly resolve the itching and the rash. This drug suppresses the inflammation of the skin but obviously has no any influence on the intestinal abnormalities. The resolution of the cutaneous lesions may be slow, and some patients must wait 1-2 years after starting on a GFD, for the complete disappearance of DH. The intestinal biopsies show identical changes to CD, but predominate with mild lesions and a patchy distribution. tTG positivity is also similar, although at lower levels, possible reflecting a milder enteropathy. One study has shown the presence of antibodies exclusively against tTG-3 (also known as epidermal transglutaminase), a cytosolic enzyme involved in cell envelope formation during keratinocyte differentiation[32]. Although these findings remain to be confirmed, these may offer some clues to understanding the difference in clinical presentation between CD patients with, or without, associated skin lesions.

## ENDOCRINE DISORDERS

CD patients can exhibit some immune-mediated endocrine disorders alongside their clinical evolution, the most common being type 1 diabetes mellitus (T1DM) and thyroid disease. Each of these conditions affects 5%-10% of CD patients throughout their lives[33].

The prevalence of CD in the T1DM patients is substantially higher than expected in the general population. Approximately one half of subjects do not have gastrointestinal (GI) symptoms and the rest have only mild digestive disturbances. Indeed, many diabetic patients undergo endoscopy to investigate the frequent GI symptoms that afflict those with T1DM. It would require little extra effort or cost, to obtain duodenal biopsies, at least once to identify CD, and the biopsy result may explain the GI procedure has been done. It is not clear what impact that discovery has, if any, on diabetic control or complications, although GI symptoms seem to improve on a GFD. The GFD influence on the control or management of thyroid disease is limited at best, and additional studies are clearly needed to reach firm conclusions[34,35].

One interesting study performed in Italian children found a high incidence of autoimmune thyroid disease in 90 of 343 (26.2%) patients with CD (62 on a GFD) and in 20 (10%) of the control subjects ($P = 0.001$). Fifty-four (15.7%) patients with CD and autoimmune markers had normal thyroid function (euthyroidism) as did 12 (6.0%) of the control subjects. Hypothyroidism was observed in 28 (8.1%) patients with CD and in 7 (3.5%) of the control subjects. Hyperthyroidism was diagnosed in four patients with CD and in none of the control subjects with autoimmune markers. An abnormal echographic pattern was seen in 37 patients with CD (16.8%) and only in one (1.6%) of the control subjects ($P = 0.002$). The high frequency of autoimmune thyroid disease found among patients with CD, even those on a GFD, may justify a thyroid status assessment at diagnosis and at follow-up evaluation of children and adults with CD[36].

## IRON-DEFICIENCY ANEMIA

Diet iron is absorbed by the proximal small intestine, the site of greatest damage in CD. It is not surprising therefore, that iron-deficiency anemia is a common finding in newly diagnosed CD. It also usually resolves with the institution of a GFD[37].

Several studies from Europe and North America have suggested that iron-deficiency anemia may be the sole manifestation of CD in the absence of diarrhea. This association may be especially high in those unresponsive to oral iron therapy[38].

Iron deficiency is common in the general population. If it occurs in young women, it is often ascribed to excess menstrual loss, an empiric therapy with oral iron supplementation is started. However, older patients or those with anemia that is refractory to treatment are often investigated further. Similarly, the persistence of anemia after menopause may be an important clue that leads to the detection of CD[39].

Indeed, female patients have undergone hysterectomies to treat the iron deficiency that persisted until the correct diagnosis was made. Anemia is rarely sought or diagnosed in children; in fact, hemoglobin is not routinely measured in children. Nevertheless, iron-deficiency anemia is a very common illness in primary care and often does not spur investigation in the younger patients. The prevalence of CD in patients referred to GI endoscopy for investigation of iron-deficiency anemia varies from 3% to 12%[40,41].

Clinicians should consider CD as a possible, although not common, cause of unexplained anemia, and gastroenterologists should biopsy the duodenum when an endoscopy is performed in patients with iron-deficiency anemia, even if biopsies are not specifically required.

## OSTEOPOROSIS

Low bone mass, is common in patients with newly diagnosed CD. The mechanism for this effect may be due to malabsorption of vitamin D and calcium and decreased intake of calcium, because of lactose intolerance. Other factors such as sex, malnutrition and physical activity, also contribute to the risk of low bone density in CD[42,43].

Decrease in bone mineral density (BMD) associated with CD responds to a GFD, with a gradual restoration to normal, over two years. The earlier in life that treatment is started, the better is the response[44]. A limited number of screening studies for CD, among patients with low bone mass (LBM), have been performed in Europe. CD was found in 3.4% in adults with LBM[45].

However, a carefully performed Canadian study in predominantly postmenopausal women has not identified an increased prevalence of CD. One likely explanation

is the way the low bone mineral density is defined. Individuals with BMD more than 2.5 standard deviations below the sex-specific peak bone mass are presumed to have osteoporosis. Therefore, it seems that screening those patients with simple postmenopausal osteoporosis, as defined by World Health Organization (WHO) criteria, is unhelpful[46].

Recently, the risk of fractures due to osteoporosis has become a major subject of interest. CD has been associated with an increase in fracture risk. What effect silent, undiagnosed CD, has on lifelong risk fracture risk, is not well known[47].

A large population-based cohort study performed in Great Britain showed that the overall hazard ratio in CD patients for any fracture was 1.30 and 1.90 for hip fracture[48].

## HYPERTRANSAMINASEMIA

The prevalence of hypertransaminasemia (HT) in children is increased in CD. In one study a total of 114 consecutive pediatric CD patients were studied (60% with classical and 40% with atypical forms). The authors found HT in 32% of patients, at the time of diagnosis. In five patients, it was the only manifestation of CD (4.3%). Patients with HT were younger (2.9 ± 0.4 year) than patients with normal aminotransferases (5.1 ± 0.5 year) ($P$ = 0.007). A higher percentage of patients with classical CD tends to have abnormal aminotransferases (73%; 95% CI = 65-81%) than do patients with atypical CD (27%; 95% CI = 19-35%) ($P$ = 0.068). A younger age was significantly associated with HT ($P$ = 0.039; OR = 0.8; 95% CI = 0.71-0.99). The aminotransferases normalized with a GFD in all 35 patients, who were followed-up for an average time of one year[49].

A significant percentage of adult patients with non-alcoholic fatty liver disease (NAFLD) have no metabolic risk factors and may be related with the concomitant presence of CD. Bardella *et al* found in a series of 59 patients that tissue transglutaminase antibodies were positive in six (10%) patients and the anti-endomysium in two (3.4%); only two (3.4%), positive for both anti-endomysium and anti-transglutaminase, demonstrated CD on histological findings. After 6 mo of a GFD, liver enzymes normalised[50].

Mild liver abnormalities are common in adult patients with celiac disease and usually resolve with a GFD. Four patients with untreated celiac disease and severe liver disease are described by Kaukinnen *et al* of Finland. Further, the occurrence of celiac disease was studied in 185 adults with previous liver transplantation using tTG and endomysium antibodies (EMA) testing. Of the four patients with severe liver disease and celiac disease, one had congenital liver fibrosis, one had massive hepatic steatosis and two had progressive hepatitis without any apparent origin. Three patients were even remitted for consideration for liver transplantation. Hepatic dysfunction reversed in all cases when a gluten-free diet was adopted. In the transplantation group, 8 patients (4.3%) had celiac disease. Six cases were detected before the operation: 3 had primary biliary cirrhosis, one had autoimmune hepatitis, one had primary sclerosing cholangitis and one had congenital liver fibrosis. Only one patient had maintained a long-term, strict gluten-free diet. The serological screening found 2 cases of celiac disease, one with autoimmune hepatitis and the other with secondary sclerosing cholangitis. The possible presence of celiac disease should be investigated in patients with severe liver disease. Dietary treatment may prevent progression to hepatic failure, even in cases in which liver transplantation is considered[51].

## NEUROLOGIC DISORDERS

Among the most common neurology problems associated with CD are peripheral neuropathy, cerebellar ataxia, epilepsy, multiple sclerosis and migraine. In a recent study of 26 patients with CD, 31% had abnormalities in neurophysiologic studies, compared with 4% of controls with reflux disease[52].

Nutritional factors have been suspected in association with neurological defects but are rarely found and their correction does not seem to influence in the prognosis. Some reports show certain neurologic symptoms that respond to a GFD, especially if it is started in the first few months after their appearance[53].

It is now evident that the link between CD and neurologic disorders results, in part, from common genetic background, most importantly, the HLA region on chromosome 6, and other markers. In addition to genetic predisposition, immunologic factors probably also play a role[54,55].

One way that this may occur is by antibody or T-cell cross-reactivity, a mechanism that is suspected of triggering the immune response in some autoimmune diseases. Alternatively, it may result from the involvement of additional autoantigens through epitope spreading.

The GFD effect on epilepsy control has been variable. In most patients, some beneficial effects have been reported such as better seizure control and a decrease in dosing of anti-epileptic medications, but without achieving a complete resolution of seizures with the diet alone[56].

Depression and other psychiatric symptoms have been reported as common complications of CD, occurring in about one third of patients. Common symptoms include apathy, excessive anxiety and irritability. All of them clearly improve after few months of adherence to a GFD[57].

## CANCER

The incidence of certain types of cancer is increased among patients with CD. These include non-Hodgkin's lymphomas (NHL) at any site, enteropathy-associated T-cell lymphoma (EATL) (a rare, high-grade T-cell non-Hodgkin's lymphoma of the small intestine), for which the outlook is poor, small intestine adenocarcinoma and esophageal and oropharyngeal carcinomas[58-60]. In one large cohort study performed on 4732 CD patients compared with 23 620 matched controls, the authors found in CD, an increased RR factor for mortality of 1.39 with a 95% CI (1.13-1.51) and for malignancy of 1.29,

CI-95% (1.06-1.55)[61]. The mechanisms responsible for the development of malignancies in CD patients are not known. The following explanations have been suggested: increased intestinal permeability of environmental carcinogens, chronic inflammation, chronic antigen stimulation, release of pro-inflammatory cytokines, immune surveillance problems and nutritional deficiencies caused by the disease or the GFD[62].

CD is clearly associated with a definite increase in the risk of developing cancer, especially EATL and other gastrointestinal cancers that are partially responsible for the overall increased mortality reported in these patients. However, the magnitude of the overall risk for NHL is much lower than previously thought, with a relative risk most probably ranging between 2 and 4[63,64]. Strict adherence to a GFD seems to protect against the development of some types of cancer[65,66].

## CONCLUSIONS

Several issues may be of help, as listed in the following decalogue: (1) Clinicians must have a better understanding of CD, have good knowledge of this common disease (1%-2% in the general population), and consider it in the differential diagnosis of multiple gastrointestinal and extraintestinal conditions. (2) It is very important to do a careful clinical history dating back to childhood, looking for a relation of periodic complaints to food ingestion, exploring the family's history of CD and searching for associated disease such as recurrent rhinitis, pharyngo-amigdalitis, otitis, sinusitis, asthma, and other immuno-allergic conditions. (3) To perform a systematic screening of CD in high risk patients such as those presenting with iron deficiency anemia, especially if it is refractory, and taking routine duodenal biopsies during upper gastrointestinal endoscopies in these patients. (4) In the presence of sustained hypertransaminasemia, in the absence of a history of liver disease, and when viral markers are negative, screen for CD, which is associated with the former conditions in around 10% of cases. (5) If endocrine disturbances are present, such as hypo- or hyperthyroidism, or positive anti-thyroidal antibodies with normal function are present, and also in the presence of associated type 1 diabetes mellitus, consider a potential case of CD. (6) Remember that screening serology, particularly the measurement of anti-transglutaminase antibodies, can sometimes be negative in adult patients. (7) Duodenal biopsy may be normal or show only minimal changes. An experienced pathologist deeply interested in the diagnosis of CD, and routinely using Marsh's classification in his or her reports, is needed. (8) Bear in mind that being DQ2 (+) is a necessary but insufficient condition, and that increasingly more cases are being diagnosed in DQ2 (-) individuals. (9) In doubtful cases, the introduction of a GFD may be suggested for a minimum of six months, after which the clinical and laboratory response is observed ("ex-iuvantibus" diagnosis). (10) Finally, the Gastroenterology Units in the tertiary hospitals should include monographic "Small Bowel Sections" for the routine study of these patients, and should be fitted with modern functional techniques and endoscopic procedures for their study, such as video-capsule and double-balloon enteroscopy.

## Abstract

Colorectal adenocarcinoma (CRC) is the third most common type of cancer and the fourth most frequent cause of death due to cancer worldwide. Given the natural history of CRC, early diagnosis appears to be the most appropriate tool to reduce disease-related mortality. A field of recent interest is clinical proteomics, which was reported to lead to high sensitivity and specificities for early detection of several solid tumors. This emerging field uses mass spectrometry-based protein profiles/patterns of easy accessible body fluids to distinguish cancer from non-cancer patients. These discrepancies may be a result of: (1) proteins being abnormally produced or shed and added to the serum proteome, (2) proteins clipped or modified as a consequence of the disease process, or (3) proteins subtracted from the proteome owing to disease-related proteolytic degradation pathways. Therefore, protein pattern diagnostics would provide easy and reliable tools for detection of cancer. This paper focuses on the current status of clinical proteomics research in oncology and in colorectal cancer especially, and will reflect on pitfalls and fears in this relatively new area of clinical medicine, which are reproducibility issues and pre-analytical factors, statistical issues, and identification and nature of discriminating proteins/peptides.

## BACKGROUND

In order to improve early detection, monitor disease outcome and find targets for more individualised therapy, there is an urgent demand for new biomarkers in oncology. A field of recent interest is clinical proteomics, which has been reported to lead to high sensitivity and specificities for early detection of several solid tumors[1,2]. This emerging field uses mass spectrometry-based protein profiles/patterns of easy accessible body fluids to distinguish cancer from non-cancer patients. This would offer a solution to the problem of cancer often being diagnosed in late stages, when curative resection of the diseased organ is no longer possible and the disease has already metastasized, thus dropping survival rates dramatically. However, after the initial positive announcements in early 2002, criticisms were raised about several aspects of serum proteomics. In this paper we describe the hopes and fears for the introduction of clinical proteomics for early detection of Colorectal adenocarcinoma (CRC).

## COLORECTAL CANCER

Colorectal adenocarcinoma is the third most common type of cancer and the fourth most frequent cause of death due to cancer worldwide. Worldwide almost one million new cases occur annually, amounting to 492 000 related deaths[3]. In developed countries it is the second most common type of tumor, with a lifetime risk of 5%, but its incidence and mortality is now decreasing[4,5]. Surgery is the cornerstone of therapy when the disease is confined to the bowel wall. This results in 70%-80% of patients who have tumors that, when diagnosed, can be resected with curative intent[6]. After curative surgery the five-year survival rate for patients with localised disease is 90%, decreasing to 65% in the case of metastasized disease to the lymph nodes. Adjuvant radiation therapy, chemotherapy, or both are useful in selected patients. Classification of tumors into pathogenetical subtypes with distinct clinical courses enables clinicians to target therapy. For CRC, the TNM staging system remains the gold standard and relies entirely on the morphological appearance of the tumor. However, tumors with similar histopathological characteristics may have different clinical outcomes and responsiveness to therapy[7]. Therefore, more individualised treatment would benefit the patient and may avoid unnecessary morbidity. Nonetheless, early detection of CRC will increase survival the most, in view of the fact that it is well recognized that CRC arises from a multistep sequence of genetic alterations that result

in the transformation of normal mucosa to a precursor adenoma and ultimately to carcinoma. Given the natural history of CRC, early diagnosis appears to be the most appropriate tool to reduce disease-related mortality[8-10].

## BIOMARKERS

In cancer research, biomarkers are molecules that indicate the presence of cancer in the body. Most biomarkers are based on mutations in genes or abnormal changes in RNA, proteins and metabolites. Since the molecular changes that occur during tumour development can take place over a number of years, some biomarkers can potentially be used to detect early colorectal cancer. Furthermore, they might be used to predict prognosis, monitor disease progression and therapeutic response. Gion *et al* classified different circulating biomarkers according to their clinical application[11]. These candidate biomarkers, however, are frequently found in relatively low concentrations amid a sea of other biomolecules. Therefore biomarker research and possible diagnostic tests depend critically on the ability to make highly sensitive and accurate biochemical measurements. Ideally, such biomarkers should be specific to the disease and easy accessible, such as in serum, plasma or urine, increasing their clinical applicability.

Carcinoembryonic antigen (CEA) is the best-characterised serologic tumor marker for CRC. However, its use as a population-based screening tool for early detection and diagnosis of CRC is hindered by its low sensitivity and specificity. Fletcher demonstrated that for screening purposes in a normal population, a cut-off concentration of 2.5 μg/L CEA would yield a sensitivity of 30%-40%. Based on these data, he calculated that there would be 250 false positive tests for every true positive test; i.e. a patient with cancer. Furthermore, 60% of the cancers would not be detected. The same poor sensitivity applies for diagnosis of CRC. In addition, as CEA can be elevated in the absence of malignancy, specificity is also impaired [12-15].

Faecal occult-blood testing (FOBT) is another biomarker for which clinical trials have shown evidence for a decreased risk of death. This approach is a non-invasive option that limits the need for follow-up colonoscopy to patients with evidence of bleeding. However, neoplasms bleed intermittently, allowing many to escape detection with faecal occult-blood testing. Annual retesting is therefore necessary but is still insufficient, detecting only 25 to 50% of colorectal cancers and 10% of adenomas. The specificity of FOBT is also limited by frequent false positive reactions to dietary compounds, medications, and gastrointestinal bleeding from causes other than colorectal cancer[16-18].

## A NEW DIAGNOSTIC PARADIGM: CLINICAL PROTEOMICS

In 2002, several studies demonstrated discrimination of patients with various cancers from healthy subjects on the basis of presence/absence of multiple low-molecular-weight serum proteins using SELDI-TOF mass spectrometry technologies[19-22]. The authors hypothesised that proteomic patterns are correlated to biological events occurring in the entire organism and are likely to change in the presence of disease. New types of bioinformatic pattern recognition algorithms were used to identify patterns of protein changes in order to discriminate cancer patients from healthy individuals with promising results.

Petricoin and his co-workers stated that finding a single disease-related biomarker is like searching for a needle in a haystack as each entity has to be separated and identified individually[23,24]. Moreover, they postulated that the blood proteome constantly changes as a consequence of the perfusion of the diseased organ adding, subtracting, or modifying the circulating proteome. These differences might be the result of proteins being abnormally produced or shed and added to the serum proteome, proteins being clipped or modified as a consequence of the disease process, or proteins being subtracted from the proteome owing to disease-related proteolytic degradation pathways. Therefore, protein pattern diagnostics would provide easier and more reliable tools for detection of cancer. The advantages of the SELDI proteomic pattern approach were stressed in several papers. In addition to the high sensitivity and specificity, cost-effectiveness, easy accessibility of body fluid and especially the high-throughput, ultimately allowing application in future screening studies, were discussed[20,25]. After these hopeful voices, soon critical notes were made on analytical reproducibility and the use of the so-called black box approach, lacking identification of discriminating proteins.

In the next paragraphs, this paper will focus on the current status of clinical proteomics research in oncology and will reflect on pitfalls and fears in this relatively new area of clinical medicine, including reproducibility issues and pre-analytical factors, statistical issues, and the identification and nature of discriminating proteins/peptides.

## REPRODUCIBILITY ISSUES AND PRE-ANALYTICAL FACTORS

Boguski and McIntosh were among the first to argue that serum proteomics may be susceptible to observational biases. They stated that any confounding factor could conceivably cause a phenotypic response that might be confused with a specific characteristic of the disease process under study[26]. Confounding factors, which not only include smoking, diet and preoperative stress, but also logistic factors such as sample collection and sample quality, make a reliable and clear differentiation between a normal or malignant status hazy. Another cause for concern, mentioned in this study, is the sample quality and number. The authors favoured use of homogeneous groups with sufficient sample size and stringent standard procedures for serum collection, which is an aspect that is also advocated in other studies[27,28]. Another critical study questioned the reliability of the presence of statistically significant signals at M/Z values less than 500, as used in one of the first studies. Sorace *et al* claimed that the presence of statistically significant bands of low M/Z includes degradation products of higher molecular weight macromolecules or

**Table 1 Recommendations of various pre-analytical variations from three MALDI-TOF based reproducibility studies**

| | Blood component | Peptide isolation | Temperature before sample handling (℃) | Time before centrifugation | Storage of serum | Freeze/ thaw cycles | Circadian rhythm effect |
|---|---|---|---|---|---|---|---|
| Baumann *et al* | Serum plasma | C3, C8, C18 beads | 21 | < 30 min | -80 ℃ | 1 | NA[1] |
| de Noo *et al* | Serum | C8 beads | 21 | Ideally < 30 min, practically < 2-4 h | NA[1] | 2 | No effect |
| West-Nielsen *et al* | Serum plasma | C8 beads | 21 | < 8 h | -20/-80℃ | 1 | NA[1] |

[1]Not applicable for this study.

a matrix effect. Furthermore, this study raised caution regarding poor reproducibility of experimental conditions of chip-based mass spectrometry[29]. This is also reported by another group, which described the poor reproducibility of the SELDI-TOF ovarian cancer data. Baggerly and colleagues postulated that this could partly be contributed to baseline correction, poor sample features in noise regions and even a change of protocol mid-experiment[30]. Most importantly, the promising results that were reported earlier could not be reproduced, therefore stressing the importance of standardised approaches and stringent experimental design. Furthermore, their study pointed out that strong pre-processing of the protein spectra is required in order to obtain reliable classification results in the search for new biomarkers.

Possible confounding factors can be categorized into three sources of variation and bias: biological variation, pre-analytical variation and analytical reproducibility. Biological variation, consisting of both environmental and individual factors, such as race, age, diet, smoking, stress, general physical condition and the use of drugs, may also influence serum protein profiles. However, at the present time no data have been published on this source of variation. Nevertheless, in a previous study our group analyzed pre-analytical and reproducibility issues of our MALDI-TOF approach[31]. The pre-analytical variations corresponded to the logistical conditions in the routine clinical setting; i.e. the effects of sample handling and storage. So far, only a few other studies have reported on the effects of different serum sample preparations and the use of a magnetic-beads-based approach to capture and concentrate serum proteins for MALDI-TOF mass spectrometry[32-34]. Villanueva *et al* mostly focused on influences of different magnetic bead capturing and automation on the reproducibility of serum protein profiles, while Baumann and co-workers mainly studied pre-analytical variation of sample handling.

In Table 1, results for sample handling experiments of the above mentioned studies are summarized. For clinical studies, the use of two freeze/thaw cycles is recommended in three manuscripts. This is mainly due to logistical reasons, such as the ´standard´ for centralized sample collection in large hospitals. The point all authors agreed on is the influence of sample handling; i.e. the time venous blood is left to stand before serum centrifugation. This aspect appears to account for the largest effect on serum or plasma protein profiles. Consequently, standardized sample collection and a well-documented population are recommended in all studies. Standardized protocols should be used from the point of sample collection, sample handling, and storage and freezing of the samples. Although the importance of homogeneity and uniformity within sample groups must once again be stressed, variation of such factors cannot totally be excluded in a clinical setting. In all, when these recommendations are strictly followed and both clinical and analytical factors are controlled, we are confident that the methodology can be standardized to a level that allows application as a tool in biomarker discovery.

## STATISTICAL ISSUES

As in all research with high dimensional data, two practical realities constrain the analysis of mass spectra in proteomics. The first is the 'curse of dimensionality', which means the number of features characterizing these data is in the thousands or tens of thousands. The second is the 'curse of dataset sparsity', which means the number of samples is limited. Somorjai *et al* showed the influences of these two curses on classification outcomes. Both the sample per feature ratio, which should ideally be 5 to 10, and feature selection are of pivotal importance for reliable classification and biological optimal relevance[35,36].

Previous to any feature selection or classification, raw mass spectra have to be submitted to so-called pre-processing. During pre-processing, the noise of protein/peptide mass spectra is reduced and the spectra are normalised. Furthermore, smoothing, binning and baseline correction are also performed during pre-processing of the data. Currently, there is a lot of discussion among several groups on how to establish the best method, because data pre-processing is extremely important. There are complex interactions between baseline subtraction, normalization, noise estimation, and peak identification, and therefore these steps should not be considered in isolation[31,37-40].

Another recurring topic for debate is the bioinformatic approach and statistical analysis of protein spectra. Clinically, the most relevant is the issue of an independent validation set for the classification of diseased versus healthy individuals. This is primarily based on a specific problem in the discovery-based research field of clinical proteomics, namely overfitting. Overfitting may occur in the analysis of large datasets when multivariate models show apparent discrimination that is actually caused by data over-interpretation, and hence give rise to results that are not reproducible[30,41,42]. The chance of overfitting, however, can be reduced by appropriate application of validatory estimation and assessment, such as through application of double cross-validation, when properly implemented[43]. Although we have shown

this in a previous study, the general opinion is in favor of performing a classification study with independent validation. In addition, feature selection is also given a lot of attention by statisticians in the field. Several experimental investigations have been made with different peak-feature selection methods. A common approach so far is analysing the data in two phases. First, the peaks in the spectra are extracted and quantified. Secondly, a resulting matrix of peak quantifications is created. For more detailed information on this statistical matter, we refer the reader to the literature[37,44-46].

## IDENTIFICATION AND NATURE OF DISCRIMINATING PROTEINS

The controversy regarding the use of protein profiles as a pattern diagnostic, without identification of the individual diagnostic biomarkers, remains to be solved before its clinical application. Whereas the first clinical proteomics studies published their classification method mainly as a black box study, at present identification of the most discriminating proteins or peptides is required for publication in most scientific journals. Identification and functional analysis of these discriminating proteins/peptides might render new insights on tumour development and environmental responsiveness, which could eventually be translated into new diagnostic and prognostic insights for the clinician. Unfortunately, little success has been achieved to date in assigning reproducible discriminating biomarkers[35,42].

Furthermore, several studies have identified their discriminating peaks as components of the coagulation cascade or complement system[47-51]. Therefore, in contrast to the original reflection that discriminating proteomic patterns would identify cancer-specific proteins, it appears that these potential markers belong to the normal serum and plasma proteome. Consequently, some investigators have argued that low molecular weight proteins in serum and the serum peptidome are biologically aspecific and therefore do not yield any reliable biomarkers in the currently technically available mass range[29,52]. Others have proposed that the discriminatory protein peaks represent acute phase reactants that are present in serum in extremely high concentrations[49,53]. Conversely, a study recently reported that although discriminating peptides do indeed belong to the well-known coagulation and complement pathways, their patterns or signatures can nevertheless indicate the presence of cancer. Villanueva *et al* showed that most of the cancer-type specific biomarker fragments were generated in patient serum by enzymatic cleavage at previously known endoprotease cleavage sites after the blood sample was collected[54,55]. They postulated that the discriminating peptides originated after *ex vivo* proteolysis by tumor specific proteases of high abundance protein fragments primarily generated by the coagulation and complement enzymatic cascades. In view of this, they consider these cancer-specific low molecular weight proteins in the serum peptidome to be an indirect snapshot of the enzyme activity in tumor cells. We support their hypothesis that proteolytic process profiles in the serum peptidome hold important information that may have direct clinical utility as a surrogate marker for the detection and classification of certain types of tumors. Unique proteases may be shed by tumor cells or reflect activity of the host immune response, which may contribute to new proteins such as chemokines and lymphokines. These processes result in subtle changes in low molecular proteomic signatures, which may ultimately be used for classification methods in various cancers and diseases in the future[54]. Proteases have been extensively implicated in the development and progression of cancer[56,57]. Song *et al* recently stated that proteolytic processing of high abundance host-response proteins actually amplifies the signal of potentially low-abundance biologically active disease markers such as proteases. Therefore, it might be expected that more convenient and reliable blood proteins and peptides simply serve as an endogenous substrate pool for proteases as surrogate markers for the detection and classification of cancer[58].

Another recurrent topic of debate concerns the type of blood component that is best for protein profiling and peptidome analysis. Some investigators favour the use of plasma because they presume that, in serum, ongoing enzymatic activity occurring during clotting is likely to cleave even proteins that are not involved in biologically relevant pathways[53,59]. Others, however, advocate the use of serum. We support the hypothesis that since the kidneys rapidly clear peptides smaller than 4 kDa, which are generated *in vivo* in the circulation, the majority of peptides in blood samples exist from *ex vivo* proteolysis. This explains the possibility that low abundance proteins, including possible tumor markers, may be totally obscured and not retraceable during direct mass spectrometry. However, it has recently been shown that exogenous proteases are functionally measurable in serum, however in higher concentrations than in plasma[54].

Functional proteomics studies allow the investigation of environmental factors over time, rendering the monitoring of metabolic responses to various stimuli. Hence, post-translational modifications can be studied, whereas they cannot be detected by genomic studies. Post-translational modification changes, like glycosylation of proteins and lipids, are a common feature in colorectal cancer influencing cancer cell behaviour and can be detected using mass spectrometry due to characteristic mass shifts[60]. We expect that both phosphoproteomics and/or glycoproteomics, enabling study of crucial post-translational modifications of proteins in the cancer pathway, will revolutionize our understanding of the function of these proteins and hence render new insights for monitoring and therapy.

## CLINICAL PROTEOMICS IN CRC

Until present, few protein profiling studies have been published on the detection of CRC, two being based on SELDI-TOF and one on MALDI-TOF mass spectrometry. The first SELDI-TOF study showed seven potential biomarkers that could differentiate CRC patients from those with colorectal adenoma with a sensitivity of 89% and specificity of 83%. The seven potential biomarkers have a large range in mass values, differing from 4654 to 21 742 Da[61]. A more recently published study found 5 possible bi-

omarkers to differentiate between healthy control subjects and CRC patients. The study consisted of a training set of samples from 40 patients with colorectal cancer (all Dukes' D) and 49 healthy controls. The second set included samples from 37 patients with colorectal cancer (1 Dukes' A, 2 Dukes' B, 12 Dukes' C, 17 Dukes' D, 5 unknown) and 31 healthy controls. For three of these potential markers, they found a sensitivity and specificity between 65% and 90%. They reported that m/z 3.100, 3.300, 4.500, 6.600 and 28.000 were the most important biomarkers. The total sample set showed that 1 of 1 Dukes' A, 1 of 2 Dukes' B, 11 of 12 (91.7%) Dukes' C, and 47 of 57 (82.5%) Dukes' D were correctly classified. Stratification by Dukes' stages showed a significantly better sensitivity of the classification trees (91.7%, 11/12) compared to CEA (25.0%, 3/12) in Dukes' C colorectal cancer, although at stage D CEA performed better. No conclusions can be drawn on the performance of our classification trees at earlier stages of colorectal cancer due to limited samples, but 2 of 3 patient samples from stage A and B were correctly classified by the trees and none when using the clinical cut-off for CEA[59]. Our group used MALDI-TOF mass spectrometry to differentiate CRC patients from healthy controls. In a randomized block design, pre-operative serum samples obtained from 66 colorectal cancer patients and 50 controls were used to generate high-resolution MALDI-TOF protein profiles[42]. After pre-processing of the spectra, linear discriminant analysis with double cross-validation, based on principal component analysis, was used to classify the protein profiles. Thirty-four patients out of thirty-seven with early stage disease (stage 1 and 2) and all patients with stage 3 or 4 disease were correctly classified as having cancer. For the misclassified control subjects, it was not possible to retrieve the current physical state as it concerned anonymous healthy controls.

A total recognition rate of 92.6%, a sensitivity of 95.2% and a specificity of 90.0% for the detection of CRC were shown. In our study two first principal components accounted for most of the between-group separation, both with a m/z between 1 and 2 kDa.

Although much research has been done using 2D gel electrophoresis to detect possible biomarkers and targets for CRC, this falls outside the scope of this review since this technique cannot be scaled up to a directly applicable diagnostic test. On the other hand, a screening assay based on an APC protein truncation test has recently been proposed and other studies mention the potential use of protein microarrays[2,60,62,63]. However, studies linking large protein expression patterns with clinical outcome in colorectal cancer are still in their infancy. To be able to predict occurrence of disease and treatment outcome, more studies on genotype-phenotype correlations are needed both in sporadic and in hereditary colorectal cancer.

## FUTURE PERSPECTIVES

The best anticancer strategies still rely on early detection followed by close monitoring for early relapse so that therapies can be appropriately adjusted[64]. In addition, new targets for therapy are a constant subject of study in oncology. In fact, increased understanding of the molecular mechanisms of cancer progression may refine treatment and management of patients. Advances in genomics and proteomics may lead to earlier detection of cancer thus enabling a more precise classification of (smaller subsets of) patients based on their predicted response to individual therapies. Conceptually, proteomics is more suitable than genomics for novel targeted therapies, since most protein biomarkers are based on aberrant protein signalling circuits represented by post-translational modifications. The dynamic range of the proteome allows more insight in the functional state of a cell, tissue or organ over a period of time. Besides, protein profiling and classification of several components of multiple aberrant cell signalling cascades would be expected to predict disease behaviour better than just single pathways in isolation[62]. Therefore, proteomics could be expected to render better insight in pathogenetic mechanisms, disease progression and treatment response. This is of paramount importance as cancer advances dynamically and affects heterogeneous cell populations, either as a part of cancer or as a part of a tumor-host reaction[49,65].

Further refinement of serum protein profiles is needed before these mass spectrometry-based techniques become part of clinical routines. Currently, several studies have carefully evaluated reproducibility, automation, sample throughput and sensitivity of serum proteomic techniques. The first problems related to these factors seem to have been overcome due to stringent standardised approaches as described earlier. However, proteomics studies still have several drawbacks: (a) current tools only allow narrow-range analyses, (b) identification of proteins of interest remains cumbersome, (c) protein studies address mixtures of high complexity. Hence, due to the dynamic ranges of the human proteome and the lack of amplification methods in protein studies, targeted proteomics techniques for (quantitive) identification of low-abundant proteins have to be investigated further[66]. Another approach to studying proteins at a functional level might be the use of array-based proteomics platforms. This technique offers the potential for highly multiplex and sensitive analysis of serum or tumor proteins[62]. Using this direct approach to study the proteomic circuitry would theoretically allow for the creation of functional signalling maps of cancers, even at the level of the individual patient. Regarding identification of potential biomarkers, limitations of direct MS/MS have been stressed previously as well as the fact that antibody-approaches may yield higher sensitivity[53,54].

In the next era, research in oncology will drift to more individualised medicine. In this view, molecular profiling forms a welcome addition to the pathology report of cancer. Until now, histopathological staging and demographics have been used to predict disease outcome. However, we believe that protein profiling and other proteomics techniques may lead to more individualised medicine and tailor made therapy[67,68]. At first, both approaches should be used complementarily instead of competitively.

It is unlikely that in the next decade, serum protein profiles will replace the current gold standard, which is colonoscopy, for the diagnosis of CRC. Nevertheless, we hypothesise that MALDI-TOF based serum protein profiles, once validated in independent studies, could be used

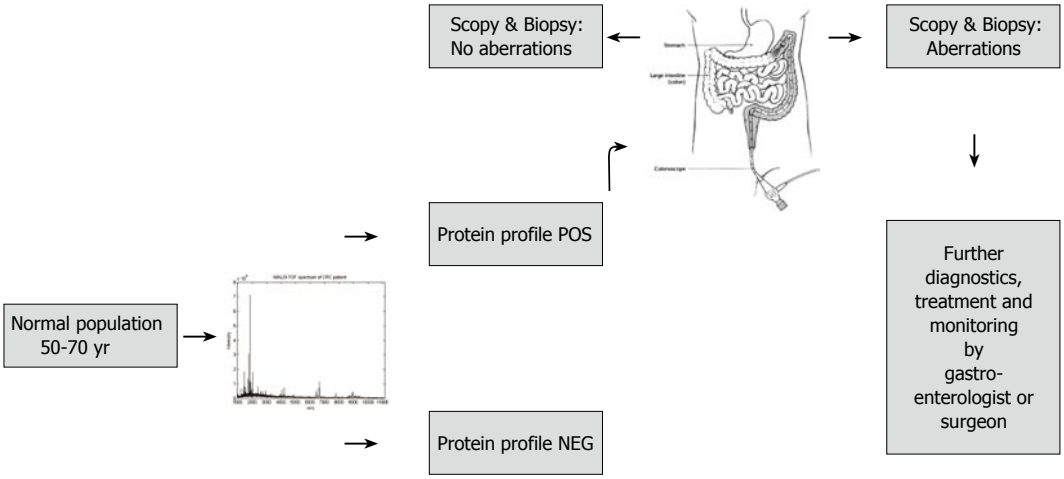

**Figure 1** Flow chart of possible clinical application of MALDI-TOF.

as selection criteria for the more invasive and time-consuming diagnostic colonoscopy (Figure 1). Eventually, with the present debate on screening programs for colorectal cancer in several countries, clinical proteomics may replace and surpass the use of faecal occult-blood testing (FOBT). When used in independent validation studies, sensitivity and specificity remain about 90%. Protein profiling might even replace FOBT, since this approach has a lower specificity and a number of disadvantages. Non-bleeding tumors and, more relevantly, polyps and adenomas cannot be detected using FOBT, whereas we expect to realise this detection with serum protein profiling within the next decade[17,18].

Although the current reality may not have kept pace with previous expectations and the translation from bench to bedside is more laborious than initially thought, there is supporting evidence for the potential vast use of clinical proteomics in oncology. Particularly, this potential will be realized when technical innovations to further increase sensitivity and specificity of proteomic techniques are implemented and more sensitive methods for protein identification on alternations are developed. In combination with the use and set-up of well-defined cases together with well-documented serum banks, including not only for CRC samples but also inflammatory disease and polyps, serum protein profiling may propel diagnostic research in CRC in the right direction.

## Abstract

In response to the global rise in obesity, bariatric surgery has become increasingly more popular and successful. As a result, the demand for body contouring following massive weight loss is rapidly growing. Although bariatric procedures may produce impressive weight loss, people who achieve massive weight loss are often unhappy with the hanging folds of skin and subcutaneous tissue that remain. This review examines the nature of the post-bariatric deformity in each body region and briefly reviews common approaches to their treatment.

**Key words**: Weight loss; Bariatric surgery; Body contour surgery

## INTRODUCTION

As we enter the 21st century, a new health crisis has dawned upon affluent western societies, the plague of obesity. In the United States, the situation is particularly acute with recent estimates showing that nearly 65% of adult Americans (127 million) are over their ideal body weight, 30% (48 million) are obese [Body mass index (BMI) $\geqslant$ 30], and nearly 5% (9 million) are morbidly or severely obese (BMI $\geqslant$ 40)[1]. Further, the obesity epidemic has expanded globally, with approximately one-fifth of the one billion overweight or obese people in the world being Chinese[2]. Although the ultimate impact of mild obesity on survival has recently been challenged, there is no doubt that morbid or severe obesity is detrimental to both the physical and psychological well being of the afflicted patient[3,4]. Morbidly obese patients have often reached a point of no return in which they are too large and physically unable to exercise.

With some exceptions, the feed-forward cycle of weight gain in the morbidly obese can be interrupted only by physically restricting oral intake. This surgical subspecialty, known as bariatric surgery, has exploded in popularity in the last decade largely because of improved outcomes, enhanced patient safety and superior techniques and devices[5,6]. Although early bariatric procedures produced impressive weight loss, they also resulted in significant morbidity both initially because of wound healing problems and anastomotic leakage, and ultimately as a result of their malabsorptive effects[7]. Modern laparoscopic surgical approaches have minimized wound healing morbidity, while the improvement of more restrictive procedures, such as the minimally invasive LAP-Band®, have made weight loss surgery in morbidly obese patients a reliable and relatively safe procedure[8-12]. According to the most recent available data, approximately 170 000 bariatric surgeries were performed in the United States in 2005[13].

However, for the morbidly obese patient, the massive weight loss that follows successful bariatric surgery is only the first step in the process[14]. After massive weight loss, patients are left "deflated". The excess skin that hangs from the torso, abdomen and extremities is not only extremely unsightly, but can be painful and susceptible to recurrent intertriginous infections[15,16]. In order for these patients to complete their transformation to a formerly morbidly obese patient, a plastic surgeon must address the deformities resulting from the massive weight loss[17].

This type of extreme body contouring has grown concomitantly with the popularity of bariatric surgery, with 55 927 procedures performed in 2004[18]. More than just excising excess skin and subcutaneous tissue, post-bariatric body contouring requires unique insights into the nature of the post-bariatric deformities[19]. In addition, there must be an appreciation of the fact that massive weight loss patients, because they are often relatively malnourished or anemic, constitute a distinct surgical cohort that must be carefully evaluated pre-operatively[20,21]. In the following sections, we will examine the nature of the post-bariatric deformity in each body region and briefly review common approaches to their treatment.

## TORSO/ABDOMEN

In formulating a strategic approach to the massive weight loss patient, the abdomen is usually the first body territory

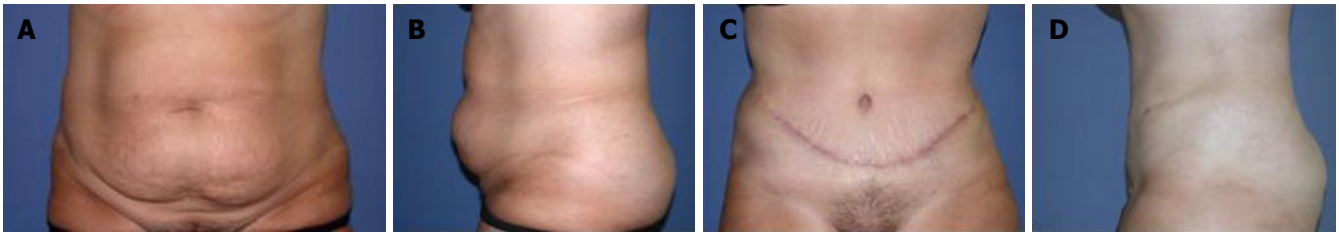

**Figure 1** Typical frontal (**A**) and lateral (**B**) appearance of the anterior abdominal wall of a (non-weight loss) post-partum female. In addition to excess skin and subcutaneous tissue, there is significant laxity of the anterior abdominal wall of this 50-year-old female; **C** and **D**: Post-operative appearance several months after standard abdominoplasty.

**Figure 2** Typical frontal (**A**) and lateral (**B**) pre-operative appearance of a panniculectomy candidate; This 41-year-old patient is status post a 60-lb weight loss. In addition to the unsightly appearance, the hanging pannus can be the source of pain and recurrent infection. Removal of the pannus (in this case with umbilical translocation) even without plication of the underlying abdominal wall resulted in significant improvement in contour and relief of symptoms (**C** and **D**). The patient also underwent a concurrent bilateral mastopexy.

addressed. The appropriate surgical intervention depends upon the amount and distribution of excess skin and subcutaneous tissue as well as the degree of abdominal wall laxity/integrity. In general, as the amount of weight loss increases, so does the aggressiveness of the surgical intervention.

For skin excess limited to the anterior abdomen, as might occur after moderate weight loss or pregnancy, a traditional abdominoplasty will suffice. In this procedure, the skin and subcutaneous tissue between the umbilicus and pubis is excised in an elliptical pattern, leaving a scar concealed within the underwear/bikini line[22]. Since there is usually an associated abdominal wall laxity, prior to closing the incision, the anterior abdominal fascia is plicated, with particular emphasis on re-creation of an appropriate waist in females[23] (Figure 1A-D).

In some weight loss patients, the resulting abdominal pannus consisting of loose hanging skin and subcutaneous tissue can be the source of significant discomfort, recurrent infection and difficulty with personal hygiene[15]. A simple elliptical excision of the pannus, which can weigh 25 kg or more, can provide immediate relief of the aforementioned symptoms, with minimal morbidity[24]. In addition, a panniculectomy is often the only post weight loss surgery that may be covered by a third party payer[25] (Figure 2A-D).

In most massive weight loss patients, however, the excess skin and subcutaneous tissue is not confined solely to the anterior abdomen[26,27]. In order to excise this "cone-like" circumferential excess, a circumferential excision or "belt lipectomy" is required[28,29]. The amount of tissue removed is tailored to the individual patient's needs. An optimal excision will not only tighten and flatten the lower abdomen but will also give a beneficial lift to the buttocks, mons pubis and lateral thighs[29] (Figure 3A-D).

In some patients (usually those with the most significant excess), the circumferential excision alone is not sufficient to address the horizontal dimension of the excess tissue. In these patients, an anterior ellipse or fleur-de-lis pattern of excision is required[30,31]. For patients who have had previous "open" bariatric surgery (and therefore already have a vertical midline scar), the additional scar burden is minimal. Even for patients without a pre-existing midline scar, the trade-off for optimal abdominal contour is usually acceptable.

Massive weight loss patients undergoing abdominal contouring procedures often have associated abdominal hernias which are not always evident on pre-operative physical exam[32,33]. The surgeon should be prepared to repair these in the course of the abdominal contouring. General complications of abdominal contouring include skin necrosis, persistent paresthesias of the abdominal wall, seroma, infection and wound dehiscence[16,34-36]. Patients are encouraged to refrain from smoking for at least 3 wk prior to surgery, as tobacco use has been shown to significantly increase the morbidity of body contouring procedures[37].

## UPPER TORSO/BREAST

Following massive weight loss, in both males and females, excess rolls (sometimes three or more per side) of skin and subcutaneous tissue remain. Because of firm underlying fascial attachments, though these may be improved somewhat by belt lipectomy[29,38], they can only be completely ablated by direct excision[26]. Usually, the deformity caused by these folds is significant enough that patients are willing to trade a horizontal scar across the upper back (hidden in the bra line in females). Furthermore, in women this excess tissue may be transferred anteriorly and used for autologous breast augmentation (see breast discussion below)[39,40].

The major deformity of the breast after massive weight loss in both men and women is ptosis or sagging of the breast which leaves the nipple areola complex (NAC) below its appropriate anatomic position. In males, the aim is to excise the excess skin and subcutaneous tissue while maintaining a flat breast profile[41]. Various patterns of

**Figure 3** A 34-year-old female status post 120-lb weight loss. Note the deflated, empty breasts and excess anterior abdominal skin and subcutaneous tissue anteriorly (**A**) and the excess skin and subcutaneous tissue posteriorly as well as the sagging buttocks (**B**); One month after circumferential abdominoplasty (and bilateral brachioplasty), there is significantly improved contour with re-creation of a feminine waistline (**C**); In addition, the buttocks have been lifted as a result of the circumferential excision (**D**). The patient is awaiting bilateral breast augmentation and bilateral medial thigh lift.

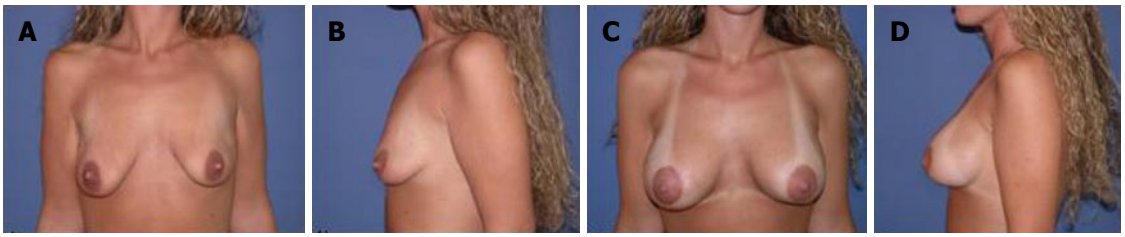

**Figure 4** Pre-operative appearance of a 23-year-old post-partum female after 60 lb weight loss. The breasts are deflated and ptotic (**A** and **B**). Status post bilateral breast augmentation (with saline prostheses) and right sided circumareolar mastopexy (**C** and **D**). Note the improved projection, especially in the upper pole. Additionally, the pre-operative asymmetry has been corrected.

excision exist to achieve this goal. In extreme cases where the NAC must be moved a long distance superiorly (more commonly in females), it can be removed and replaced as a full thickness skin graft[42]. Patients must be warned that this will cause the NAC to become insensate and may lead to de-pigmentation[43].

Although the NAC can be returned to its normal anatomic position by various means (at the level of the inframammary fold for women), a major challenge in female weight loss patients is recreation of breast fullness and projection. In most cases of massive weight loss, women are left with deflated empty "pancake" breasts. For female patients, the goal is to excise excess breast envelope skin while preserving as much volume as possible.

For most massive weight loss patients, satisfactory volume and projection can only be achieved with breast implants placed in combination with a breast lifting skin excision or mastopexy[19,32,39,44] (Figure 4A-D). The choice of implant used for breast augmentation is currently limited to saline-filled, silicone-shelled devices or (for surgeons involved in certain manufacturer study protocols) silicone-filled, silicone-shelled devices (since 1992 the Food and Drug Administration (FDA) has banned the routine use of silicone-filled implants in the United States, although they remain largely the implants of choice in Europe and the rest of the world and are available to a handful of surgeons in the United States who are part of ongoing clinical trials concerning their use).

The most common complication of these devices (regardless of the implant filler material used) is capsular contracture, in which excessive fibrous scar tissue forms around the implant leading to firmness, distortion of the implant and pain[45,46]. Implant removal or revision of excessive scar tissue may be required in 15%-35% of cases[46,47]. Other known but less frequent complications of breast implants are infection, malposition and rupture[45]. Breast implants have not been shown to cause autoimmune disorders[48,49] or increase the risk of (delayed detection) of breast cancer, although special mammographic views may be required[50-52].

In some patients, autologous volume augmentation can be achieved by recruiting local folds of tissue that might be otherwise excised in the course of body contouring. Most commonly the excess folds of the upper lateral chest or back tissue are de-epithelialized and rotated anteriorly into the breast[39,40]. Other surgeons utilize excess tissue on the upper anterior abdomen from a "reverse abdominoplasty". Common complications of breast lift with or without autologous augmentation are hematoma, infection, seroma and changes in NAC appearance and sensitivity (although many massive weight loss patients have little or no NAC sensitivity pre-operatively)[53-55]. In rare instances, the NAC may be partially or totally lost secondary to ischemic changes caused by surgery and patients should be fully informed pre-operatively[56] of this unfortunate possibility.

## EXTREMITIES

Contour deformities of the extremities after massive weight loss can be quite significant. Large amounts of excess skin draped from the proximal half of the arm gives the appearance of a "bat wing", while excess skin hanging from the thigh is unsightly and prevents patients from wearing bathing suits and shorts[19]. The unsightly appearance of their extremities will often prompt patients to wear long sleeves and pants at all times. To correct these deformities, the excess tissue must be directly excised. The pattern of excision used is similar for both the arms and the legs, since the deformity is essentially the same (a circumferential excess)[26,57,58].

For patients with a mild excess of tissue, the incision can usually be hidden in either the axilla (for a brachioplasty or arm lift)[59] or the groin (for a thigh lift)[60-62] using an elliptical pattern of excision perpendicular to the long axis of the extremity. This type of excision ("mini" brachioplasty or thigh lift) is usually insufficient to

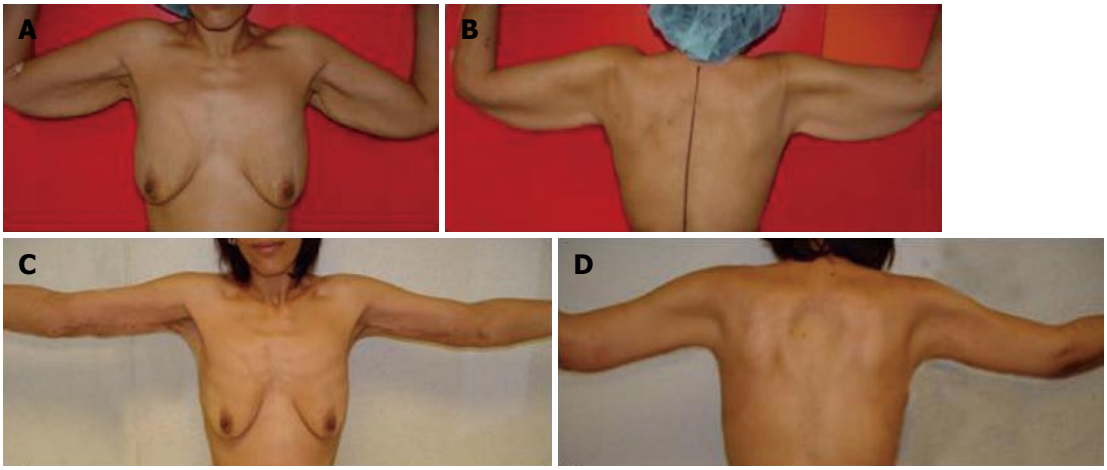

**Figure 5** Typical appearance of upper extremity deformity after massive weight loss. Note the "bat-wing" appearance of the proximal arm (**A** and **B**); One month after brachioplasty, there is significant improvement in contour (**C** and **D**). The incision is designed to keep the resultant scar on the medial surface of the upper extremity so that it is hidden when the patient stands at rest with her arms at her side.

correct the amount of excess skin present in most massive weight loss patients[63].

For more significant deformities, an ellipse parallel to the longitudinal axis of the extremity is utilized, with or without the aforementioned perpendicular ellipse[58] (Figure 5A-D). Although this approach can provide remarkable improvement, brachioplasty scars are long and tend to hypertrophy[64,65]. Furthermore, contractures across the axilla may occur despite use of "z-plasty" designs. For brachioplasty, the longitudinal scar is best placed along the medial surface of the upper arm where it is not visible while the patient's arms are at rest[32,66,67]. Similarly, for thigh lifts a scar is best placed medially along the thigh, although some surgeons advocate use of an anteriorly or laterally based excision[62,68,69]. Patients must be thoroughly counseled regarding the inevitable scars as well as other common complications, such as persistent edema, parasthesias and dysesthesias as well as delayed wound healing, particularly in the groin area[62].

## SUCTION-ASSISTED LIPECTOMY (LIPOSUCTION, SAL)

Although some patients may experience an evenly distributed massive weight loss resulting in a relatively thin layer of subcutaneous tissue throughout their body, for most patient this is not the case. In order to address these recalcitrant adipose deposits which are common in the upper abdomen, back, flanks, arms and legs, plastic surgeons utilize suction-assisted lipectomy (SAL), more commonly known as liposuction[70]. Liposuction is not for weight loss, although as much as 6-8 liters or more of fat may be removed safely in a single session[71]. Liposuction is used to "sculpt" areas of the body that need further refinement in their contour. SAL, like most procedures, is effective and safe when performed by a board certified plastic surgeon in an appropriately monitored setting. Although SAL alone is commonly performed as an ambulatory procedure, when more than 5 liters of lipoaspirate is removed in one session, the procedure is considered "large volume" liposuction and overnight monitoring is required[71]. SAL may be used concurrently with any of the above mentioned contouring procedures, or may be used afterwards to fine tune the results. Although not very painful, liposuction can prolong swelling and edema when used in conjunction with other body contouring procedures. A less frequent complication of SAL is persistent seroma. Transient paresthesias and bruising may also occur after SAL[72].

## SEQUENCE OF SURGERY

Body contouring after massive weight loss is a significant undertaking on the part of both the surgeon and the patient. As stated earlier, many of these patients are chronically malnourished which predisposes them to increased surgical morbidity[21,73]. The surgery itself is laborious and sometimes involves considerable blood loss. For these reasons, most surgeons stage the procedures[19]. Usually the abdomen and torso are treated first and, in less severe cases, may be combined with brachioplasty, thigh lift and or breast lift. The number of procedures performed at one time depends upon the health of the patient and the number of surgeons available. In centers where a "total body lift" is performed, two teams operating simultaneously are mandatory to limit time under anesthesia, although such procedures may still take eight or more hours[39].

As mentioned previously, special consideration must be given to the massive weight loss patient, since they are often relatively malnourished and even anemic secondary to their weight loss. Although severe complications such as pulmonary embolism or even death are relatively rare (0.02% or less)[74], minor complications such as seroma, infection or delayed wound healing are common with some surgeons reporting a greater than 70% total complication rate, especially in refractory smokers[16]. However, most patients will gladly trade these minor complications for the significant improvements in their body contour and by direct extension, their self image and confidence.

## MOLECULAR ADVANCES IN WEIGHT LOSS

Few drugs remain approved for weight loss. The dearth of pharmaceutical solutions is not for a lack of effort on the part of medical researches, but rather the complex nature of obesity. Most promising advances in weight loss technology surround the hormones leptin and ghrelin,

and the peptide known as PYY. These molecules all help regulate mechanisms of obesity. Currently, pharmaceutical companies are developing a variety of compounds to modulate the effects of these compounds.

## CONCLUSION

Body contouring after bariatric surgery is currently the fastest growing field within plastic surgery[75]. At the same time, body contouring after massive weight loss continues to evolve as surgeons refine patient selection, technique, and improve safety. However, the surge in weight loss-related surgeries has resulted in ethical questions, such as who should be treated, which operation is best, and who should be performing the surgeries. For these reasons, national consortiums have been founded to develop consensus responses to some of these questions. Meanwhile, though post-bariatric surgery is associated with a greater frequency of complications than "traditional" body contouring, the major transformation imparted by these procedures results in a high degree of patient satisfaction.

## Abstract

Surgical resection with lymphadenectomy is the mainstay of treatment for all resectable esophagogastric junction tumors, prior to systemic generalization of the disease. This makes accurate pre-treatment staging and classification of the tumors most demanding. A well-established and internationally accepted classification for adenocarcinomas of the esophagogastric junction (AEG) helps to choose the appropriate surgical approach and to make results from different institutions comparable. Distal esophageal adenocarcinomas (AEG Ⅰ) are distinguished from true cardia carcinomas (AEG Ⅱ) and subcardiac gastric cancers (AEG Ⅲ). Substantial advancements in this surgical field during the preceding decades have clearly revealed that individualization of the surgical strategy is the key to successfully approaching these entities. In this review we discuss the surgical management of esophagogastric junction tumors with a tailored surgical strategy.

**Key words:** Adenocarcinoma of the esophagogastric junction; Esophageal cancer; Gastric cancer; Surgical resection

## INTRODUCTION

Different tumor entities arise in the vicinity of the esophagogastric junction. The appropriate classification of these entities is essential for choosing the appropriate surgical approach and making results from different instutions comparable. Surgical resection is the mainstay of treatment for esophagogastric junction tumors of all resectable tumor stages prior to systemic generalization of the disease. Therefore a meticulous pretreatment staging is mandatory for planning the therapeutic approach. The major goal of surgical resection is complete removal of primary tumor together with its lymphatic drainage, because R0-resection (microscopic complete removal of the tumor) as well as nodal status and lymph node ratio (number of infiltrated nodes per node removed) are major prognostic factors. In locally advanced tumors, with low chances for R0 resection by means of primary surgery, multimodality treatment is attempted, aiming at downsizing the primary tumor and possibly downstaging the disease.

## CLASSIFICATION

The appropriate and uniform classification of carcinomas arising within the vicinity of the esophagogastric junction is essential both for planning therapeutic/surgical approaches and for making results from different institutions comparable. Well-established and meanwhile increasingly used world-wide is the classification of "adenocarcinomas of the esophagogastric junction" (AEG)[1,2]. Adenocarcinomas of the distal esophagus (AEG type Ⅰ) are distinguished from carcinomas arising at the level of the anatomical cardia (AEG type Ⅱ) and subcardiac gastric cancers (AEG Ⅲ). The classification has been introduced 17 years before from a surgical viewpoint[1,2]. But meanwhile it becomes more and more evident, that this classification also reflects the pathophysiology of different entities very well[3].

The center of the main tumor mass in relation to the anatomical cardia comprises the basis for the AEG-classification. For clinical usage, a definition of the anatomical cardia from the endoscopist's viewpoint is required. The cardia is localized, where the gastric folds end. The Z-line (correlative to the squamocolumnar junction) is shifted proximally in Barrett's esophagus but not at the level of the cardia, like it is under physiologic conditions[4,5]. The AEG classification is recommended by the consensus conference of the International Society for Diseases of the Esophagus[2] and increasingly accepted and used worldwide[6-11].

## PATHOPYSIOLOGY AND EPIDEMIOLOGY

AEG type I tumors are found in the majority of patients with Barrett's cancers, arising within the precancerous

Barrett's esophagus[12]. In patients with no evidence of Barrett's metaplasia on initial work-up, this can be due to an advanced primary tumor "overgrowing" the intestinal metaplasia. It has been shown that Barrett's metaplasia can get "unmasked" by preoperative chemotherapy in a substantial number of cases[13]. In the series by Theisen *et al*[13] over 97% of the patients with AEG I tumors are associated with Barrett's esophagus.

Carcinogenesis within the specialized intestinal metaplasia follows a metaplasia-intraepithelial neoplasia-carcinoma sequence. Initiation and progression of the disease process are promoted by the chronically damaging effect of gastroesophageal reflux[4,5]. Gastroesophageal reflux disease and its complication Barrett's esophagus are associated with a compromised lower esophageal sphincter. Patients have a high prevalence of hiatal hernia, which has been evaluated as a risk factor for esophageal adenocarcinoma[14,15]. Furthermore, patients are often obese (pathologically elevated body mass index), and only occasional alcohol drinkers in sharp contrast to patients with squamous cell cancers of the esophagus. It has been clearly demonstrated that the histological tumor types (esophageal adenocarcinomas and squamous cell cancers) comprise two entirely different entities[16] occurring in completely different types of patients.

The association of hiatal hernias and obesity with cancer development decreases in patients with tumors localized more distally. In patients with AEG Ⅱ/Ⅲ tumors long-lasting GERD and correlated morbidity (hiatal hernias, obesity) have diminished importance as risk factors[14,17]. AEG Ⅱ and Ⅲ tumors also have only a weak or no association with specialized intestinal metaplasia of the esophagus in the majority of patients[3]. Regarding the pathophysiology, these tumors seem to have more similarities with gastric cancers. A strong association with *H pylori* and intestinal metaplasia at or below the gastric cardia has been demonstrated[18].

Nevertheless, there are numerous hints supporting the concept of distinguishing these entities from gastric cancers, and regarding them as own entities. Especially striking is the fact that their incidence is increasing, compared to the decreasing incidence of gastric cancers.

## PRE-TREATMENT STAGING

Accurate pre-treatment staging is most demanding, because therapy for esophagogastric junction tumors must be performed by adjusting stage of the disease. Tailored surgical strategies are based on accurate localization of the primary tumor and its classifcation.

For all upper gastrointestinal tumors, endoscopy is the basic staging modality, allowing direct visualization of the primary tumor, exact localization and establishment of the diagnosis by means of biopsy. An up-to-date practice guideline by the American Society for Gastrointestinal Endoscopy deals with the use of endoscopy for esophageal cancer, and addresses the broad spectrum of endoscopy. New developments in the field of endoluminal diagnostics make recognition of early lesions more and more precise, especially by introduction and evaluation of new technologies, i.e. high resolution devices[19].

The depth of tumor invasion defines the T-category according to the TNM-classification system of the UICC, which is commonly used for staging[20]. For defining depth of invasion of a primary tumor in the clinical setting, endoscopic ultrasound (EUS) is the best staging modality. It has a major impact on choosing the appropriate treatment strategy (retrospective, but blinded evaluation)[21]. Furthermore, definition of T- and N-categories by EUS has been demonstrated to be of value for predicting long-term survival (prospective evaluation of 150 patients)[22].

CT scan remains the preferred staging method for exclusion of systemic tumor spread[23], providing anatomical information. The more functional positron emission tomography with fluorodeoxyglucose (FDG-PET), visualizing the regional glucose metabolism, is increasingly used for staging[23,24] and response evaluation during multimodality treatment[24,25]. Many studies have assessed the value of PET as a staging method and the former is meanwhile decreasing to a more realistic view. By critically reviewing their data, Kneist *et al* have demonstrated that the use of PET does neither lead to a different therapeutic approach nor provide new information on the indication for surgery.

In our experience, the use of FDG-PET as a staging method should be limited to early tumor stages, namely early cancers (T1) with very low prevalence of lymphatic or systemic tumor spread, and systemically disseminated disease. This is the clue to make usage of FDG-PET cost-effective.

## MULTITREATMENT MODALITY

In the Western world, neoadjuvant treatment concepts for administering systemic antineoplastic therapy (i.e. chemotherapy or chemoradiation prior to subsequent surgical resection) are preferred over adjuvant chemotherapy. Studies on treating adenocarcinomas of the esophagogastric junction are scarce, due to non-uniform classification. These tumors are either included in esophageal or gastric cancer trials. Furthermore some studies on esophageal cancer still have not distinguished adenocarcinoma from squamous cell cancers, although this is essential, because these histological tumor types comprise two entirely different entities[16].

Only two studies on neoadjuvant treatment of esophageal cancer have been able to show a survival benefit with this concept[26,27]. Meta-analyses including 9 and 11 randomized trials[28,29] have demonstrated decent survival benefits. But these studies deal with esophageal cancer, and not exclusively adenocarcinoma. Nevertheless, the major message of these trials is probably true for carcinomas of the esophagogastric junction. Only a subgroup of patients undergoing neoadjuvant treatment experiences a survival benefit. These are the 'responders'. 'Non-responders' by contrast do progress or deteriorate during preoperative treatment. In our experience the response frequency to the preoperative antineoplastic regimens accounts for 30%-60%[26,27].

An amazing concept for assessing the early response

during the course of the antineoplastic regimen is response evaluation with FDG-PET. This has been demonstrated in esophageal squamous cell cancers[24,30] and also in AEG tumors and gastric cancers[25,31]. It has been recognized that tumors responding to chemotherapy show an early decrease of glucose uptake. This tool has been used and intensively studied concerning the selective usage of neoadjuvant protocols.

## SURGICAL STRATEGIES

Complete removal of the primary tumor (R0 resection) is one of the major prognostic factors in adenocarcinomas of the esophagogastric junction[12]. Its predictive value is strong as demonstrated by univariate analysis[32] (Figure 1). Multivariate analysis demonstrates that R0 resection is independent of other strong predictors of survival, like T, N and M[12]. Thus, the primary goal of surgical resection of esophagogastric junction tumors is complete removal of the primary tumor, together with its lymphatic drainage. Which surgical approach best suits this purpose is still controversial. A vast variety of approaches for surgical resection of tumors of the esophagogastric junction has been proposed, including abdominothoracic *en bloc* esophagogastrectomy, subtotal esophagectomy with resection of the proximal stomach, total gastrectomy with transhiatal resection of the distal esophagus, limited resection of the esophagogastric junction.

In the past 20 years we have operated on more than 1500 patients with AEG tumors. A variety of approaches have been assessed[13]. Based on this surgical experience tailored surgical strategies have been developed, with respect to distinct requirements of the different AEG tumor types and different stages of the disease. Although still practiced[33], complete esophagogastrectomy has been abandoned as a procedure for carcinomas within the esophagogastric junction.

### *AEG Ⅰ tumors (distal esophageal adenocarcinomas)*

It is beyond dispute that AEG I tumors require an esophagectomy. Resection must include complete removel of the precancerous Barrett's esophagus[1]. For this purpose, preoperative clipping of the oral margin (level of the squamocolumnar junction) by the endoscopist is recommended. These tumors, which are mostly Barrett's cancers, have been shown to metastasize predominantly to the mediastinal lymph nodes[34]. But lymphatic spread occurs later than in esophageal squamous cell cancers and the prevalence of lymphatic metastases is lower in distal esophageal adenocarcinomas[12].

The transthoracic or transhiatal resection of Barrett's cancers is the best approach which is a topic of intensive research. Transthoracic esophagectomy with *en bloc* removal of esophagus and adjacent lymph nodes is the optimal approach in respect to radical resection of tumors. These lymph nodes are left behind with transhiatal (transmediastinal) esophagectomy, because a formal lymphadenectomy is not performed with this technique. The transhiatal approach can result in a reduced postoperative morbidity and mortality, because

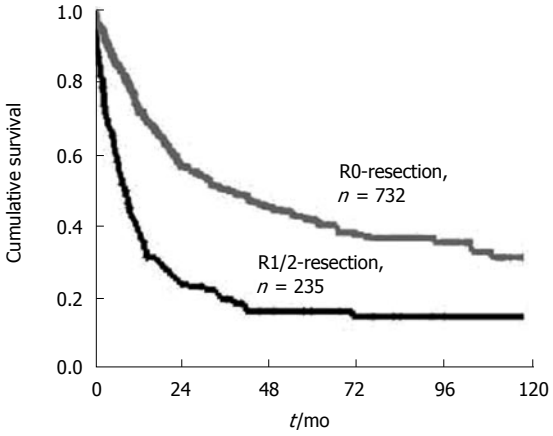

**Figure 1** Overall 10-year survival rate of patients with resected adenocarcinoma of the esophagogastric junction. Patients with complete macroscopic and microscopic tumor resection (R0 resection) versus patients with resection (R1/R2 resection) (Date of the Chirurgische Klinik und Poliklinik, Klinikum rechts der Isar der TU Munchen 1982-1999).

thoracotomy is avoided. This view is not supported by a recent multicenter trial from the USA[35]. In this large scale investigation the reported differences between transhiatal and transthoracic approaches in respect to morbidity and mortality are not statistically significant.

Another prospective trial, a recent single center study from Amsterdam/The Netherlands, comparing the two approaches in a series of patients with distal esophageal adenocarcinomas[36] showed that patients may benefit from transthoracic resection, thus having a longer survival. A clear superiority of either procedure has not been demonstrated, requiring individualized strategy. For all patients who are likely to benefit from the complete nodal clearance, transthoracic *en bloc* esophagectomy appears to be the procedure of first choice. In terms of radical resection, transhiatal esophagectomy is appropriate for earlier distal esophageal adenocarcinomas (with low propability of lymphatic involvement) and patients with substantial co-morbidity (who may benefit from avoiding the thoracotomy)[3,34].

### *AEG Ⅱ/Ⅲ tumors (cardia carcinomas and subcardiac gastric cancers)*

In our experience, total gastrectomy with transhiatal resection of the distal esophagus (transhiatally extended gastrectomy) is the best approach for AEG Ⅱ tumors[37]. Short-term postoperative results, i.e. morbidity and mortlity, are better with this approach, compared to transhiatal esophagectomy (e.g. 5.6% *vs* 1.9% mortality in a consecutive patient series of 46 transmediastinal esophagectomies and 103 extended total gastrectomies). Multivariate analysis has shown that R0 resection is the single most important prognostic factor. Regression analysis of the subgroup of R0-resected patients has demonstrated that absence of lymph node metastases and extended gastrectomy are two independet predictors of long-term survival[37] (Figure 2). This approach (extended gastrectomy superior to transhiatal esophagectomy for AEG Ⅱ) is also supported by data from other institutions[38,39].

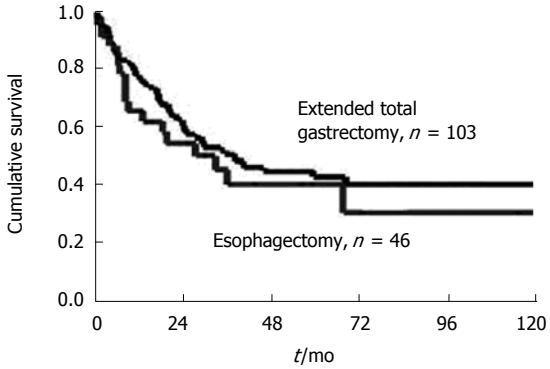

**Figure 2** Ten-year survival rate of patients with R0-resected true carcinoma of the gastric cardia (AEG Type-Ⅱ). Radical transmediastinal esophagectomy versus extend total gastrectomy (Date of the Chirurgische Klinik und Poliklinik, Klinikum rechts der Isar der TU Munchen 1982-1999).

## EXTENT OF LYMPHADENECTOMY AND SPLENECTOMY

The required extent of lymphadenectomy for AEG tumors has never been studied systematically. Similar to the findings of Japanese institutions, we have demonstrated that patients with tumors limited to the mucosa (pT1a) have virtually no lymph node involvement. Furthermore lymph node metastases are uncommon in carcinomas invading only the submucosa (pT1b). This holds also true, when more sensitive methods (immunohistochemistry/PCR techniques) are used for detection of micrometastases. Patients with more advanced AEG Ⅱ carcinomas harbor metastases in lymph nodes of paracardial region, lesser and greater curvatures, left gastric artery towards celiac axis, splenic artery, superior border of the pancreas towards the splenic hilum, lower posterior mediastinum, left adrenal gland and left renal vein[34,27,40,41].

This comprises the basis for the current concept of standard lymphadenectomy for AEG Ⅱ and Ⅲ tumors. Lymphadenectomy (in addition to lymph nodes adjacent to the gastrectomy specimen) starts with removal of the lymph nodes along the splenic artery towards the splenic hilum. Lymph nodes around the left renal vein are included. Formerly a retroperitoneal lymphadenectomy with left-sided pancreatic resection plus splenectomy is frequently performed in addition. Although the number of resected lymph nodes is increased with this procedure, the negative side-effects are predominant. A substantial number of septic complications, pancreatic fistulae and abscess formation have been observed[42-44].

## LIMITED RESECTION

Extended gastrectomies, especially esophagectomies, are associated with a considerable morbidity and mortality. Although these indicators for short-term postoperative outcome have been markedly improved during recent years[2,45,46], the remaining risk is nevertheless substantial. Furthermore, the quality of life after esophagectomy and gastrectomy is compromised. This fact has led to limited resections of adenocarcinomas of the esophagogastric junction. Resection of the distal esophagus and esophagogastric junction, with regional lymphadenectomy and jejunal interposition for reconstruction, has been described as a suitable surgical alternative[5,6]. Reconstruction is done by jejunal interposition and the short- and long-term results are excellent and the quality of life is improved as expected.

## THERAPEUTIC STRATEGIES

Esophagectomy is the appropriate approach for surgical resection of AEG Ⅰ tumors, whereas transhiatally extended gastrectomy is recommended for AEG Ⅱ and Ⅲ tumors. In our experience it is not necessary to perform more extended procedures in most cases, like esophagogastrectomy. Limited resection of the esophagogastric junction and reconstruction with interposition of a jejunal loop can be successfully applied to early cancers arising in the vicinity of the EGJ[6]. The value of neoadjuvant treatment concepts is not entirely clear as yet. Although a subset of patients benefits from chemotherapy preoperatively, the effective tool for response prediction is positron emission tomography (PET).

## FUTURE PERSPECTIVES

Further individualization of surgical strategies can be expected. The most striking problem with surgery of esophagogastric junction tumors is that the subset of patients who benefit from neoadjuvant protocols is unknown. Therefore the patients who do not respond to this aggressive regimen would suffer from the side-effects of this therapy. Response prediction for defining subsets of patients benefiting most from neoadjuvant treatment regimens would become a matter of molecular characterization. It might become possible to distinguish responders from non-responders before initiating the treatment according to their genetic profiles. The molecular characterization by genomic profiling perhaps can predict lymph node status and survival, as in gastric cancer[47] and Barrett's cancer[48] and other entities. Regarding the surgical technique, progress can be achieved with the technique of sentinel lymph node biopsy[49]. This technique helps us to individualize the extent of required lymphadenectomy, which is important because it is a major factor contributing to postoperative morbidity and mortality.

In the near future, new technical devices like a new FDG-PET hand device, help to identify metastatic lymph node intraoperatively. Further development in the field of nuclear medicine with new tracers and more sensitive detection systems is perhaps helpful regarding pre-treatment staging and intra-operative identification of metastatic disease. The combination of functional (PET/scintigraphy) and antomical (CT) information helps to summarize information of the major staging methods for esophagogastric junction tumors. Although at its very beginning of clinical application[50], PET/CT is an amazing tool.

## KEY ISSUES

Surgical resection is the mainstay of treatment for esophagogastric junction tumor prior to its systemic generalization.

A meticulous preoperative staging based on appropriate classification is required for choosing the appropriate therapeutic approach and surgical strategy.

Endoscopy, endoscopic ultrasound, pharyngoesophagography and CT scan are the basic staging modalities. The functional FDG-PET scan, visualizing areas of increased glucose uptake, is increasingly used for staging and response evaluation during multi treatment modality.

Uniform classification of tumors within the vicinity of the esophagogastric junction is important for choosing the appropriate surgical approach and making results from different institutions comparable. The classification of adenocarcinomas of the esophagogastric junction (AEG), can distinguish distal esophageal adenocarcinomas (AEG I) from true cardia carcinomas (AEG Ⅱ) and subcardiac gastric cancers (AEG Ⅲ).

AEG I tumors are usually Barrett's cancers arising in the precancerous Barrett's esophagus under the chronically damaging effect of acid. AEG Ⅱ and Ⅲ tumors share more properties with gastric cancers, but comprise nevertheless distinct entities

Esophagectomy is the appropriate surgical procedure for AEG I tumors, whereas transhiatally extended gastrectomy (with resection of an esophageal sleeve) is the best procedure for AEG Ⅱ and Ⅲ tumors. Esophagogastrectomy has been abandoned in most institutions, because it is associated with a substantial morbidity and mortality as well as a bad quality of life of the patients. Although its value has not been fully defined yet, a substantial number of patients with locally advanced tumors seem to benefit from neoadjuvant treatment concepts, aiming at down staging and down sizing of the primary tumor.

## Abstract

**AIM:** To establish a multidrug resistant (MDR) cell subline from the human hepatocarcinoma cell line (HepG2) in nude mice.

**METHODS:** HepG2 cell cultures were incubated with increasing concentrations of adriamycin (ADM) to develop an ADM-resistant cell subline (HepG2/ADM) with cross-resistance to other chemotherapeutic agents. Twenty male athymic BALB/c-nu/nu mice were randomized into HepG2/nude and HepG2/ADM/nude groups (10 in each group). A cell suspension (either HepG2 or HepG2/ADM) was injected subcutaneously into mice in each group. Tumor growth was recorded, and animals were sacrificed 4-5 wk after cell implantation. Tumors were prepared for histology, and viable tumor was dispersed into a single-cell suspension. The $IC_{50}$ values for a number of chemotherapeutic agents were determined by 2, 3-bis (2-methoxy-4-nitro-5-sulfophenyl)-2H-tetrazolium-5-carboxanilide inner salt (MTT) assay. Rhodamine-123 retention/efflux and the level of resistance-associated proteins were determined by flow cytometry. The mRNA expression of *mdr1*, *mrp* and *lrp* genes was detected using reverse transcriptase polymerase chain reaction (RT-PCR) in HepG2/nude and HepG2/ADM/nude groups.

**RESULTS:** The appearances of HepG2/nude cells were slightly different from those of HepG2/ADM/nude cells. Similar tumor growth curves were determined in both groups. A cross-resistance to ADM, vincristine, cisplatin and 5-fluorouracil was seen in HepG2/ADM/nude group. The levels of P-glycoprotein and multidrug resistance-associated proteins were significantly increased. The mRNA expression levels of *mdr1*, *mrp* and *lrp* were higher in HepG2/ADM/nude cells.

**CONCLUSION:** ADM-resistant HepG2 subline in nude mice has a cross resistance to chemotherapeutic drugs. It may be used as an *in vivo* model to investigate the mechanisms of MDR, and explore the targeted approaches to overcoming MDR.

**Key words:** Hepatocarcinoma; Multidrug resistance; Adriamycin; Model; Nude mouse

## INTRODUCTION

Tumor cell drug resistance represents a significant obstacle to successful chemotherapy. Cells which have acquired resistance to one anti-tumor drug usually show resistance to other anti-tumor drugs[1]. This cellular resistance is known as multidrug resistance (MDR). Overexpression of P-glycoprotein (P-gp), multidrug resistance-associated protein (MRP), and lung resistance-related protein (LRP) is associated with development of MDR in cancer cells[2]. P-gp acts as an energy-dependent outward transport pump and can decrease intracellular drug accumulation by removing chemotherapeutic drugs from the cytoplasm[3]. A correlation between *mdr1* mRNA expression and drug resistance has been demonstrated using human cancer cell lines[4]. MRP is an ATP-dependent transmembrane protein related to MDR[5], and LRP is also expressed in a MDR lung cancer line[6]. The *mrp* and *lrp* genes encoding MRP and LRP, respectively, have been cloned in MDR cell lines that do not exhibit P-gp overexpression.

Several cell lines from resistant carcinomas have been established to elucidate the mechanisms of MDR. MDR cell lines and the expression of three resistance-associated markers (P-gp, MRP and LRP) have been extensively studied *in vitro*[7]. These resistant tumor cell lines have been established *in vitro* from P-gp negative cell lines *via* the exposure of chemotherapeutic drugs such as adriamycin (ADM), and their acquired resistance is mainly dependent on P-gp expression levels[8]. Unfortunately, it seems that the predictive value of MDR in established cell lines *in vitro* for determining the responsiveness of a relative tumor in clinical practice is poor. This misinterpreted role of

MDR may explain the failure of *in vivo* strategies to reverse MDR by using modulators in solid tumors[9,10]. The aim of this study was to establish a multidrug resistant subline from a human hepatocellular carcinoma line (HepG2) in nude mice, and to acquire more insights into *in vivo* drug resistance.

## MATERIALS AND METHODS

### Drugs and chemicals

2, 3-bis (2-methoxy-4-nitro-5-sulfophenyl)-2H-tetrazolium-5-carboxanilide inner salt (MTT), ADM, vincristine (VCR), cisplatin, (CDDP), 5-fluorouracil (5-Fu), 2-(6-amino-3-imino-3H-xanthen-9-yl)-benzoic acid methyl ester (rhodamine123, Rh123), and dimethyl sulphoxide (DMSO) were obtained from Sigma (St Louis, Missouri, USA). Mouse monoclonal antibody MRK16 was supplied by Santa Cruz Biotechnology (Santa Cruz, California, USA). Rat monoclonal antibody MRPr1 and mouse monoclonal antibody LRP56 were obtained from Caltag Laboratories (Burlingame, California, USA). Fluorescein isothiocynate (FITC)-labeled goat anti-mouse immunoglobulin G (IgG) was from Tago Immunologicals (Camarillo, California, USA), and mouse monoclonal IgG was from Chemicon (Temecula, California, USA). TRIzol, RT-PCR kit, and primers were supplied by Life Technologies Inc. (Rockville, Minnesota, USA).

### Cell lines

HepG2 was provided by the Institute of Biochemistry and Cell Biology (Chinese Academy of Sciences, Shanghai, China). Cells were grown as monolayers in RPMI 1640 medium, supplemented with 10% (v/v) heat-inactivated fetal calf serum, 1.0 mmol/L sodium pyruvate at 37℃ in a humidified atmosphere containing 50 mL $CO_2$. ADM was added to HepG2 cell cultures in stepwise increasing concentrations (starting at 0.001 mg/L and ending up to 1.0 mg/L) to develop a drug resistant cell subline (HepG2/ADM). After removal of dead cells, the remaining viable cells were identified as being drug resistant, and then cultured in a higher concentration of anticancer drug again. With the gradual increase in drug concentration, cells could finally be maintained in a culture medium containing 1000 μg/L ADM. The MDR characteristics of these HepG2/ADM cells were tested at various concentrations of anticancer drugs including ADM, VCR, CDDP and 5-Fu.

### Animal experiments

The animal study was approved by the Experimental Animal Committee of Chongqing University of Medical Sciences, and all animal experiments adhered to the Animal Welfare Committee guidelines. Male athymic BALB/c nu/nu mice (4-6 wk old) were obtained from the Institute of Materia Medica (Chinese Academy of Sciences, Shanghai, China) and housed in laminar-flow cabinets under specific pathogen-free (SPF) conditions.

Twenty male athymic BALB/c-nu/nu mice were randomized into HepG2/nude and HepG2/ADM/nude groups, 10 in each group. A suspension of either HepG2 or HepG2/ADM cells ($10^7$ cells in 0.15 mL of Hanks' solution) was injected into the right subaxillary region of mice in each group. After implantation, the tumor growth was detected daily by measuring its diameter with Vernier caliper. Tumor weight (TW) was calculated using the following formula: TW (mg) = tumor volume ($mm^3$) = $d^2 \times D/2$, where d and D are the shortest and longest diameters, respectively. Animals were sacrificed 4-5 wk after implantation when the subcutaneous tumor reached the size of 1.5 cm in diameter, and samples were harvested. Tumor tissue blocks were created for histological examinations. Viable tumor tissue was ground into a single-cell suspension in a loose-fitting ground glass homogenizer. Cell suspensions were washed twice with DMEM, and cultured in RPMI 1640 medium supplemented with 10% fetal calf serum.

### MTT assay

MTT cell proliferation assay was performed to determine the percentage of viable HepG2 or HepG2/ADM cells *in vitro,* or HepG2/nude and HepG2/ADM/nude cells were derived from viable tumor tissues *in vivo* after incubation with various concentrations of anti-tumor drugs. In brief, cell suspensions were seeded in 96-well culture plates at a density of $1 \times 10^5$ cells/well. After 24 h incubation, the cells were exposed to the drug under study for 72 h, followed by 4 h incubation with the tetrazolium staining. Using a multiwell spectrophotometer reader (Molecular Devices, Menlo Park, California, USA), the optical intensity at 570 nm was measured, and cell viability was assessed in each well from the level of a dark blue formazan crystal created. Each assay was performed in triplicate, and RPMI 1640 medium was used as a blank control. The $IC_{50}$ values were defined as the concentration resulting in 50% cell survival. After the dose-response curve was plotted, the $IC_{50}$ for each anti-tumor drug was determined. The relative resistance to anti-tumor drugs was determined by dividing the $IC_{50}$ values obtained for HepG2/ADM cells by those of HepG2 cells.

### Rhodamine 123 assay

A total of $1 \times 10^6$ HepG2 or HepG2/ADM cells were seeded into each well of a 12-well culture plate, and incubated for 24 h. After the culture medium was replaced by Hanks' solution supplemented with 10 mmol/L HEPES buffer and 10% fetal calf serum (FCS), the cells were incubated for 15 min at 37℃. Rhodamine 123 (Rh123) was then added to give a final concentration of 10 g/L. The cells were further incubated for 30 min, washed twice with ice-cold PBS, harvested with trypsin, and suspended in PBS. The cells were further incubated in Rh123-free medium for 30 min to determine the Rh123 efflux. Cell surface-associated fluorescence was measured after addition of ice-cold Rh123 to the cells. Using the FACS caliver system (Elite ESP, Coulter Electronics, Miami, USA), the fluorescence intensity of Rh123 was measured at excitation and emission wavelength of 485 nm and 530 nm, respectively.

### Flow cytometry

The protein levels of P-gp, MRP and LRP were determined by flow cytometry using the monoclonal

antibodies MRK16, MRPr1 and LRP-56. A total of 1 × $10^6$ HepG2 or HepG2/ADM cells were incubated in suspension with 10 g/L of the primary antibodies and an isotype-matched mouse IgG2a, respectively, for 1 h at 37℃. After washing, the cells were incubated with 0.175 g/L FITC-labeled goat anti-mouse IgG (for P-gp and LRP-56) or FITC-labeled goat anti-rat IgG (for MRPr1) for 1 h at 37℃. The fluorescence intensity (excitation wavelength 488 nm) was determined using an Epics ESP flow cytometer (Coulter Electronics, Miami, USA). The ratio of the specific fluorescence intensity of the HepG2/ADM cells to that of the HepG2 cells indicated the relative level of resistance-associated proteins.

### RT-PCR

Reverse transcriptase polymerase chain reaction (RT-PCR) was used to measure the mRNA expression of *mdr1*, *mrp* and *lrp* genes. The primers of *mdr1*, *mrp* and *lrp* are as follows: *mdr1*: 5'-GGC TCC GAT ACA TGG TTT TCC-3', 3'-TTC AGT GCG ATC TTC CCA GC-5'; *mrp*: 5'-TGA AGG ACT TCG TGT CAG CC-3', 5' GTC CAT GAT GGT GTT GAG CC-3'; *lrp*: 5'-CCT CGA GAT CCA TTG TGC TGG-3', 5'-CAC AGG GTT GGC CAC TGT GCA-3'. β-actin expression was used as a control for the amount of RNA used, and its primer was 5'-ACC CCC ACT GAA AAA GAT GA-3', and 5'-ATC TTC AAA CCT CCA TGA TG-3'. Total RNA was extracted from cells using TRIzol. *mdr1*, *mrp*, *lrp* and β-*actin* RNA transcripts were detected using RT-PCR. An aliquot of each reaction mixture was then analyzed by electrophoresis using 1.5% agarose gel. Densitometry was performed with an UVP gel image analysis system (BIO-RAD, Melville, NY, USA) and the ratio between the target and control PCR products was determined by dividing the densitometric volume of the target band by that of the control band.

The PCR cycle included heat denaturation at 94℃ for 45 s, annealing at 60℃ for 45 s, and polymerization at 72℃ for 90 s. cDNA was prepared from 4.5 mg of total RNA using the GeneAmp RNA PCR kit. The reaction mixture was incubated at 42℃ for 30 min and then heated for 5 min at 99℃ to inactivate MMLV reverse transcriptase. The cDNA derived from 0.15 mg of total RNA was mixed with 20 mL reaction mixture (10 mmol/L Tris-HCl, pH 8.3, 50 mmol/L KCl, 1.25 mmol/L $MgCl_2$, 188 nmol/L gene-specific primers and 0.625 U AmpliTaq DNA polymerase) with β-actin (0.765 amol). Thirty-two cycles of PCR were performed, each consisting of heat denaturation at 94℃ for 45 s, annealing at 55℃ for 1 min, and polymerization at 72℃ for 2 min.

### Statistical analysis

All observed data were expressed as mean ± SD. The statistical significance of any observed difference between the mean values of HepG2 and HepG2/ADM groups was evaluated using the Student's *t* test. $P < 0.05$ was considered statistically significant.

## RESULTS

### Histology

Both HepG2/nude and HepG2/ADM/nude tumor cells demonstrated polygonal epithelial-like morphology, with firm attachment to the culture flask. They had conspicuous large nuclei. Electron microscopy showed abundant microvilli and projections on the cell surface in both cell lines. Some of the projections on HepG2/nude cells were long, terminated with swellings, while those of HepG2/ADM/nude cells were short and compact. Both cell types had many lysosomes in the cytoplasm and were usually concentrated on one side of the HepG2/nude cells, but scattered around the cytoplasm in HepG2/ADM/nude cells. No obvious desmosomes and tight junctions were observed in the cells.

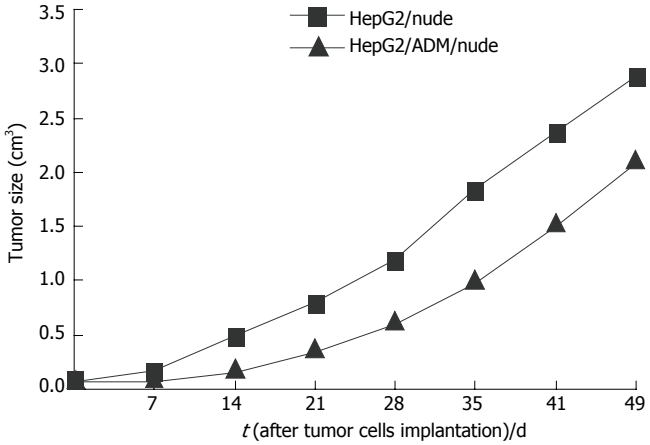

**Figure 1** Growth curves of tumors after implantation of HepG2 or HepG2/ADM cells in nude mice. Athymic mice were injected s.c. with 1 × $10^7$ (0.2 mL/mouse) HepG2 or HepG2/ADM cells on d 0. Symbols and bars denote the means and SD for 10 nude mice in the HepG2 group and 10 nude mice in the HepG2/ADM group.

### Tumor growth

Tumor growth was evaluated in nude mice after subcutaneous implantation of HepG2/nude and HepG2/ADM/nude cells. Mean tumor volumes measured with a Vernier caliper are shown in Figure 1.

### MDR characteristics

HepG2/ADM tumor cells became drug resistant following incubation of HepG2 cells with increasing concentrations of ADM (Table 1). In addition to direct resistance to ADM, these cells were also resistant to other chemotherapeutic agents including VCR, 5-FU and CDDP. The $IC_{50}$ values for the drugs were significantly greater in the HepG2/ADM group than in the HepG2 group (Table 1), indicating that HepG2/ADM tumors awarded MDR characteristics to nude mice. However, the resistant index for ADM and VCR was significantly lower in the HepG2/ADM/nude group than in the HepG2/ADM group (ADM: 26.31 *vs* 51; VCR: 6.17 *vs* 57.06), but that for CDDP and 5-Fu was higher (CDDP: 6.45 *vs* 2.33; 5-Fu: 4.09 *vs* 1.49).

### Rh123 retention and efflux

Compared to both HepG2 and HepG2/nude tumor cells, either decreased retention or increased efflux of Rh123 was observed in the HepG2/ADM and HepG2/ADM/nude tumor cells in nude mice. The pattern of altered retention or efflux of Rh123 in the ADM resistant cells is shown in Figure 2.

**Table 1 Sensitivity of *in vitro* and *in vivo* HepG2 and HepG2/ADM tumor cells to chemotherapeutic agents (mean ± SD)**

| Drug | IC50 values (mg/L) | | | | RIa | RIb |
|---|---|---|---|---|---|---|
| | HepG2 | HepG2/ADM | HepG2/nude | HepG2/ADM/nude | | |
| ADM | 0.02 ± 0.015 | 1.02 ± 0.326[b] | 0.16 ± 0.015 | 4.21 ± 0.012[d] | 51.00 | 26.31 |

**Table 2 Levels of resistance-associated proteins in HepG2 and HepG2/ADM cells (mean ± SD)**

| Tumor cell | P-gp | MRP | LRP |
|---|---|---|---|
| HepG2 | 1.00 ± 0.04 | 0.16 ± 0.10 | 0.001 ± 0.00 |
| HepG2/ADM | 4.68 ± 0.63[b] | 1.40 ± 0.15[b] | 0.785 ± 0.04 |
| HepG2/nude | 1.00 ± 0.04 | 0.16 ± 0.08 | 0.001 ± 0.00 |
| HepG2/ADM/nude | 4.73 ± 0.68[d] | 1.43 ± 0.16[d] | 0.771 ± 0.02 |

[b]$P < 0.01$ *vs* HepG2; [d]$P < 0.01$ *vs* HepG2/nude.

### *Level of resistance-associated proteins*

The relative expressions of resistance-associated proteins were given as the ratios of the specific fluorescence intensity of HepG2/ADM and HepG2/ADM/nude cells to those of HepG2 and Hep2/nude cells respectively. As shown in Table 2, HepG2/ADM/nude tumors co-expressed the resistance-associated proteins, P-gp, MRP and LRP respectively. Compared to the HepG2/nude cells, the levels of P-gp and MRP were significantly increased in the HepG2/ADM/nude cells ($P < 0.01$), whereas no significant change in LRP expression was observed between the HepG2/nude and HepG2/ADM/nude groups ($P > 0.05$).

### *mRNA expression of mdr1, mrp and lrp genes*

Positive mRNA expression of the *mdr1* and *mrp* genes and negative mRNA expression of the *lrp* gene were seen in both HepG2 and HepG2/nude cells. However, mRNA expression *of the mdr1*, *mrp* and *lrp* gene*s* was greater in HepG2/ADM and HepG2/ADM/nude tumor cells than in HepG2 and HepG2/nude tumor cells (Figure 3).

## DISCUSSION

As drug resistance is one of the major barriers to the successful treatment of malignancies, investigation of the mechanisms of drug resistance and approaches to overcoming it has been widely performed in the past decades. Many MDR cell lines have been established *in vitro* as clinically relevant cancer models in these studies. However, compared to *in vitro* studies, the results *in vivo* are unsatisfactory in the treatment of solid tumors with modulators of Pg-p[9]. It appears that the predictive

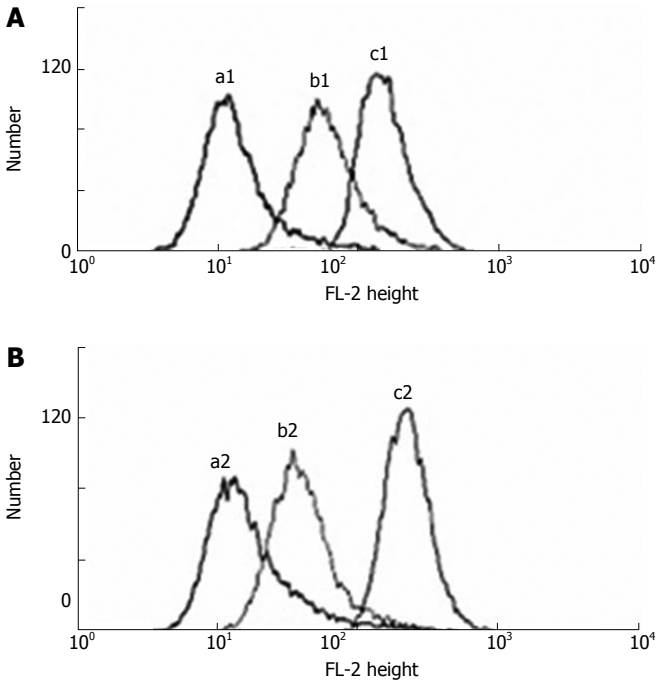

**Figure 2** Retention and efflux of rhodamine 123 in HepG2/ADM/nude cells measured by flow cytometry. **A**: Intracellular Rh123 retention. a1: HepG2/ADM/nude cells incubated in RPMI 1640 medium; b1: HepG2/ADM/nude cells incubated with Rh123; c1: HepG2/nude cells incubated with Rh123; **B**: Rh123 Efflux. a2: HepG2/ADM/nude cells incubated in RPMI 1640 medium; b2: HepG2/ADM/nude cells incubated with Rh123; C2: HepG2/nude cells incubated with Rh123.

value of MDR *in vitro* is not so good for determining the responsiveness of tumors in clinical practice[10]. In addition to tumor heterogeneity in the expression of MDR[11], several reasons are given for these negative results. The interface between MDR modulators and chemotherapeutic agents increases drug toxicity[12]. Furthermore, MDR represents the net effect of the expression of a variety of genes involved in the development of drug resistance[13,14]. Finally, some MDR results obtained in *ex vivo* studies have been overvalued or misunderstood[15]. Tumor cells grown in solid tumors *in vivo* are less vulnerable to drugs than the same cells grown in monolayer culture *in vitro* due to inadequate drug penetration, a reduced growth fraction and a decreased sensitivity mediated by cell-cell interactions. It is therefore important to establish a well-characterized and standardized MDR model *in vivo* for drug screening and prediction of clinical drug response.

In this study, we established an ADM-resistant subline *in vitro* from the human HepG2 cell line with increasing concentrations of ADM. This subline (HepG2/ADM) demonstrated cross resistance to other chemotherapeutic drugs. The MTT assay showed that HepG2/ADM cells not only presented direct resistance to MDR-related drugs such as ADM (51-fold) and VCR (57-fold), but also were sensitive to non-MDR-related compounds such as CDDP (2.33-fold) and 5-Fu (1.49-fold). Furthermore, it showed characteristics of MDR tumor cells, including expression of MDR-associated genes, and presence of resistance-associated proteins. However, it is important to confirm whether these resistant characteristics could be maintained

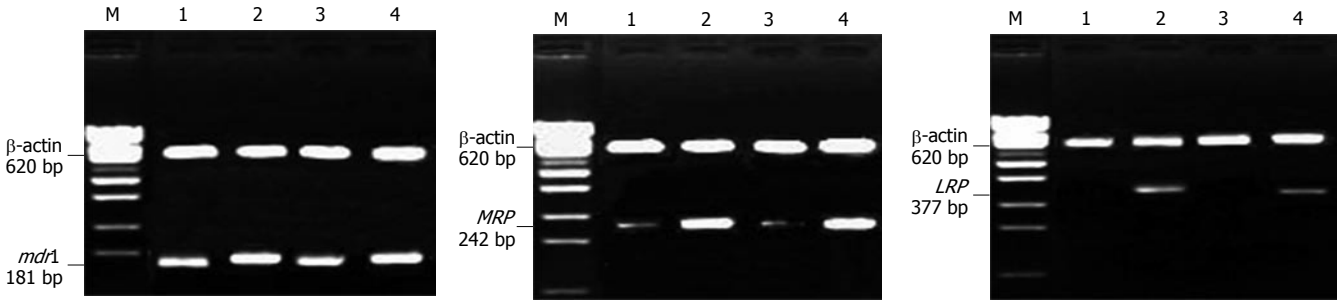

**Figure 3** mRNA expression of *mdr*1, *MRP* and *LRP* in HepG2/nude and HepG2/ADM/nude cells. Lane M: 100-bp DNA marker; lane 1: HepG2 cell line; lane 2: HepG2/ADM cell subline; lane 3: HepG2 cells in nude mice; lane 4: HepG2/ADM in nude mice.

*in vivo* following their implantation in nude mice.

Slight differences were observed under light microscope in HepG2/nude cells, and HepG2/ADM/nude tumor cells. These changes became more apparent under electron microscope, especially in the shape of cellular microvilli and the distribution of lysosomes in the cytoplasm. These changes had no significant effects on tumor growth between the two experimental groups. However, the *in vivo* tumor growth rates were almost similar between the two groups. Furthermore, the chemoresistance *in vitro* was confirmed *in vivo* after subcutaneous implantation of HepG2/ADM cells in nude mice. The $IC_{50}$ values for ADM and VCR were significantly higher in the HepG2/ADM group than in the HepG2/ADM/nude group, but those for CDDP and 5-Fu were lower in the HepG2/ADM group than in the HepG2/ADM/nude group, indicating that a partial transfer of resistance ability acquired *ex vivo* to the *in vivo* situation is possible.

In the present study, a number of proteins involved in the development of drug resistance were analyzed quantitively using flow cytometry to determine the level of MDR-associated proteins *in vivo*, including P-gP, MRP and LRP. The levels of P-gP, MRP and LRP were significantly higher in the HepG2/ADM/nude subline than in the HepG2/nude cells, but no statistical difference was seen between HepG2/ADM and HepG2/ADM/nude groups. Similar results were seen in the *in vivo* expression of MDR-associated genes (*mdr1*, *mrp* and *lrp*) on mRNA levels. Although RT-PCR used in this study was semi-quantitative, it showed the mRNA expression in HepG2/ADM/nude tumor cells induced by ADM. These findings confirmed quantitively by both immunoflow cytometry might be beneficial for protein and functional rhodamine assays.

However, it still remains unclear why the resistant index changed significantly in *ex vivo* conditions compared to *in vivo* conditions. This can be probably explained by the assumption that other MDR mechanisms are involved in the subline[16], such as the increase of ATP dependent glutathione S-conjugate transporter[17], and the decrease of DNA topoisomerase Ⅱ activity[14].

In conclusion, a MDR model of nude mice can be successfully established using human hepatocarcinoma cell line HepG2. This new model shows resistance to chemotherapeutic drugs, and mRNA expression of various MDR-associated genes on the protein levels. It can be used as an *in vivo* model to investigate the molecular mechanisms involved in MDR-related genes of hepatocarcinoma and to explore the targeted approaches tor overcoming MDR in tumor cells.

## Abstract

**AIM:** To conduct a retrospective study in 400 chronic hepatitis B patients in order to identify hepatitis B viral factors associated with complications of liver disease or development of hepatocellular carcinoma.

**METHODS:** The mean follow-up time was 83.6 ± 39.6 mo. Alpha-fetoprotein test and abdominal ultrasound were used for cancer surveillance. Hepatitis B basal core promoter mutants, precore mutants, genotypes, hepatitis B viral DNA (HBV DNA) level and hepatitis B e antigen (HBeAg) were measured. Univariate analysis and logistic regression were used to assess odds ratios for viral factors related to liver deaths and hepatocellular carcinoma development.

**RESULTS:** During follow-up, 38 patients had liver deaths not related to hepatocellular carcinoma. On multivariate analysis, older age [odds ratio: 95.74 (12.13-891.31); $P < 0.0001$], male sex [odds ratio: 7.61 (2.20-47.95); $P = 0.006$], and higher $\log_{10}$ HBV DNA [odds ratio: 4.69 (1.16-20.43); $P < 0.0001$] were independently predictive for these liver related deaths. Also, 31 patients developed hepatocellular carcinoma. Multivariate analysis showed that older age [odds ratio: 26.51 (2.36-381.47); $P = 0.007$], presence of precore mutants [odds ratio: 4.23 (1.53-19.58); $P = 0.02$] and presence of basal core promoter mutants [odds ratio: 2.93 (1.24-7.57); $P = 0.02$] were independent predictors for progression to hepatocellular carcinoma.

**CONCLUSION:** Our results show that high levels of baseline serum HBV DNA are associated with non-hepatocellular carcinoma-related deaths of liver failure, while genetic mutations in the basal core promoter and precore regions are predictive for development of hepatocellular carcinoma.

**Key words**: Basal core promoter mutants; Precore mutants; Hepatitis B viral genotypes; Hepatitis B viral DNA; Hepatitis B e antigen; Liver failure; Hepatocellular carcinoma

## INTRODUCTION

Infection with hepatitis B virus (HBV) results in different clinical outcomes which are related to age of exposure. Previous studies have shown that up to 90% of infants born to hepatitis B surface antigen (HBsAg) positive, hepatitis B e antigen (HBeAg) positive mothers become chronic carriers, while acute HBV infection in adults leads to chronicity in 5% to 10% of individuals[1,2]. Thereafter, 15% to 40% of patients with chronic hepatitis B will progress to cirrhosis and hepatocellular carcinoma (HCC)[3]. In a previous report, we showed that 9.5% of our HBsAg positive patients died of non-HCC related liver complications and another 7.8% developed HCC over a mean seven year follow-up period[4]. Significant clinical and biochemical factors which predicted all deaths of HBV infection in this group of patients include decreased serum albumin, low platelet levels and presence of cirrhosis. However, the reasons for the differences in these clinical outcomes remain unknown.

Hepatitis B viral factors such as HBeAg, HBV DNA, HBV genotype, basal core promoter (BCP) mutants and precore (PC) mutants may either alone or in combination play a major role in determining the progression of disease

in patients with chronic hepatitis B. A report from Taiwan indicates that the relative risks for HCC is 9.6 among men who are positive for HBsAg alone but rise to 60 in those who are positive for both HBsAg and HBeAg[5]. Also, the risk for HCC is increased in patients with high circulating levels of serum hepatitis B viral DNA (HBV DNA)[5,6]. Other studies from Asia indicate that HBV genotypes B and C are associated with an increased risk for HCC[7-11]. A dual mutation in the BCP region of the HBV genome involving an A to T substitution at nucleotide 1762 and a G to A substitution at nucleotide 1764 has been associated with more severe liver damage and HCC development[12-16]. In addition, a mutation in the PC region of the HBV genome involving a G to A change at nucleotide 1896 has been described in patients with HBeAg negative chronic hepatitis[17]. However, its role in the pathogenesis of severe liver disease and HCC is less clear[14,18,19].

In the present report, we describe the baseline hepatitis B virologic profiles of 400 HBsAg positive patients who were followed up in our liver center. The clinical endpoints in this study were either death of non-HCC related liver disease or of progression to HCC. Odds ratios were used to identify significant hepatitis B viral factors associated with these serious and lethal complications.

## MATERIALS AND METHODS

### Patients

From January 1989 to March 1998, we followed up 400 HBsAg positive patients who presented to our clinic. Patients who were hepatitis C antibody positive, human immunodeficiency virus antibody positive, and had a history of chronic alcoholism with other chronic liver diseases were excluded. In this report, patients who received liver transplantation for non-HCC hepatic decompensation or for HCC were considered as deaths. The baseline demographic information, laboratory tests and outcomes have been reported recently[4].

### Laboratory tests

At baseline, HBeAg and hepatitis B e antibody (anti-HBe) were measured with commercially available kits (Abbott Laboratories, North Chicago, IL). Serum was also collected at the initial visit and stored at -70℃. In 2004, we collaborated with the Hepatitis Research Center at National Taiwan University Hospital in Taipei, Taiwan, and serum samples were sent for analysis of HBV DNA, HBV genotypes, PC and BCP mutants.

Serum HBV DNA was quantified by a real-time polymerase chain reaction assay in the linear range from $10^2$ to $10^{11}$ copies/mL[20]. For reporting purposes, the HBV DNA values were $\log_{10}$ transformed. The identification of HBV genotypes was performed by melting curve analysis[20], and supplemented by direct sequencing of the pre-S amplicon and phylogenetic analysis by comparing the nucleotide sequence with 33 reference HBV strains obtained from GenBank as previously described[21].

Amplification and sequencing of PC (nucleotides 1814-1900) and BCP (nucleotides 1742-1849) genes were performed as previously described[14,22]. Nucleotide sequences of the amplified products were directly determined by using fluorescence labeled primers with 3100 automatic sequencer (Applied Biosystems, Foster City, CA, USA). Sequencing conditions were specified in the protocol for the Taq DyeDeoxy terminator cycle sequencing kit (Applied Biosystems). The inner primer pair was used as sequencing primers for both directions of the gene.

### HCC surveillance

For HCC surveillance, abdominal ultrasound examinations and serum alpha-fetoprotein (AFP) testing were performed every 6 to 12 mo in non-cirrhotic patients and every six months in patients with cirrhosis. If the serum AFP was elevated or if a lesion was noted by abdominal ultrasound, further investigations using computerized tomography scan, magnetic resonance imaging or biopsy of the lesion were used to confirm the diagnosis of HCC.

### Statistical analysis

Categorical data were summarized by using frequencies and analyzed by chi-squared methods for assessment of differences. All continuous data were descriptively summarized with means and standard deviations, and further analyzed for assessment of differences by ANOVA with *post-hoc* pair-wise Student's *t*-tests. All variables found to be significant by univariate analysis were subjected to multivariate analysis utilizing step-wise logistic regression. The odds ratio was defined as previously described[23]. Analyses were conducted by using SAS software version 9.1 (Cary, NC). Statistical significance was defined as two-sided $P$ values $< 0.05$.

## RESULTS

### Patients

One hundred and thirty-nine of 400 HBsAg positive patients had liver biopsy confirmed cirrhosis and were classified in the Child-Pugh Class A category. The remaining 261 were non-cirrhotic patients with chronic hepatitis B. Seventy-eight percent of our patients were of Asian descent. The mean follow-up time was 83.6 ± 39.6 mo.

### Baseline virologic characteristics

**Basal core promoter 1762/1764 mutants:** Of 280 patients who had detectable BCP sequences, 124 (44.3%) had BCP 1762/1764 mutants and 156 (55.7%) had BCP 1762/1764 wild type sequences (Table 1). Patients with BCP 1762/1764 mutants were older than those with BCP 1762/1764 wild type sequences ($P = 0.01$). Seventy-four percent of patients with BCP 1762/1764 mutants had genotype C ($P < 0.0001$). Patients with BCP 1762/1764 wild type sequences had higher mean serum HBV DNA levels than those with BCP 1762/1764 mutants ($P = 0.003$). No concordance was noted between patients with BCP 1762/1764 mutants and PC 1896 mutants ($P = 0.8$, Kappa = 0.001). Also, there was no significant difference in the HBeAg status among patients with BCP 1762/1764 mutants.

**Precore 1896 mutants**: Of 382 patients who had detec-

[1]Precore.

**Table 2 Demographic and virologic characteristics of precore 1896 mutants**

| Characteristic | Mutant | Wild type | *P* |
|---|---|---|---|
| Number | 112 | 270 | |
| Age (yr) (mean ± SD) | 49.7 ± 14.8 | 47.3 ± 15.1 | 0.16 |
| Male/Female | 77/35 | 192/78 | 0.6 |
| Asian/Non-Asian | 99/13 | 201/69 | 0.002 |
| Genotype, *n* (%) | | | < 0.0001 |
| A | 2/93 (2.1) | 54/227 (23.8) | |
| B | 53/93 (56.9) | 39/227 (17.2) | |
| C | 38/93 (40.9) | 128/227 (56.4) | |
| Baseline HBV-DNA level (mean ± SD, copies/mL) | 5.5 ± 2.0 $Log_{10}$ | 6.5 ± 2.3 $Log_{10}$ | < 0.0001 |
| HBeAg, *n* (%) | | | < 0.0001 |
| + | 33/109 (30.1) | 161/268 (60.1) | |
| − | 76/109 (69.7) | 107/268 (39.9) | |

table PC sequences, 112 (29.3%) had PC 1896 mutants and 270 (70.7%) had PC 1896 wild type sequences (Table 2). More Asian patients had PC 1896 mutants ($P = 0.002$). Among the PC 1896 mutants, only 2.1% had genotype A ($P < 0.0001$). The mean serum HBV DNA levels were significantly higher in patients with PC 1896 wild type sequences ($P < 0.0001$). Patients with PC 1896 mutants were most often HBeAg negative ($P < 0.0001$).

**HBV genotypes**: In 332 patients who had detectable genotypes, genotype A was present in 56, genotype B in 92, genotype C in 166, genotype D in 10, genotype E in 2, and mixed HBV genotypes in 6 patients (Table 3). HBV genotype C followed by genotype B was detected more frequently in Asian patients, while genotype A was more frequent in non-Asian patients ($P < 0.001$). Patients with HBV genotype C had the highest serum HBV DNA levels compared to those with genotypes A and B ($P = 0.003$). A majority of genotype A and genotype C patients were HBeAg positive, and more genotype B patients were HBeAg negative ($P = 0.0002$). Genotype B patients had more PC 1896 mutants ($P < 0.0001$). Genotype C patients had more BCP 1762/1764 mutants ($P < 0.0001$).

**Serum HBV DNA level**: Baseline serum HBV DNA levels in 390 patients ranged from 2.1 $log_{10}$ to 11.5 $log_{10}$ copies/mL (median 6.1 ± 2.3 $log_{10}$ copies/mL). Males had higher mean HBV DNA levels than females (6.39 ± 2.30 $log_{10}$ copies/mL *vs* 5.52 ± 2.14 $log_{10}$ copies/mL; $P = 0.0007$, Table 4). HBeAg positive patients had significantly higher serum HBV DNA levels than HBeAg negative patients ($P < 0.0001$).

**HBeAg**: At baseline, 197 of 395 (49.9%) patients were HBeAg positive and 198 (50.1%) were HBeAg negative. HBeAg positive patients were younger than HBeAg negative patients (45.2 ± 15.9 years *vs* 49.9 ± 13.7 years, $P = 0.002$). Also, more males than females were HBeAg positive [150 of 278 (53.9%) *vs* 47 of 117 (40.2%), $P = 0.01$].

### *Non-HCC related deaths*

During follow-up, 38 patients died of non-HCC related deaths. Twenty-seven died of liver failure, seven of bleeding esophageal varices, and four of sepsis. Four other patients died of non-liver related disease. Univariate analysis showed that older age, male sex, presence of cirrhosis and high baseline serum HBV DNA levels were associated with non-HCC related liver deaths (Table 5). On multivariate analysis, old age (OR: 95.74; 95% CI: 12.13-891.31; $P < 0.0001$), male sex (OR: 7.61; 95% CI: 2.20-47.95; $P = 0.006$), and high baseline HBV DNA (OR: 4.69; 95% CI: 1.16-20.43; $P = 0.03$) were independently predictive of non-HCC related liver deaths. HBeAg, HBV genotype, PC 1896 mutants and BCP 1762/1764 mutants were not associated with non-HCC related liver deaths.

### *HCC development*

During follow-up, HCC developed in 31 (7.8%) patients. Twenty-two of 139 (15.8%) patients with cirrhosis and nine of 261 (3.4%) patients without cirrhosis progressed to HCC. Baseline tests in these 31 patients showed that 12 (38.7%) were HBeAg positive, 18 (58.1%) were anti-HBe positive, and one HCC patient was positive for both. In comparing the 31 patients who developed HCC to those who did not, univariate analysis of baseline variables showed that older age, male sex, cirrhosis, presence of PC 1896 mutants and BCP 1762/1764 mutants were associated with development of HCC (Table 6). Multivariate analysis showed that age (OR: 27.51; 95% CI: 2.36-381.47; $P = 0.007$), presence of PC 1896 mutants (OR: 4.23; 95% CI: 1.53-19.58; $P = 0.02$) and BCP 1762/1764 mutants (OR: 2.93; 95% CI: 1.24-7.57; $P = 0.02$) were independent predictors for HCC development. HBeAg, HBV genotype, and serum HBV DNA were not predictive for development of HCC.

## DISCUSSION

Our findings of death of non-HCC liver complications and development of HCC in hepatitis B patients in the United States are in accordance with natural history studies

**Table 3 Demographic and virologic characteristics of HBV genotypes**

| Characteristics | Genotype A | Genotype B | Genotype C | *P* |

| Asian/Non-Asian | 16/40 | 84/8 | 157/9 | < 0.0001 |
| HBV-DNA (mean ± SD, copies/mL) | 6.68 ± 2.53 $Log_{10}$ | 6.12 ± 2.08 $Log_{10}$ | 6.94 ± 1.81 $Log_{10}$L | 0.003 |
| HBeAg, *n* (%) | | | | 0.0002 |
| + | 37/55 (67.3) | 35/91 (38.5) | 104/165 (63.0) | |
| - | 18/55 (32.7) | 56/91 (61.5) | 61/165 (37.0) | |

from Asia and Europe. The highest complication rate occurred in the 139 patients who presented with cirrhosis. During follow-up, 38 (27.3%) patients died either of liver failure, bleeding esophageal varices or of sepsis. Our annual rate of non-HCC related liver deaths was 3.9% per year and is similar to 2.4%-4% reported elsewhere[24,25]. Also, 9 (3.4%) of 261 patients without cirrhosis and 22 (15.8%) of 139 patients with cirrhosis developed HCC, resulting in annual rates of 0.5% and 2.3%, respectively. These also are similar to 1.5%-3.8% in Europe[26] and 0.7%-2.2% in Asia[27,28].

In the present report, BCP 1762/1764 mutants were detected in 44% of our HBsAg positive patients. The BCP 1762/1764 mutants were most often detected in our patients with genotype C compared to genotype A or B patients (59%, 30% and 35%, respectively). A recent report from Taiwan showed that genotype C has a significantly higher prevalence of BCP 1762/1764 mutants than genotype B. Also, BCP 1762/1764 mutants are more frequently detectable in patients with HCC than in chronic carriers or patients with chronic hepatitis[12,14]. In one report from Guangxi Zhuang Autonomous Region in China, BCP 1762/1764 mutants were detectable in all 11 HCC tissues tested[14]. Other studies indicated that BCP 1762/1764 mutants were most often present in patients who had more progressive liver disease and hepatic decompensation than in those with stable liver disease[13-16]. In the present study, the presence of BCP 1762/1764 mutants was closely associated with non-HCC liver deaths as well as HCC development.

The significance of PC 1896 mutants is less clear. A study from Taiwan showed that the frequency of PC 1896 mutants was similar in both HCC patients and inactive carriers[14]. Also, no difference has been found in the prevalence of PC 1896 mutants between Chinese patients with or without cirrhosis related complications[15]. Another report from Japan suggested that acquisition of mutation in the PC 1896 region may contribute to inactivation of chronic liver disease[13]. In our study, 29.3% of patients had the PC 1896 mutants, which were primarily HBeAg negative, but 30% were HBeAg positive. One study from China also showed that PC mutants were already present in HBeAg-positive patients who had not yet experienced seroconversion to anti-HBe[15]. These authors suggested that development of HCC may not be related to PC 1896 mutations but probably due to the persistence of significant viremia after HBeAg seroconversion. The low incidence of PC 1896 mutants in our genotype A patients is in accordance with other reports since genotype A patients have a C at nucleotide 1858 which destabilizes the stem loop region and precludes emergence of the PC 1896 mutants[29,30]. In our report, 42% of the patients with PC 1896 mutants had cirrhosis, and 45.2% of patients who developed HCC had PC 1896 mutants. The role of PC 1896 mutants in disease progression requires further investigation.

**Table 4 Demographic and virologic characteristics of baseline serum HBV-DNA Levels (mean ± SD, copies/mL)**

| Characteristics | Mean HBV-DNA levels | *P* |
|---|---|---|
| Sex | | 0.0007 |
| Male | 6.39 ± 2.30 $Log_{10}$ | |
| Female | 5.52 ± 2.14 $Log_{10}$ | |
| Race | | 0.24 |
| Asian | 6.05 ± 2.21 $Log_{10}$ | |
| Non-Asian | 6.39 ± 2.57 $Log_{10}$ | |
| HBeAg | | < 0.0001 |
| + (*n* = 194) | 7.42 ± 1.97 $Log_{10}$ | |
| − (*n* = 191) | 4.86 ± 1.81 $Log_{10}$ | |

The distribution of genotypes A, B, C, and D (16%, 27%, 49%, and 3% respectively) in our patients is consistent with the results of a recent survey of HBV genotypes in patients with hepatitis B from the western part of the United States where there is a predominant Asian population (18%, 34%, 41%, and 5% respectively)[29]. In the latter study, the ethnic distribution in the southern part of the United States was predominantly Caucasians, and in this area, 63% of the patients have genotype A. HBV genotypes A and D appear to be more common in Caucasians, while HBV genotypes B and C are predominantly found in Asians[7,8,10,31]. However, no HBV genotypes were found to be predictive for either non-HCC liver deaths or progression to HCC in our study. Studies from Asia showed that the prevalence of genotypes B and C is similar in patients with cirrhosis and HCC, but progression to cirrhosis might be slower in genotype B patients[10]. Another report indicated that genotype B may be responsible for HCC development in children and young non-cirrhotic adult males in Taiwan[11,32]. These conflicting findings indicate that the role of genotypes in the natural history of HBV is still unclear.

Recently, the role of HBV DNA in predicting

progression to cirrhosis and HCC has been reported from Taiwan[6,33]. These authors showed that elevated levels of baseline HBV DNA were associated with increased deaths of cirrhosis[6,33]. Also, levels of HBV DNA ⩾ 10 000 copies/mL at baseline and at follow-up were a strong predictor of HCC development, which was independent of HBeAg, serum ALT and cirrhosis[6]. In our report herein, patients who died of non-HCC related liver complications had significantly higher baseline HBV DNA levels than those who remained alive. Thus, chronic inflammation caused by the host immune response to active viral replication appears to be more responsible for the non-HCC related liver deaths than mutations in the HBV genome[34]. However, the baseline levels of HBV DNA in our patients who developed HCC during follow-up were similar to patients who did not progress to HCC.

The role of HBeAg in predicting progression of liver disease is unclear. A recent study from Taiwan showed that the presence of HBeAg positivity significantly increased the risk of developing HCC. Also, another study from Europe showed that HBeAg positivity was associated with worse survival and that the risk of death decreased after HBeAg seroconversion. However, in our report 53% of our cirrhosis patients were HBeAg positive on presentation, and 47% were HBeAg negative, indicating that progression to cirrhosis occurs regardless of HBeAg status. Also, we noted that HBeAg positive patients had higher baseline HBV DNA levels than HBeAg negative patients, and our HBeAg negative patients had more PC 1896 mutants than HBeAg positive patients. However, during our analysis of deaths of non-HCC liver complications or development of HCC, HBeAg did not appear to play a predictive role in predicting either complication.

HCC developed in 31 of our patients during follow-up. In comparing patients who developed HCC to those who did not, both PC 1896 mutants and BCP 1762/1764 mutants were independent predictors for development of HCC. Our findings confirm studies from Asia which have

implicated BCP 1762/1764 mutants and HCC. In addition, our observations indicate that patients with PC 1896 mutations also have an increased risk of developing HCC. Since the majority of our HBsAg positive patients are from Asian countries, the risk of developing HCC persists in those with pre-existing BCP 1762/1764 mutants and PC 1896 mutants, even after years of immigration from their native countries to the USA.

There were the limitations in our study. The analyses of HBV genotypes and BCP 1762/1764 mutations were not possible in some of our patients because of low or undetectable levels of HBV DNA, which did not permit adequate amplifications of the serum samples. In addition, this study only described analysis of laboratory tests performed at the time of presentation, and no longitudinal analyses were completed. It is well known that patients with chronic hepatitis B experience exacerbations and remissions which are usually accompanied with abnormal liver tests and varying levels of HBV DNA[35]. However, our primary endpoints in this study were either death of liver disease or development of HCC, and our aim was to identify hepatitis B viral factors at presentation which may predict these serious outcomes.

In summary, the presence of high baseline serum HBV DNA levels can predict non-HCC related liver deaths, while mutations in the BCP and PC regions of the HBV genome are more predictive for HCC development. These findings will assist in the planning of treatment strategies to prevent these serious and lethal complications which occur in patients with chronic hepatitis B infection.

## Abstract

**AIM:** To evaluate and compare the expression profiles of CXCL12 (SDF-1), CCL19 (MIP-3β), CCL20 (MIP-3α) and CCL21 (6Ckine, Exodus2) and their receptors on RNA and protein levels in hepatocellular carcinoma (HCC) versus colorectal liver metastases (CRLM) and to elucidate their impact on the carcinogenesis and progression of malignant liver diseases.

**METHODS:** Chemokine expression was analyzed by RT-PCR and ELISA in 11 cases of HCC specimens and in 23 cases of CRLM and corresponding adjacent non-tumorous liver tissues, respectively. Expressions of their receptors CXCR4, CCR6 and CCR7 were analyzed by RT-PCR and Western blot analysis in the same cases of HCC and CRLM.

**RESULTS:** Significant up-regulation for CCL20/CCR6 was detected in both cancer types. Moreover, CCL20 demonstrated significant overexpression in CRLM in relation to the HCC tissues. Being significantly up-regulated only in CRLM, CXCR4 displayed an aberrant expression pattern with respect to the HCC tissues.

**CONCLUSION:** Correlation of CXCR4 expression with CRLM suggests CXCR4 as a potential predictive factor for CRLM. High level expression of CCL20 and its receptor CCR6 in HCC and CRLM with marked up-regulation of CCL20 in CRLM in relation to HCC tissues indicates involvement of the CCL20/CCR6 ligand-receptor pair in the carcinogenesis and progression of hepatic malignancies.

**Key words:** Chemokines; Chemokine receptors; Gene expression; Hepatocellular carcinoma; Colorectal liver metastases

## INTRODUCTION

Chemokines represent a family of small chemotactic cytokines, initially identified as mediators of leucocyte trafficking and homing. In the last few years, chemokines have been shown to participate also in tumor growth and the lymphatic and even distant spread of malignant tumors[1,2]. Here we compare the expression profiles of several chemokine/chemokine receptor pairs, namely CXCL12/CXCR4, CCL20/CCR6 and CCL19/CCL21/CCR7 in hepatocellular carcinoma (HCC) versus colorectal liver metastases (CRLM). We chose to investigate this group of chemokines and their receptors because their roles in tumor growth and metastasis have recently gained increasing importance[3,4]. Like HCC, which is a highly malignant tumor with a poor prognosis due to its rapidly progressing and infiltrating growth, colorectal cancer (CRC) also still remains one of the leading causes of cancer-related death worldwide[5-8]. The mortality of CRC is principally attributable to the development of metastases, which primarily infest the liver, and CRLM are present in up to 95% of patients in the advanced disease stage.

The CC-chemokines CCL19 and CCL21 are highly expressed in lymph nodes and signal through a common receptor, the lymphocyte chemoattractant receptor CCR7[9-10]. While CCR7 was recently reported to predict lymph node metastasis in colorectal carcinoma and other cancer types[11,12], the cognate CXCL12 receptor CXCR4 has been suggested as a risk factor for the outgrowth of colon carcinoma micrometastases[13] and the invasion and spreading of several other cancers[15-17]. Also CCL20/CCR6 involvement in the neoplastic progression and cancer-specific metastasis of several tumor types is presently

reported, with major focus on the amplification of local necroinflammatory response in the liver[18-19], suggesting CCR6 as an important factor in the recruitment of lymphocytes from peripheral blood to HCC[20-21]. However, data concerning the expression profiles and clinical impact of CCL20/CCR6 in HCC and CRLM are still limited and no expression data are currently available concerning the pathophysiological relationship of chemokines in HCC and CRLM. While our group and others previously suggested an association between the CCL20/CCR6 expression in CRC and the promotion of CRLM[22-23], we now demonstrate a correlation between the CCL20/CCR6 expression profile in HCC and CRLM with a marked overexpression of the CCL20 gene product in relation to HCC tissues. Consequently, we hypothesize that the CCL20/CCR6 chemokine receptor pair may be of general importance in the development of hepatic malignancies of different origins.

## MATERIALS AND METHODS

### Patients

HCC and CRLM specimens and corresponding non-tumorous liver tissues were collected from 11 HCC and 23 CRLM patients who underwent resection in our department between 2002 and 2006. All patients provided informed consent for tissue procurement, which was approved by the ethics commission of the Ärztekammer of the Saarland. The clinical variables presented in Table 1 were obtained from clinical and pathological records according to the UICC TNM classification[24] system.

### Tissue preparation

Immediately after resection tissue samples were collected and processed under nucleic acid sterile conditions, snap frozen in liquid nitrogen and then stored at -80℃ until RNA and protein were extracted. For corresponding normal tissue we used adjacent healthy tissue from the same resected liver specimen. All tissues obtained were reviewed by an experienced pathologist and examined for the presence of tumor cells. As minimum criteria for usefulness for our studies we only chose tumor tissues in which tumor cells occupied a major component (> 60%) of the tumor biopsy.

### Single-strand cDNA synthesis

Total RNA was isolated using RNeasy columns from Qiagen (Hilden, Germany) following the manufacturer's instructions and RNA integrity was confirmed spectrophotometrically and by electrophoresis on 1% agarose gels. For cDNA synthesis, 5 μg of each patient's total RNA sample were reverse-transcribed in a final reaction volume of 50 μL containing 1 × TaqMan RT buffer, 2.5 μmol/L random hexamers, 500 μmol/L each dNTP, 5.5 mmol/L $MgCl_2$, 0.4 U/μL RNase inhibitor, and 1.25 U/μL Multiscribe RT. All RT-PCR reagents were purchased from Applied Biosystems (Applied Biosystems, Foster City, CA). The reaction conditions were 10 min at 25℃, 30 min at 48℃, and 5 min at 95℃.

**Table 1 Clinical characteristics of patients with HCC and CRLM**

### Real-time PCR

All qRT assays containing the primers and probe mix were purchased from Applied Biosystems, (Applied Biosystems, Foster City, CA) and utilized according to the manufacturer's instructions. PCR reactions were carried out using 10 μL 2 × Taqman PCR Universal Master Mix No AmpErase® UNG and 1 μL gene assay (Applied Biosystems, Foster City, CA), 8 μL Rnase-free water and 1 μL cDNA template (50 mg/L). The theoretical basis of the qRT assays is described in detail elsewhere[25]. All reactions were run in duplicates along with no template controls and an additional reaction in which reverse transcriptase was omitted to allow for assessment of genomic DNA contamination in each RNA sample. For the signal detection, ABI Prism 7900 sequence detector was programmed to an initial step of 10 min at 95℃,

followed by 40 thermal cycles of 15 s at 95℃ and 10 min at 60℃ and the log-linear phase of amplification was monitored to obtain $C_T$ values for each RNA sample. Gene expression of all target genes was analyzed in relation to the levels of the slope matched housekeeping genes Cyclophilin C (CycC) and ß2-Microtubulin (B2M)[26]. Since reporting of data obtained from raw $C_T$ values falsely represent the variations, we converted the individual $C_T$ values to the linear form as follows:

$$\text{Fold difference} = 2^{-(\text{mean } C_T \text{ pathological tissue-mean } C_T \text{ calibrator})} = 2^{-\text{delta } C_T}$$

Hence, the liver of the tumor-neighboring tissue became the 1 × sample, and all other quantities were expressed as an n-fold difference relative to this tissue.

### Isolation of total protein

Protein lysates from frozen tissues were precipitated with the RIPA buffer. Protein quantitation was performed using the Pierce BCA protein assay reagent kit (Pierce, Rockford, USA).

### Western blot analysis

Chemokine receptors were detected with anti-CXCR4 (1:500, Serotec, AHP442 rabbit anti-human, Serotec, Oxford, UK; 1:5000, BioRad cat. 170-6515 goat anti-rabbit HRP, BioRad, Muenchen, Germany), anti CCR6 (1:500, Biomol, goat anti-human C2099-70B, Biomol, Hamburg, Germany; 1:5000 Santa Cruz, sc-2056 donkey anti-goat HRP) and anti-CCR7 (1:500, Santa Cruz, sc-9700 goat anti-human; 1:5000, Santa Cruz, sc-2056 donkey anti-goat HRP, Santa Cruz Biotechnology, Santa Cruz, CA USA), visualized by ECL Western blotting analysis system (Amersham Biosciences, Piscataway, NJ, USA), and quantified densitometrically. Human cell lysates HL-60 (sc-2209, Santa Cruz Biotechnology, Santa Cruz, CA, USA), Imgenex cell lysates A375, and HeLa (Imgenex, San Diego, USA) served as positive controls.

### Enzyme-linked immunosorbant assay

Chemokine protein levels in the different tissue lysates were determined by sandwich-type ELISA according to the manufacturer's protocol: R&D systems (R&D Systems Inc. Minneapolis, Minnesota, USA) for the quantification of CCL19, CCL20, CXCL12 or ProSci (ProSci, San Diego, USA) for CCL21**.** The absorbance was read at 450 nm.

### Laser capture microdissection

Laser microbeam microdissection (LMM) was employed for obtaining pure tumor cell and pure normal cell samples for subsequent genetic analysis. LMM was performed on three samples for each tissue type and each chemokine, respectively. Histochemical staining was used on cryo sections before microdissection. Specimen preparation, microdissection and catapulting were performed following a laser pressure catapulting protocol according to the manufacturer's instructions (P.A.L.M. Microlaser Technologies, Bernried, Germany). RNA was extracted using the P.A.L.M. RNA extraction kit and for reverse transcription the invitrogen reverse transcription kit (Invitrogen Life Technologies, Karlsruhe, Germany) was applied. Subsequently quantitative PCR analysis was performed as described earlier.

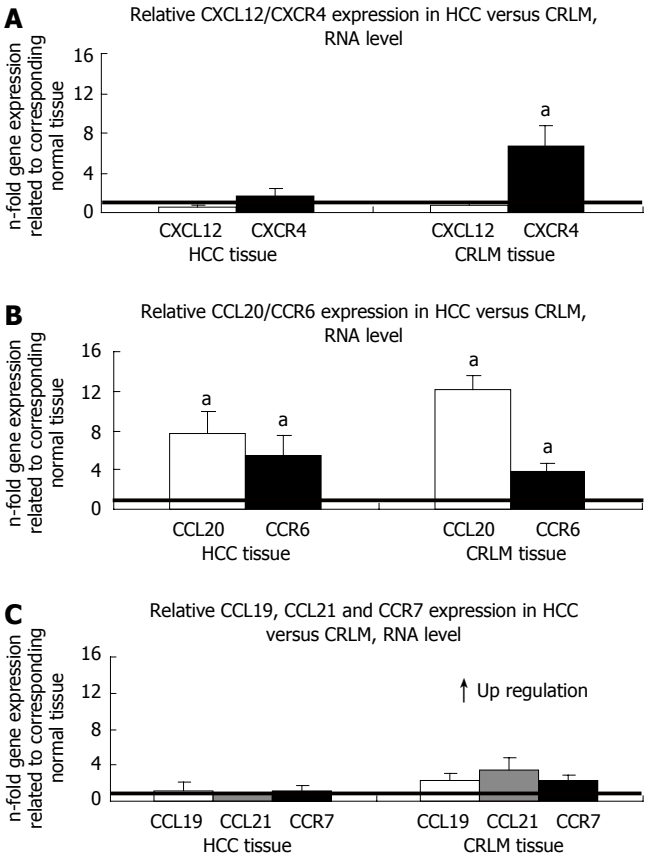

**Figure 1** Expression of chemokine/chemokine receptor pairs in HCC and CRLM as determined by Q-RT-PCR. **A**: CXCL12/CXCR4 expression; **B**: CCL20/CCR6 expression; **C**: CCL19/CCL21/CCR7 expression (mean ± SE, $^aP < 0.05$, $n = 11$ and 23, respectively).

### Statistical analysis

The statistical significance of differences in chemokine and chemokine receptor expression were summarized using mean and SEM (standard error of the mean). All statistical calculations were done with the MedCalc software package (MedCalc software, Mariakerke, Belgium)[27]. Where appropriate, either the Student's t-test or the Wilcoxon's rank sum test was applied to test for group differences of continuous variables. $P < 0.05$ was considered significant.

## RESULTS

### Chemokine/chemokine receptor expression

To assess potential differences in chemokine/chemokine receptor expression levels in HCC *vs* CRLM, we performed quantitative RT-PCR analysis in 11 HCC and 23 CRLM specimens and their corresponding tumor neighboring tissues, respectively. The adjacent, non tumor invaded liver tissues of the HCC and CRLM patients served as control groups. qRT analysis of the chemokine ligand CXCL12 displayed no significant difference in gene expression between the tumor and the tumor neighboring tissues in HCC or CRLM as shown in Figure 1A. In contrast to its ligand, the CXCL12 receptor CXCR4 demonstrated

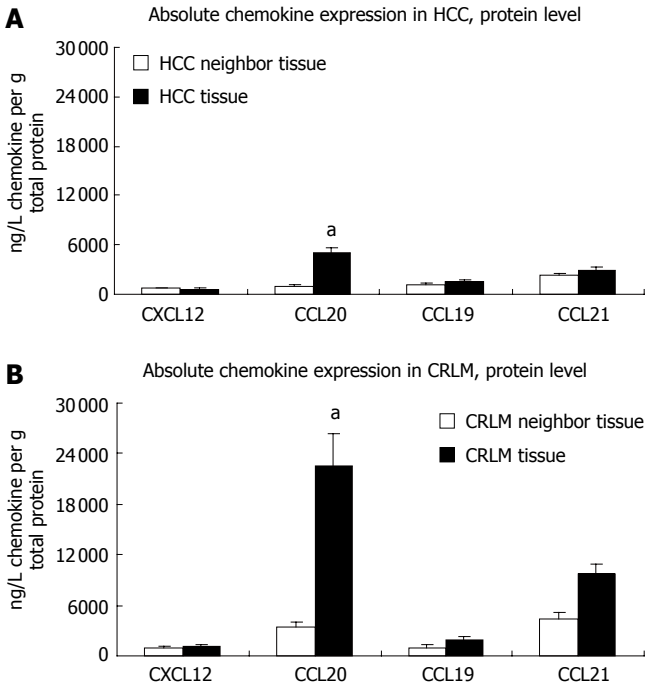

**Figure 2** Expression of CXCL12, CCL20, CCL19 and CCL21 in HCC and CRLM as determined by the enzyme-linked immunosorbant assay (ELISA). **A**: Chemokine expression in HCC; **B**: Chemokine expression in CRLM. (ng/L chemokine ligand related to 1 g total protein for the HCC and CRLM tissues. mean ± SE, $^{a}P < 0.05$; $n = 11$ and 23, respectively).

significant up-regulation in the CRLM compared with the tumor neighboring liver tissues ($P < 0.05$) thus demonstrating that CXCL12 and CXCR4 are inversely expressed in CRLM (Figure 1A). However, no significant difference in gene expression was detected for CXCR4 in the HCC tissues between the tumor and the tumor neighboring liver tissues thus indicating a clear difference in CXCR4 expression between HCC and CRLM. CC-chemokine CCL20 was found to be significantly up-regulated in the tumor tissue of patients with HCC and CRLM in comparison to their tumor neighboring tissues ($P < 0.05$), as shown in Figure 1B. Similarly, the CCL20 receptor CCR6 revealed a significantly higher mRNA expression in the tumor specimens of both HCC and CRLM patients in relation to the corresponding normal liver tissues, respectively ($P < 0.05$) (Figure 1B). In contrast, we observed no significant difference in CCL19 and CCL21 gene expression between the tumor and tumor neighboring tissues in either tissue type as demonstrated in Figure 1C. Likewise, no significant up- or down-regulation was detected for the corresponding receptor CCR7 in the HCC or CRLM tissues, respectively (Figure 1C). Analysing the differences between gene expressions from matched normal/cancer samples corresponded widely with the results presented in Figure 1 thus ensuring that averaging out the Ct values did not mask significant differences between individual paired samples. Sections of tumor and normal cells have been microdissected in three CRLM and HCC tissue specimens, respectively, followed by subsequent chemokine qRT gene expression analysis that corresponded well with the results presented in Figure 1.

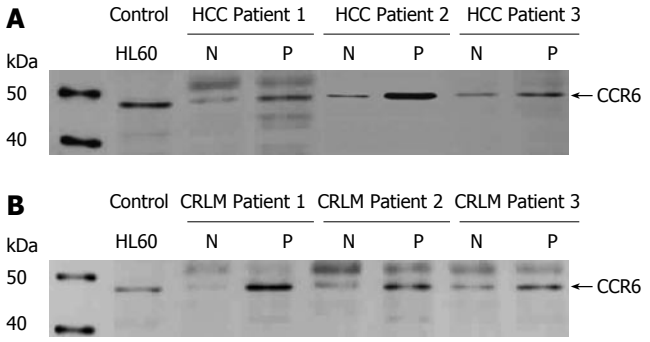

**Figure 3** Expression of chemokine receptor CCR6 in HCC and CRLM as determined by Western blot analysis. **A**: Chemokine expression in HCC; **B**: Chemokine expression in CRLM. Total cell lysates of tumor (P) and corresponding normal tissues (N) of three patients with HCC and CRLM, respectively, were immunoblotted with antibodies specifically recognizing chemokine receptor CCR6. Cell line HL60 served as a positive control for the detection of CCR6. ($n$ = 11 and 23, respectively).

### *Chemokine/chemokine receptor expression on the protein level*

Consistent with our RNA data, gene expression data for CXCL12, as assessed by enzyme-linked immunosorbant assay (ELISA), showed no significant difference in expression between the tumor and tumor neighboring tissues in either tissue type (Figure 2). Similarly, absolute CXCL12 protein quantities were largely the same in HCC and CRLM tissues. In contrast, we found statistically relevant up-regulation of CCL20 protein expression in both CRLM and HCC tissues compared with the respective tumor neighboring tissues ($P < 0.05$). These findings are again well in line with the RNA expression profiles. Comparative analysis of the absolute protein quantities between CRLM and HCC tissues revealed a significantly higher CCL20 expression of almost 24000 ng/L CCL20 in the CRLM tissues compared to approximately 6000 ng/L CCL20 in the HCC tissues ($P < 0.05$) as shown in Figure 2. In accordance with our qRT results we found no significant difference in protein expression for CCL19 and CCL21 between the tumor and tumor neighboring tissues in either tissue type (Figure 2). Despite a seemingly higher CCL21 protein expression level in the CRLM tissues compared with the HCC tissues, this difference was statistically not significant.

As assessed by western blot analysis and subsequent densitometric measurements, no significant difference in gene expression was observed for CXCR4 in the HCC tissues, whereas a statistically relevant 4-fold up-regulation of CXCR4 expression was detected in the CRLM tissues ($P < 0.05$), thus confirming the RNA transcript level analysis. Likewise, we found statistically relevant up-regulation of CCR6 expression in both tissue types ($P < 0.05$) as shown in Figure 3, but no significant difference in CCR7 expression between the HCC and CRLM tissues thus paralleling our qRT results.

## DISCUSSION

To date, various studies implicate chemokines CXCL12,

CCL20, CCL19 and CCL21 and their corresponding receptors not only in inflammatory cell recruitment but also in the tumorigenic process and metastatic homing of tumor cells. Recent data focus special emphasis on their roles in CRC, HCC and liver metastasis of different origins[21,28-31]. These findings prompted us to comparatively investigate their expression profiles in HCC and CRLM as the primary site of hematogenous metastases in CRC.

In recent years chemokine receptor CCR7 attracted considerable interest as a key receptor in determining lymph node metastasis in various malignant processes and tumor types such as leukemia, melanoma, gastric or non-small cell lung cancer[12,32-35], whereas also anti-tumorigenic effects have been demonstrated for the corresponding CCR7 ligand CCL21[36]. However, we observed no correlation between CCR7 expression and HCC or CRLM, respectively. Similarly, the corresponding ligands CCL19 and CCL21 showed no significant difference in their gene expression between the tumor and tumor neighboring tissues in either cancer type. Therefore, we believe that an association of these chemokine/receptor pairs with the progression of CRLM or HCC is rather unlikely.

While investigating CXCL12/CXCR4 expression, we made the interesting observation that CXCR4 was significantly up-regulated in the CRLM compared with the tumor neighboring liver tissues, yet no significant difference in gene expression was detected for CXCR4 in the HCC tissues thus indicating a distinct difference in the CXCR4 expression pattern between HCC and CRLM. These results are in line with recent findings that report CXCR4 gene expression in primary CRC demonstrated significant associations with recurrence and survival suggesting CXCR4 as a prognostic factor for poor disease outcome[29]. Unlike CXCR4, the chemokine ligand CXCL12 displayed no significant difference in gene expression between the tumor and the tumor neighboring tissues in HCC or CRLM thus indicating that CXCL12 and CXCR4 are inversely expressed in CRLM. This type of expression pattern was also demonstrated for CRC cell lines[37]. CXCL12 is presently discussed controversially with respect to its role in promoting tumor growth and metastasis. Various studies suggest CXCL12 involvement in metastasis, angiogenic activity and modulation of tumor immunity[3,14,15,38-40], while others describe efficient antitumor responses promoted by the CXCL12/CXCR4 interaction, suggesting that secretion of CXCL12 in tumors may mediate T-cell-dependent antitumor responses[41-43].

CCL20 is also presently controversially discussed with respect to its role in tumorigenesis. With regard to the chemoattractant properties of CCL20 for dendritic cells (DC), Fushimi *et al* reported on the tumor suppressive properties of this chemokine showing that CCL20 transgenes attract DC to established murine tumors and suppress tumor growth[44]. However, other studies correlate CCL20 transfection into a mouse tumor cell line with decreased immunogenicity and enhanced tumor growth[45] and recent data correlate increased serum levels of CCL20 in HCC with cancer-related factors[46]. Other reports allocating tumor growth promoting qualities with CCL20, associate CCR6 expression with hepatic metastasis in a rodent model and recent results, based on chemotactic and actin polymerization assays, correlate CCR6 expression with intrahepatic metastasis of HCC[30,47]. In our study, CCL20/CCR6 was the only pair among the chemokine ligand/receptor pairs under investigation that displayed a prominent expression pattern in HCC and CRLM, showing significant up-regulation in the tumor tissues of patients of both cancer types in comparison to the tumor neighboring tissues, respectively. We assume that these high expression levels in the malignant liver tissues of different origins - in one case primary tumor, in the other case liver metastases - indicate a possible pathogenetic role of CCL20 and its receptor in the development of hepatic malignancies. Moreover, we detected significantly higher CCL20 expression in the CRLM tissues compared with the HCC tissues. One possible explanation for this marked CCL20 overexpression in the hepatic metastases could be related to the ferocious malignity of metastatic cells. In other words, the malignant status of a cancer cell might be correlated with CCL20 expression. It is well known that the survival rate for patients is far worse when they have developed metastases at the time of surgery as compared to patients with the same primary tumor who have not developed metastases. It seems that as the chemokine metabolism of a cancer cell becomes increasingly unbalanced the further the malignity of the cell proceeds and the more aggressive a cancer tissue turns. This assumption is supported by previous clinico-pathological findings of our group[19], which demonstrate a significant increase in CCL20 expression rates in HCC tissues from grade Ⅲ tumors in comparison to HCC tissues from grade Ⅱ tumors. Consequently, the marked CCL20 up-regulation in CRLM in comparison to the HCC tissues reported here could be interpretated as an indication of the extent of alteration in the tumor cells. In line with this theory, we would expect higher CCL20 expression rates in liver metastases in comparison to the moderately differentiated tumor cells of the HCC tissues, since metastatic cells virtually show the highest grading level of tumor differentiation, usually bearing no resemblance with normal liver cells.

In summary, the results presented in this study suggest an association of the CCL20/CCR6 pair and the development and progression of hepatic malignancies and we propose CCL20 as a predictive pathogenetic marker for tumor grading and the existence of liver metastases. Since we also presented evidence for a correlation between CXCR4 expression and CRLM, our results also support theories that suggest CXCR4 as a potential predictive factor for colorectal metastasis of the liver. Since the identification of chemokines as key targets in cancer and metastasis has emerged as a quickly progressing research topic, various chemokine receptor antagonist compounds are presently being developed. The identification of the CCL20/CCR6 and CXCL12/CXCR4 pairs as novel targets in CRLM and other metastatic processes may be of potential clinical value for the staging of primary tumors and the prevention of hepatic recurrences.

## Abstract

**AIM:** To evaluate survival in patients undergoing palliative resection versus non-resection surgery for primary colorectal cancer in a retrospective analysis.

**METHODS:** Demographics, TNM status, operating details and survival were reviewed for 67 patients undergoing surgery for incurable colorectal cancer. Palliative resection of the primary tumor was performed in 46 cases in contrast to 21 patients with non-resection of the primary tumor and bypass surgery. Risk factors for postoperative mortality and poor survival were analyzed with univariate and multivariate analyses.

**RESULTS:** The two groups were comparable in terms of age, gender, preoperative presence of ileus and tumor stage. Multivariate analysis showed that median survival was significantly higher in patients with palliative resection surgery (544 *vs* 233 d). Differentiation of the tumor and tumor size were additional independent factors that were associated with a significantly poorer survival rate.

**CONCLUSION:** Palliative resection surgery for primary colorectal cancer is associated with a higher median survival rate. Also, the presence of liver metastasis and tumor size are associated with poor survival. Therefore, resection of the primary tumor should be considered in patients with non-curable colon cancer.

**Key words:** Palliative surgery; Colorectal cancer

## INTRODUCTION

Colorectal cancer is the second leading cause of death by malignancy in western countries. About 30% of patients, detected by screening programs for colorectal cancer, present with distant metastases[1] and non-resectable distant metastases are the threshold for curative approaches in these patients. Regardless of the palliate situation, these patients often require surgical treatment due to acute complications such as bowel obstruction and perforation. In addition colon cancer can lead to chronic symptoms such as anaemia. In principal, two surgical approaches are optional. First, the primary colon cancer can be resected and the passage of the gut can be achieved by direct anastomosis or alternatively by a stoma. Second, the primary tumor can be left in place and the passage of the gut is achieved by bypassing the tumor or a stoma. Choices for surgical approach are based on several aspects. Frequently, patients with advanced colon cancer are poor risk candidates for surgery, considering that many of the patients are elderly with concomitant medical diseases and have been debilitated by the advanced malignancy. Obviously, leaving the primary tumor in place is often less demanding for the patient and surgical palliation can be as minimal as possible.

On the other hand, experimental evidence suggests that the primary tumor might control dormancy of distant metastasis. The phenomenon by which a primary tumor is able to inhibit growth of distantly spread foci of the same tumor has been demonstrated[2]. Thus removing the primary tumor in an advanced stage of colon cancer might promote metastatic progression and determine survival time of the patient.

We reviewed the results of non-curative surgery for patients with primary colorectal cancer and analyzed factors that might influence the operative mortality rate, postoperative morbidity and the survival of these patients.

## MATERIALS AND METHODS

Palliative surgery was defined as surgery with the presence of residual local disease in the operative field and the presence of non-resectable distant metastases. Between April 1993 and December 2003, 69 patients (45 men, 24 women; mean age 62 years, range 26-85) fulfilled study criteria and were subsequently entered prospectively into a database of colorectal malignancies in the Department of Surgery, University of Regensburg. Survival data, medical record, the locations of primary cancers and metastases,

operative details, postoperative outcomes, and patients' demographics were reviewed. Morbidity was defined as any post-operative complication that led to a prolonged hospital stay, additional procedures or post-operative mortality. Operative mortality was defined as death that occurred within 30 d from surgery. Two patients left Regensburg shortly after the surgery. Their follow-up data were incomplete, and they were excluded from the survival analysis.

Forty-five (65%) patients were admitted to the hospital with symptoms. The leading cause of admission was rectal bleeding in 39 (57%) patients. Urgent presentation with intestinal obstruction or perforation occurred in 5 patients. In addition to symptomatic patients, 21 (30%) of the tumors were detected by screening programs. Concomitant medical diseases were present in 47%, particularly prevalent in elderly patients (Table 1).

Table 2 presents the sites of the primary cancer. Tumors distal to the splenic flexure were found in 54 (80%) patients. The TNM characteristics are listed in Table 3. No statistical difference between the two groups was found. The type of surgery is shown in Table 4. Resection of the cancer was performed in 46 of the 69 patients.

**Table 4 Types of surgery *n* (%)**

| | Resection | Non-resection |

| Morbidity | 3 (7) | 0 (0) |
| Presence of distant metastasis | 38 (82) | 13 (62) |
| Median day of hospital stay (range) (postoperative mortality excluded) | 16.6 (7-60) | 14.7 (7-41) |

[1]Mann-Whitney *U* test.

Categorical variables were analysed by the $\chi^2$ test or Fisher's exact test when appropriate. Continuous variables were presented in median values with range; they were analysed by the Mann-Whitney *U* test. Survival was calculated from the time of surgery. Analysis of survival excluded patients who died during the postoperative period. Survival data were analysed by the Kaplan-Meier method. Factors were compared by log-rank test. Multivariate analysis used the Cox proportional hazard model, and factors with *P* values less than 0.05 in univariate analysis were included in the multivariate analysis. Presentation of results includes hazard ratio (HR) and 95% confidence interval (CI). *P* values less than 0.05 were considered statistically significant.

## RESULTS

Patients who underwent resection of the primary tumor or a non-resection procedure were comparable in terms of age, peritoneal seedings and operative mortality, as shown in Table 5. Furthermore, there was no difference in the presence of co-morbidities. Surgery was elective in 65 patients, and the remaining 2 were operated on as urgent surgery. The operative mortality rate was 4 patients, 3% with resection and 0% with non-resection procedure. Mean hospital stay was 15, 9 d (range 7-60). The median range of hospital stay (d) was not different between the two groups.

Post-operative therapy (47 chemotherapy alone, 2 radiation therapy, 6 combined chemoradiation) was given to 55 patients and was most prevalent for those who were

younger in age or had a lower incidence of co-morbid medical diseases (Table 6). Since type of chemotherapy might influence the post-operative survival rate, stratification of the survival rates was performed according to the different drugs used. 12 different chemotherapeutic agents or combination of agents were used and no significant impact on survival was observed.

The median survival of patients with resection and without resection was 544 *vs* 233 d, respectively ($P < 0.001$; Figure 1).The analysis of risk factors that might affect the survival is shown in Table 7. Multivariate analysis showed poor survival to be associated with non-resection surgery ($P < 0.001$) and differentiation of the tumor ($P < 0.001$; Figures 2 and 3).

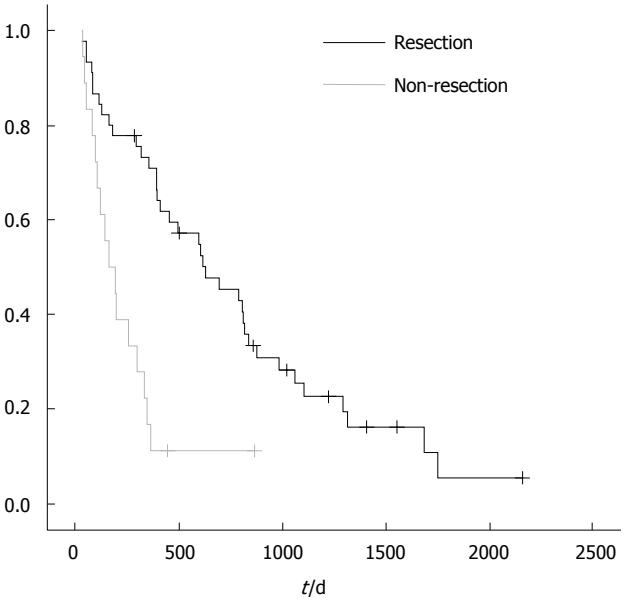

**Figure 1** Survival rates of patients with resection and non-resection.

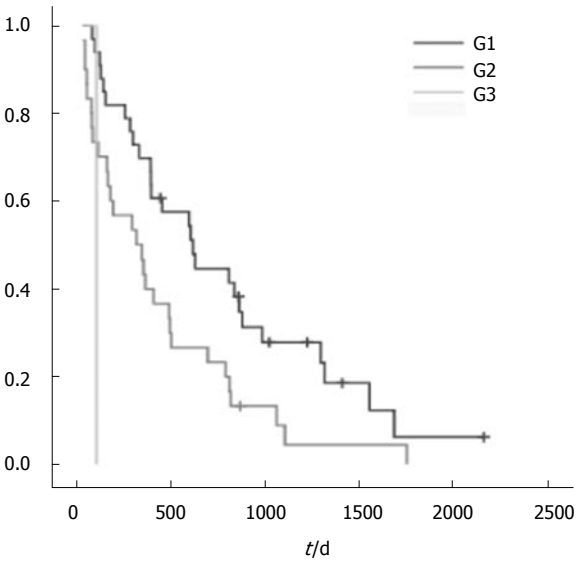

**Figure 2** Survival rates of patients dependent on differentiation of the tumor.

## DISCUSSION

Patients with incurable colorectal cancer are usually compromised by the presence of advanced malignancy and many of them also suffer from concomitant medical diseases, rendering surgical treatment an option with high risk. Therefore, the main objectives of the operative treatment are avoiding complications such as obstruction, perforation and profuse bleeding. In addition, surgery is worthwhile only if a reasonable length of survival can be achieved and the operative risk is acceptable. At present, only a few studies with detailed analysis of the results of palliative surgery for primary colorectal cancer are available making surgical treatment for patients with incurable colorectal cancer controversial[3-6]. We evaluated survival in patients undergoing palliative resection versus non-resection surgery for primary colorectal cancer in a retrospective analysis and found a significant longer survival rate for patients with resected primary tumors. Interestingly, patients with resection of the primary tumor did not benefit from chemotherapy to a greater extent compared to non-resected patients.

Bleeding and obstruction are reported to be the main presenting symptoms in patients with palliative surgery[3,7] in colorectal cancer. 67% of our patients had symptoms of bleeding or obstruction. The symptoms were usually discrete resulting in only 3% of emergency operations. As an alternative to urgent surgery, self-expanding metallic stents have been discussed as an effective non-operative means to relieve acute colonic obstruction[8-12]. However, stents may dislocate or cause bleeding in up to 30% of

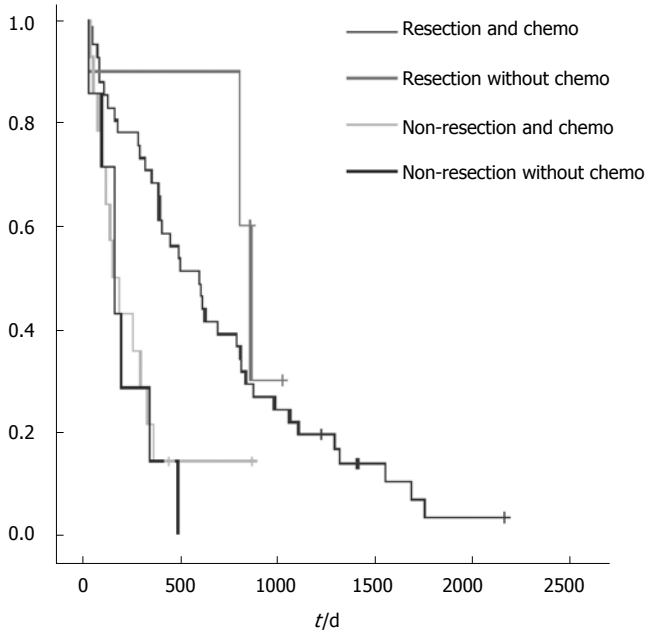

**Figure 3** Survival rates of patients with resection and non-resection and chemo therapy.

stent-treated patients. Furthermore after dilatation of the obstruction with a stent the tumor is obviously left in place. None of our patients was treated with a stent because the main symptom was bleeding, but further development of this technique might reduce side effects and it may be a better alternative to surgical treatment.

Our approach to palliative surgery was aggressive, aiming for resection of the primary tumor. Non-resection was carried out in patients who were in very poor condition or if the resection was hazardous. This point of view has also been offered by other authors[4] and is seen as better palliation. The resection rate in our cohort was 66%, which is comparable to other studies ranging from 69%[5] to 90%[3]. In contrast to other reports, age or location (rectum or rectosigmoid) of the cancer did not influence the likelihood for resection. There was a tendency to perform non-resection in patients with peritoneal seeding.

The operative mortality in this study was 2.8%. This is lower than in other studies reporting non-curative surgery[3,5]. Both patients died after anastomosis leakage and subsequent peritonitis. Anastomosis in palliative surgery for rectal cancer has been advocated by others[13] reporting one case of anastomotic leakage in 60 patients with palliative anterior resection. Our rate of anastomosis leakage is comparable and thus we would not recommend avoiding anastomosis in a palliative situation. Restoring bowel continuity is not a hazardous procedure and can improve quality of life. Non-resection was not an independent factor for high post-operative mortality (none of the non-resected patients died post-operatively). This stands in contrast to other studies, which reported high mortality rates up to 17% in patients without resection, while rates in those with resection were 9% and 5%. However, it should be emphasized that in those studies the patients who did not receive resection had advanced diseases, severe co-morbidities or unstable haemodynamic status during surgery. Both groups of our patients were comparable in these respects and lower operative trauma might be reflected in the lower mortality of non-resected patients.

Others found that extensive liver involvement and poorly differentiated tumors, the presence of ascites and the absence of other therapies, age over 75 years, and cardiovascular disease were associated with poor survival. We have found that poorly differentiated tumors are associated with poor survival in surgery for incurable colorectal cancer in our patients. Only 5 patients were older than 75 years and therefore no relation between age and outcome could be demonstrated in our study. Others propose that surgical treatment is only worthwhile if the patients do not have severe symptoms. Obviously the decision may need individual consideration, and the potential benefits and risks should be balanced carefully.

Thus non-resection, which is associated with similar morbidity and mortality rates and hospital stay lengths as resection, may be the only option to palliate complications such as obstruction or perforation. The aim must be to discharge the patient to enjoy a mediocre quality of life in the remaining days. This option, however, must be weighted against overall survival. In our cohort, the resected patients had a significant benefit in survival. Thus the enhanced operative mortality versus better survival should be considered in the individual patient, and good clinical judgment is needed to balance the benefits and risks of surgery.

We also found that the use of therapeutic chemotherapy and/or radiation therapy was not associated with better survival. Unfortunately, there were 12 different schemes of therapy given and thus no statistical difference was determined. There were only a few patients who did not receive palliative chemotherapy and thus no statistically significant level was reached. However, improved survival is likely to be achieved in current chemotherapeutic regimens. Traditional 5-fluorouracil based chemotherapy for metastatic colorectal cancer has a response rate of about 30%[14-18]. Better quality of life and improved survival have been demonstrated in patients who underwent chemotherapy than in those with the best supportive treatment[16]. Furthermore, irinotecan and oxaliplatin have been shown to produce a survival benefit and to improve quality of life in patients not responding to 5-fluorouracil based chemotherapy[19].

Taken together, palliative surgery for colorectal cancer is associated with an acceptable mortality rate, especially in patients without resection. Furthermore, anastomosis in a palliative situation is a safe procedure enhancing the quality of live for the patient. In addition, leaving the primary tumor in place is associated with poor survival. In the presence of these poor risk factors, good clinical judgment and careful consideration of balance between the risks and benefits are necessary before embarking on surgical palliation.

## Abstract

**AIM:** To assess whether a liver specific nitric oxide (NO) donor (V-PYRRO/NO) would prevent the development of portal hypertension and liver fibrosis in rats with bile duct ligation (BDL).

**METHODS:** Treatment (placebo or V-PYRRO/NO 0.53 μmol/kg per hour) was administered i.v. to rats 2 d before BDL (D-2) and maintained until the day of hemodynamic measurement (D26). Intra-hepatic NO level was estimated by measuring liver cGMP level. Effects of V-PYRRO/NO on liver fibrosis and lipid peroxidation were also assessed.

**RESULTS:** Compared to placebo treatment, V-PYRRO/NO improved splanchnic hemodynamics in BDL rats: portal pressure was significantly reduced by 27% ($P < 0.0001$) and collateral circulation development was almost completely blocked (splenorenal shunt blood flow by 74%, $P = 0.007$). Moreover, V-PYRRO/NO significantly prevented liver fibrosis development in BDL rats (by 30% in hepatic hydroxyproline content and 31% in the area of fibrosis, $P < 0.0001$ respectively), this effect being probably due to a decrease in lipid peroxidation by 44% in the hepatic malondialdehyde level ($P = 0.007$). Interestingly, we observed a significant and expected increase in liver cGMP, without any systemic hemodynamic effects (mean arterial pressure, vascular systemic resistance and cardiac output) in both sham-operated and BDL rats treated with V-PYRRO/NO. This result is in accordance with studies on V-PYRRO/NO metabolism showing a specific release of NO in the liver.

**CONCLUSION:** Continuous administrations of V-PYRRO/NO in BDL rats improved liver fibrosis and splanchnic hemodynamics without any noxious systemic hemodynamic effects.

**Key words:** Nitric oxide; Portal hypertension; Liver fibrosis; Hemodynamics; Rats

## INTRODUCTION

Chronic liver diseases generally progress slowly from inflammation to fibrosis and in many cases to portal hypertension (PHT) and cirrhosis. PHT is responsible for the development of collateral venous circulation and esophageal varices which may bleed and are life-threatening[1,2]. PHT results from increased intrahepatic vascular resistance due to not only hepatic architectural changes inherent to fibrosis but also contraction of liver vascular smooth muscle cells, myofibroblasts and hepatic stellate cells (HSCs). Indeed, not only are HSCs involved in collagen deposition and development of liver fibrosis, but they also regulate intrahepatic blood flow by sinusoid contraction/constriction[3-5]. Therefore, liver fibrosis and PHT are usually two major therapeutic targets in chronic liver diseases that might be prevented by a single agent[6].

Nitric oxide (NO), a potent vasodilator was recently shown to modulate the intrahepatic vascular tone in normal rats[7,8]. Interestingly, NO has anti-fibrotic potentials which are related to its reactive oxygen species (ROS) scavenging capabilities. Cumulative evidences suggest that PHT in cirrhosis is partly due to a decreased liver NO production from the liver sinusoidal endothelial cells[9-11]. The deficiency of NO in the cirrhotic liver may also be involved in liver fibrosis and, inversely, intrahepatic NO supplementation may prevent liver fibrosis. Several NO donors (nitroglycerin, S-nitroso-N-acetyl penicillamine and sodium nitroprusside) were shown to exert a direct anti-

fibrogenic effect by inhibiting proliferation, motility, and contractility of HSCs induced by several ROS generating systems or by platelet-derived growth factor[12-14].

Contrasting with liver NO level, systemic NO level is increased in chronic liver diseases causing deleterious effects on systemic hemodynamics[11]. Thus, NO-based drug therapy in PHT should target the liver without systemic delivery of NO. Recently, it has been shown that transduction of liver with recombinant adenovirus carrying the neuronal NOS gene significantly reduced intrahepatic resistance and portal pressure in bile duct ligation and $CCl_4$ models of cirrhosis[15]. A promising pharmacological approach has also been reported with NCX-1000, a selective liver NO-releasing derivative of ursodeoxycholic acid (UDCA)[16]. NCX-1000, but not UDCA, was shown to reduce intrahepatic resistance in the $CCl_4$ model and to inhibit HSC contraction *in vitro*, suggesting that NCX 1000-derived NO was responsible for these effects. In contrast, both NCX 1000 and UDCA reduced liver collagen deposition in that study and it was unclear whether NCX 1000-derived-NO could have antifibrotic effects by itself. Beneficial effects of selective liver NO release need to be further assessed since UDCA derivative NCX 1000 yielded encouraging results for PHT and liver fibrosis treatment[16].

V-PYRRO/NO ($O^2$-vinyl 1-(pyrrolidin-1-yl) diazen-1-ium-1, 2-diolate) was reported to specifically deliver NO in the liver[17-19]. These (presumably cytochrome P450 and epoxide hydrolase) convert V-PYRRO/NO into PYRRO/NO by removal of the O-substituted vinyl ether group[17]. In contrast to V-PYRRO/NO, PYRRO/NO is an unstable anionic diazeniumdiolate with a very short half-life (3 s at pH 7.4, 37℃) and spontaneously decomposes into NO[17]. In other words, intra-hepatic production of NO from V-PYRRO/NO is due to the hepatic enzyme-dependent metabolism of V-PYRRO/NO. Using Alzet minipumps to deliver V-PYRRO/NO into rat systemic circulation for up to 24 h, Saavedra *et al* found no significant change in the mean arterial pressure, while liver protective effects were observed in TNFalpha / galactosamine hepatotoxic model[17]. This study suggested that NO derived from V-PYRRO/NO was present mainly in the liver rather than in the systemic circulation[17]. *In vitro* studies showed consistently that V-PYRRO/NO was specifically metabolized by hepatocytes and not by other cell types examined (endothelial cells plus Kupffer cells, pulmonary artery smooth muscle cells, pulmonary artery endothelial cells and the macrophage cell line Raw 264.7)[17].

The aim of our study was to determine the effects of an early and continuous administration of V-PYRRO/NO on liver fibrogenesis and on systemic/splanchnic hemodynamics in an appropriate model of liver injury. The bile duct ligation (BDL) model was chosen for several reasons. Like the $CCL_4$ model, BDL is one of the most common models of liver fibrosis and PHT. However, using BDL rather than $CCl_4$ to induce liver fibrosis and PHT should be preferable in our study because V-PYRRO/NO and $CCl_4$ both require cytochrome P450 to be metabolized. $CCL_4$ would therefore introduce a bias in our study. The main aim of the present study was to assess the effects of V-PYRRO/NO when administered continuously two days before BDL operation, for a total of four weeks. We found that V-PYRRO/NO was efficient in decreasing both hemodynamic disorders and liver fibrosis associated with BDL and that V-PYRRO/NO anti-fibrotic effect may be due to a decrease in lipid peroxidation.

## MATERIALS AND METHODS

### Animal model of cirrhosis

Male Sprague-Dawley rats (Faculty of Medicine, Angers, France) with an initial body weight of 210 to 350 g underwent BDL under ether anesthesia. The surgical procedure was performed on day 0, as previously described[20]. Under the same conditions, sham-operated rats with an initial body weight of 220 to 320 g had a laparotomy without ligation of bile duct and served as controls. According to published recommendations[21], all rats received weekly subcutaneous injections of vitamin K1 (50 μg) to decrease mortality from hemorrhagic diathesis. Protocols performed in this laboratory were approved by the French Agriculture Office in conformity with the European legislation for research involving animals.

### Therapeutic regimen

Our study aimed to assess the effects of early and continuous administration of V-PYRRO/NO in rats with BDL. For that purpose, treatment (V-PYRRO/NO or placebo) was administered two days before BDL or sham-surgical operation (D2) and maintained until the day of hemodynamic measurement four weeks later (D26). Continuous treatment was made using Alzet osmotic minipumps (model 2ML2, Alzet®, USA). Because of their two-week half-life characteristic, these pumps were replaced on D12 with new pumps filled with freshly diluted solutions of V-PYRRO/NO, prepared from stock solutions of V-PYRRO/NO (100 mg in 2 mL ethanol) diluted 1:10 in NaCl 0.9%. Final concentration of V-PYRRO/NO at 5 mg/mL was chosen in order to obtain a delivery rate of 0.53 μmol/kg per hour into the rat circulation using Alzet minipumps with a 2 mL volume capacity and a 5 μL/h delivery rate (giving a two-week half-life to these minipumps). The rat average weight was around 300 g. The minipumps were inserted subcutaneously to the back of the rats under anesthesia (ether) and connected to the left femoral vein of the animals with a polyethylene catheter (PE-60, Clay Adams, NJ, USA). The study included 4 groups of rats treated either with V-PYRRO/NO ($0.53\ \mu mol.kg^{-1}.h^{-1}$) or with placebo (ethanol diluted 1:10 in NaCl 0.9 %) from D2 to D26. The groups were as follows: sham with V-PYRRO/NO ($n$ = 13), sham with placebo ($n$ = 9), BDL with V-PYRRO/NO ($n$ = 21), and BDL with placebo ($n$ = 22).

### Rat conditioning

Hemodynamic measurement was performed on rats anesthetized with an intraperitoneal injection of 1mL/100 kg pentobarbital (Nesdonal® 0.5 g, Rhône-Poulenc, Paris, France). All rats were given free access to food and water until 14 to 16 h before the study. Food was withdrawn to avoid digestive influences on splanchnic hemodynamics[22].

During hemodynamic measurement, body temperature was maintained at 37℃ with a homeothermic blanket system (Homeothermic Blanket Control Unit, Harvard Apparatus Inc, Natick, USA). Hemodynamic measurement was performed 30 min after manipulation, i.e. when values had stabilized, which included: mean arterial pressure (MAP), heart rate (HR), portal pressure (PP), cardiac output (CO) or index (CI), systemic vascular resistance (SVR), and splenorenal shunt (SRS) blood flow. After hemodynamic measurement, the animals were killed by exsanguination under anesthesia. Body weight and liver mass were recorded at the time of death. Gains in body mass in each group were calculated as: (final body mass - initial body mass)/initial body mass.

### Hemodynamic and ascites measurement

MAP, HR, PP, SRS blood flow and CO were measured in anesthetized rats as described previously[23-25]. CO and SRS blood flow, an accurate index of collateral circulation blood flow, (as shown before[24]) were measured using the transit time ultrasound (TTU) devices. Amounts of ascites were estimated roughly and indicated with the following grades: 0: no ascites, 1: ascites absorbing less than half a compress, 2: ascites absorbing a compress, 3: ascites absorbing more than one compress.

### Liver fibrosis evaluation

Area of liver fibrosis. The area of liver fibrosis was measured by image analysis as described in our laboratory[26]. Briefly, three liver sections ( > 1 $cm^2$ each) were randomly taken from the right, median and left liver lobes of each rat. Liver sections were stained in 0.1% picrosirius red solution and histomorphometric analysis was performed on a Leica Quantimet Q570 image processor. Total liver area of fibrosis was expressed as the mean fibrosis percentage in the 3 liver sections. In each of them, 30 fields were evaluated.

Hepatic hydroxyproline content. As a liver fibrosis marker[27], hepatic hydroxyproline-content was measured using a modified version of the method described by Jamall *et al*[28] and Seifert *et al*[29]. Briefly, 3 liver fragments (250 mg) from each rat were homogenized in 6N HCl and then hydrolyzed at 110℃ for 18 h. After cooling, the hydrolysate was filtered through a 0.45-μm Millipore filter and aliquots of the hydrolysate were neutralized with NaOH 6N. Chloramine T was added to a final concentration of 2.5 mmol/L. After 5 min, 410 mmol/L paradimethyl-aminobenzaldehyde was added and the mixture was incubated for 30 min at 60℃. After cooling to room temperature, the samples were read at 560 nm with a control reagent which contained the complete system without added tissues.

The concentration of hydroxyproline in each sample was determined from a standard curve generated from known quantities of hydroxyproline. Mean hepatic hydroxyproline for each rat corresponds to three liver samples analyzed. The final result was expressed as μg of hydroxyproline/g liver protein. Liver protein content was measured in the fourth fragment of liver with a BCA Protein Kit (Pierce, Rockford, USA).

### Other biochemical measurements

Liver and kidney function tests. At the end of the hemodynamic measurement, blood samples (from the femoral artery) were immediately centrifuged at 4℃, and sera were kept at -80℃ until the biochemical assays were performed. Each rat underwent blood liver function tests including total bilirubin, alkaline phosphatases (ALP), alanine aminotransferase (ALT), aspartate aminotransferase (AST) activities and blood renal function tests including urea and creatinine.

Liver cGMP assay. Hepatic cGMP levels, reflecting hepatic NO level, were measured by enzyme immunoassay using a commercially available kit (Amersham-Pharmacia Biotech, Uppsala, Sweden).

Total liver NOS activity. NOS activity was measured by converting L[$^{14}$C] arginine into L[$^{14}$C] citrulline based on the modified method from Cahill *et al*[30]. Tissues were minced and homogenized by sonication (Vibracell, Bioblock, Illkirch, France) at 4℃ in a buffer containing 320 mmol/L sucrose, 50 mmol/L Tris-HCl, 1 mmol/L ethylendiaminetetra-acetic acid, 1 mmol/L DTT, 100 mg/L PMSE 10 mg/L leupeptin, 10 μg/ml trypsin-inhibitor and 2 mg/L aprotinin. After centrifugation (1000 × *g* for 5 min at 4℃), 50 μL of the supernatant (50-100 μg protein) was incubated in a total volume of 160 μL Tris-HCI (pH 7.4) containing 0.1 mmol/L ethylendiaminetetra-acetic acid, 3 μmol/L tetrahydrobiopterin, 1 mmol/L NADPH, 5 mmol/L valine, 5 mmol/L of ethylene glyco-bi-aminoethylether-N-tetra-acetic acid (EGTA), and 1 37 KBq/Ml [$^{14}$C] arginine. L[$^{14}$C] citrulline was separated by applying the samples to columns containing pre-equilibrated DOWEX AGW-X8 and eluting them with 1 mL of 1 mmol/L citrulline. The amount of radioactivity was measured by scintillation counting (Beckmann, LS 3801, Irvine, CA, USA). Enzyme activity was expressed as pmol of citrulline formed per mg of proteins per hour. Protein concentration was measured in the supernatant using a commercially available protein kit (BCA Protein Kit, Pierce, Rockford, USA).

Serum nitrate/nitrite levels. The systemic NO production was evaluated through the measurement of serum nitrate/nitrite levels using a commercially available colorimetric assay (Nitrate/Nitrite endpoint determination colorimetric assay kit, Cayman Chemical, Ann Arbor, USA).

Liver malonedialdehyde assay (MDA). Hepatic MDA level, a marker of lipid peroxidation, was determined by the thiobarbituric acid reaction and quantified by fluorometry (excitation wavelength: 515 nm, emission wavelength: 548 nm), using 1, 1, 3, 3-tetraethoxypropane as standard[31]. Hemodynamic, biochemical assays and morphometric studies of the liver were performed by two observers unaware of the treatment given.

### Statistical analysis

Quantitative variables were expressed as mean ± SD. Multiple quantitative variables were compared using the analysis of variance or by the Kruskall and Wallis test when variances were heterogeneous. Post hoc comparisons were performed using parametric tests for homogeneous (Tukey) or heterogeneous (Tamhame) variances or non-parametric test (Mann-Whitney). Box plots indicate median, interquartile range and extremes. An $\alpha$ risk < 5% was considered to be statistically significant. The qualitative variable 'mortality' has been studied using the $\chi^2$ test. The statistical software

## RESULTS

### General characteristics of rats

Initial body weight was not significantly different among the groups. As expected in placebo-treated rats, body mass gain was significantly lower in BDL rats than in sham rats. Moreover, liver mass/body weight ratio was significantly higher in BDL rats than in sham rats. V-PYRRO/NO treatment did not influence liver mass in any group but seemed to reduce the presence of ascites in BDL rats (no ascites was observed in the V-PYRRO/NO BDL rats, in contrast with placebo BDL rats) (Table 1).

### Liver and kidney serum function tests

BDL rats had a significant increase in AST and ALP activities and bilirubin level compared to their respective control groups. V-PYRRO/NO had no effect on liver or renal tests in sham or BDL rats (Table 2).

### Hemodynamics

As expected, BDL rats had a significant reduction in MAP and SVR, and a marked increase in CI and portal pressure as compared to their respective control groups. In the placebo groups, SRS blood flow was significantly increased in BDL rats *vs* sham rats. V-PYRRO/NO did not significantly change the systemic hemodynamics (MAP, HR, CI and SVR) in both BDL and sham rats. In contrast, V-PYRRO/NO significantly affected portal hemodynamics in BDL rats: a 27% decrease in PP and a 74% decrease in SRS blood flow (Table 3).

### Liver fibrosis and lipid peroxidation

Liver fibrosis was quantified in each group of rats based

**Table 4 Liver fibrosis of rats**

| | Sham | | BDL | | *P* |

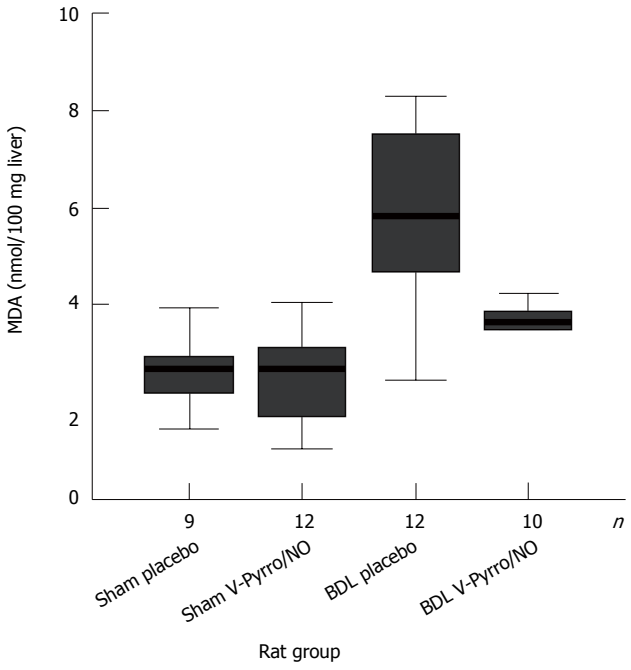

**Figure 1** Liver malonedialdehyde content (Kruskal-Wallis test: $P = 0.002$).

on the area of liver fibrosis and hepatic hydroxyproline content (Table 4). As expected, BDL operation induced a dramatic increase in both markers of liver fibrosis. V-PYRRO/NO significantly reduced the area of liver fibrosis and hepatic hydroxyproline content in BDL rats (by 31% and 30%, respectively). Since NO has ROS scavenging capabilities and lipid peroxidation products are known to stimulate fibrogenesis, we measured liver MDA levels in each group of rats to determine whether the anti-fibrotic effect of V-PYRRO/NO was related to the inhibition of lipid peroxidation. V-PYRRO/NO significantly decreased liver MDA level in BDL rats by 44%, $P = 0.007$ (Figure 1).

### *Measurements reflecting NO level*

V-PYRRO/NO significantly increased liver cGMP levels in BDL rats ($P = 0.04$) (Figure 2) but decreased liver total NOS activity ($P = 0.04$) (Figure 3). V-PYRRO/NO did not significantly change the serum nitrate/nitrite levels in BDL rats (82 ± 19 *vs* 72 ± 16 μmol/L, NS) (data not shown).

## DISCUSSION

V-PYRRO/NO had no noxious effects on body and liver

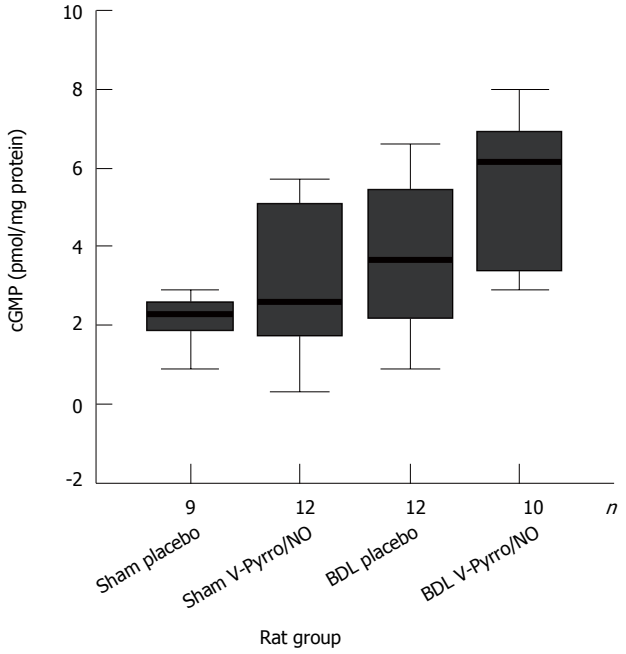

**Figure 2** Liver cGMP level (Kruskal-Wallis test: $P = 0.003$).

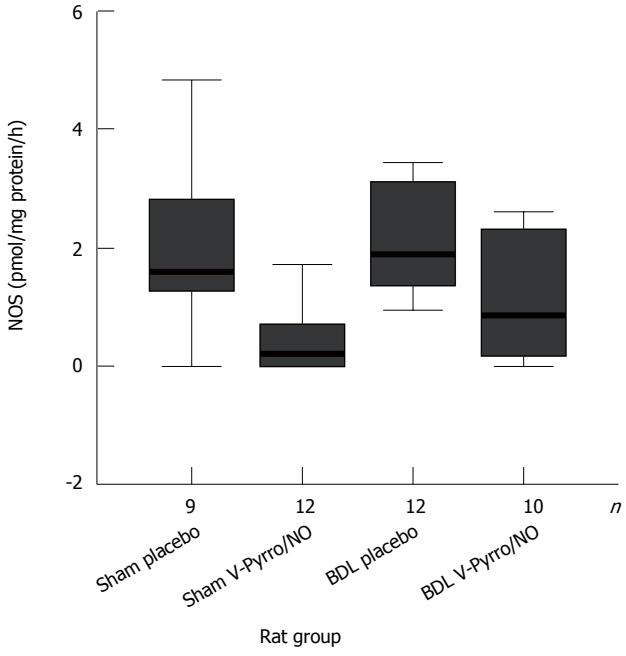

**Figure 3** Liver total NOS activity (Kruskal-Wallis test: $P = 0.001$).

weight gains, hepatic and renal functions, and did not significantly alter systemic hemodynamics (MAP, CI, or SVR) in both sham and BDL rats. Our data on V-PYRRO/NO systemic effects after continuous administration complete those of Saavedra *et al* showing that acute systemic administration of V-PYRRO/NO had no effect on MAP in the normal rats[17,19]. On the other hand, V-PYRRO/NO significantly decreased PP and SRS blood flow (an index of collateral circulation) in BDL rats. The decrease in PP can be attributed to reduced hepatic vascular resistance and/or diminished fibrogenesis. The decrease in SRS blood flow might be partly due to the reduction in PP or to other

mechanisms. Concerning the effect of liver-specific NO donor on PP, Fiorucci *et al*[32] reported a decrease in PP upon NCX-1000 administration for 5 d in four-week BDL rats whereas Loureiro-Silva *et al*[33] did not document such a decrease in their 10-12 week $CCl_4$ rats treated for 14 d with the same dosage of NCX-1000. The reason for NCX-1000 effect on PP is not obvious but may be model-related[34]. Our findings support this concept in the BDL model where V-PYRRO/NO did decrease PP.

Our study showed that V-PYRRO/NO limited the development of liver fibrosis in BDL rats (there was a significant decrease in the area of liver fibrosis and liver hydroxyproline content). Products of lipid peroxidation are known to stimulate fibrogenesis. To determine whether the anti-fibrotic effect of V-PYRRO/NO was related to the inhibition of lipid peroxidation, we measured MDA level (a marker of lipid peroxidation) in the livers of each group. Consistently with a study in the acetaminophen-induced hepatotoxicity murine model[35], we found that V-PYRRO/NO decreased hepatic MDA level in BDL rats. The decrease in liver lipid peroxidation in our V-PYRRO/NO rats may result from a reduction in hepatocyte death as suggested by several *in vitro* studies[17-19,35]. Thus, the mechanism underlying the anti-fibrotic effect of V-PYRRO/NO may be a NO-mediated protection against lipid peroxidation.

In the present study, V-PYRRO/NO treatment increased hepatic cGMP levels (reflecting hepatic NO generation) but decreased hepatic total NOS activity. This may be due to NO feedback inhibition on NOS activity, as suggested in a recent study[36]. As discussed in the introduction section, V-PYRRO/NO was designed to be a stable molecule until metabolized into PYRRO/NO by enzymes predominant in the liver. Hepatocytes contain high levels of enzymes capable of metabolizing V-PYRRO/NO and incubation with V-PYRRO/NO (24 h, 1 mmol/L) resulted in increased nitrite/nitrate levels in the supernatant of these cells in contrast to four other cell types examined[17]. Confirming other studies, we observed no systemic hemodynamic change and unaltered nitrate/nitrite levels in the serum of our BDL and sham rats after V-PYRRO/NO treatment (0.53 μmol/L per hour for 24 d), supporting the absence of systemic diffusion of NO from V-PYRRO/NO[17-19]. Moreover, in agreement with a study using acute administration of V-PYRRO/NO[17], we found that cGMP increased in the liver but not in a non-liver tissue (such as lungs, data not shown) of the rats chronically treated with V-PYRRO/NO. Our study also suggests that exogenous NO production in the liver is beneficial to the treatment of liver fibrosis and PHT. Additional experiments are however needed to rule out an effect of the bio-converted drug (i.e. the carrier compound without NO group).

In conclusion, the present *in vivo* study showed that early and continuous administration of V-PYRRO/NO via osmotic minipumps resulted in a decrease in liver lipid peroxidation and fibrosis, as well as splanchnic hemodynamic improvement (decrease in portal pressure and in collateral circulation development), without systemic hemodynamic effects. This result supports other studies showing that NO derived from V-PYRRO/NO was delivered preferentially to the liver rather than in the systemic circulation. Taken together, our study suggests that targeting NO delivery to the liver might be an interesting option for the treatment of liver fibrosis or early cirrhosis.

## ACKNOWLEDGMENTS

We would like to thank Mr. Jérôme Roux and Mr. Pierre Legras and Jean Luc Grandpierre for their technical help, Mrs Emanuelle Métayer, Anita Omasta and Dale Roche for their contributions in this work.

## Abstract

**AIM:** To study isolation and chemical characterization of pectin derived from the common cranberry *Vaccinium oxycoccos* L. (oxycoccusan OP) and the testing of its preventive effect on experimental colitis.

**METHODS:** Mice were administrated orally with OP two days prior to a rectal injection of 5% acetic acid and examined for colonic damage 24 h later. Colonic inflammation was characterized by macroscopical injury and enhanced levels of myeloperoxidase activity measured spectrophotometrically with o-phenylene diamine as the substrate. The mucus contents of the colon were determined by the Alcian blue dye binding method. Vascular permeability was estimated using 4% Evans blue passage after i.p. injection of 0.05 mol/L acetic acid.

**RESULTS:** In the mice treated with OP, colonic macroscopic scores (1.1 ± 0.4 *vs* 2.7, $P < 0.01$) and the total square area of damage (10 ± 2 *vs* 21 ± 7, $P < 0.01$) were significantly reduced when compared with the vehicle-treated colitis group. OP was shown to decrease the tissue myeloperoxidase activity in colons (42 ± 11 *vs* 112 ± 40, $P < 0.01$) and enhance the amount of mucus of colitis mice (0.9 ± 0.1 *vs* 0.4 ± 0.1, $P < 0.01$). The level of colonic malondialdehyde was noted to decrease in OP-pretreated mice (3.6 ± 0.7 *vs* 5.1 ± 0.8, $P < 0.01$). OP was found to decrease the inflammatory status of mice as was determined by reduction of vascular permeability (161 ± 34 *vs* 241 ± 21, $P < 0.01$). Adhesion of peritoneal neutrophils and macrophages was also shown to decrease after administration of OP (141 ± 50 *vs* 235 ± 37, $P < 0.05$).

**CONCLUSION:** Thus, a preventive effect of pectin from the common cranberry, namely oxycoccusan OP, on acetic acid-induced colitis in mice was detected. A reduction of neutrophil infiltration and antioxidant action may be implicated in the protective effect of oxycoccusan.

## INTRODUCTION

Inflammatory bowel disease (IBD), including Crohn's disease and ulcerative colitis (UC), are characterized by chronic and spontaneously relapsing inflammation resulting in tissue destruction[1]. At present, there is no radical treatment for UC. Steroids and salicylic acid preparations are usually used to control and suppress the inflammation. However, adverse reactions and a high relapse rate are problems arising from these therapies[2]. Acute intestinal inflammation is associated with the infiltration of a large number of leukocytes into the bowel mucosa. A decrease in leukocyte number and function has been shown to prevent bowel inflammation[3]. Therefore, leukocytes are assumed to be a potential target of colitis drug research.

Pectic polysaccharides are well known to be a component of dietary fiber and to possess immunomodulating capacity with a predominant effect on neutrophils and macrophages. Feeding with pectins has been found to reduce a degree of experimental bowel injury induced by acetic acid[4] and by dextran sulfate

sodium[5]. Oral pretreatment with comaruman, a pectin from cinquefoil *Comarum palustre* L., has been shown to prevent the development of experimental colitis in mice[6].

It is well known that physiological effects are determined by the pectin structure[7]. Pectins used as food additives consist mostly of linear chains of galacturonic acid residues[8], whereas pectins of fruits, vegetables and herbs are characterized by an abundance of diversity of the macromolecular structure[7]. Therefore, the search and chemical characterization of new pectins with colon-protecting capacity is of great interest.

*Vaccinium* sp. (Ericaceae) is widespread throughout the cool temperate Northern Hemisphere, including the northern parts of Europe, Asia and North America. Cranberries are widely used in food as well as in ethnomedicine[9]. Regular drinking of cranberry juice has been shown to reduce the recurrence of urinary tract infections due to its action against coliform bacteria[10]. Cranberries were found to contain fructose[11] and a high molecular weight constituent of an unknown nature[12] that inhibits the adherence of bacteria to eukaryotic cells. The non-dialyzable material prepared from the cranberry juice concentrate has been shown to decrease the pro-inflammatory cytokine response of macrophages induced by LPS[13]. Cranberries are among the richest food sources of procyanidins, which are polyphenols possessing a potent anti-oxidant capacity[14]. Phenolic compounds of cranberries have been found to inhibit the growth of human gastrointestinal pathogens[15].

Cranberries have been far reported to contain a high amount of pectic polysaccharides[16,17]. However, the structure and anti-inflammatory activity of pectin derived from cranberries have not been studied until now.

The present work is devoted to testing the preventive effect of the pectin from the common cranberry *Vaccinium oxycoccos* L. on experimental colitis.

## MATERIALS AND METHODS

### Materials

Oxycoccusan OP was extracted from the ripe berries of the common cranberry *Vaccinium oxycoccos* L. (*Oxycoccus palustre* Pers.) with aqueous ammonium oxalate as described previously[18]. OP was shown to consist of primarily of galacturonic acid residues (82%) together with the minor residues of rhamnose (1.5%), arabinose (8%), glucose (5%) and galactose (3%) (Mw = 100-300 kDa). The apple pectin (MP Biomedicals, Inc.) was determined to consist of the galacturonic acid residues (70%) together with residues of glucose (29%) and traces of rhamnose, arabinose and galactose residues (Mw = 200-400 kDa). Prednisolone (Akrihin), *o*-phenylene diamine, horseradish peroxidase (Roanal), alcian blue, fetal calf serum, thiobarbituric acid (Sigma), and 96-well flat-bottom tissue culture plates (Linbro®, MP Biomedicals, Inc.) were used in this study.

### Animals

The structure of this study and the animal experimental procedures were approved by the Ethical Committee of the Komi Science Center of the Russian Academy of Sciences on Animal Care and Use.

Male A/HeJ mice weighing 20-25 g were used. They were housed in standard environmental conditions and fed with rodent diet and water ad libitum. The mice were fasted for a night before the induction of colitis but had free access to drinking tap water. Colitis was then induced and its severity was evaluated morphologically in three experiments. One of the biochemical parameters, including myeloperoxidase (MPO), malondialdehyde (MDA) or mucus content, was measured in the individual experiment after morphological observation. Each experimental group consisted of 7 animals.

### Application of OP and induction of experimental colitis

The mice were lightly anesthetized with ether. A plastic catheter (2 cm long, external diameter 1 mm) was inserted rectally into the colon so that the tip was 3 cm proximal to the anus. Acetic acid (5%, pH 2.5, 0.15 mL,) was instilled into the colon lumen through the catheter, and saline was instilled as a control[19].

Animals were treated orally with OP at the dose of 25-100 mg/kg (dissolved in water) by using a flexible rubber catheter two days before the induction of colitis. The control mice received the same amount (0.2 mL) of water. The positive control and reference groups received prednisolone (5 mg/kg) and commercial apple pectin (100 mg/kg), respectively.

### Assessment of colitis severity

Mice were killed by cervical dislocation one day after the administration of acetic acid. The entire colon was isolated and opened longitudinally, and rinsed with phosphate buffered saline (PBS). The macroscopic scoring of the colon damage was performed using the following criteria: 0, no macroscopic change; (1) mucosal erythema alone; (2) mild mucosal oedema, slight bleeding or small erosion; (3) moderate oedema, bleeding ulcers or erosion, oedema and tissue necrosis[20]. For each mouse, the ulcer area was determined by summing the sizes of lesions measured macroscopically by two blinded observers. The total area of damage was expressed as the relative percentage (%) of the total surface area of the colon.

### Determination of colonic myeloperoxidase (MPO) activity

After the macroscopic measurements, the excised colons (100-150 mg) were homogenized in PBS (pH 7.4) and centrifuged at 10 000 × *g* for 20 min at 4℃. MPO activity in the supernatants was then assayed by mixing the supernatant with citric phosphate buffer (pH 5.0) containing 0.4 mg/ml of *o*-phenylene diamine and 0.015% hydrogen peroxide. The change in absorbance (A) at 492 nm was measured spectrophotometrically and compared with a standard dilution of horseradish peroxidase[21]. MPO activity was expressed as units/mg of tissue.

### Measurement of the levels of lipid peroxidation

Malondialdehyde (MDA) formation was used to quantify lipid peroxidation in the intestinal wall and was measured as thiobarbituric acid-reactive material[22]. The intestinal samples were homogenized (100 mg/mL) in 1.2% KCl buffer. Two hundred microliters of the homogenates were then added to a reaction mixture consisting of 0.8%

aqueous thiobarbituric acid (0.75 mL), 8.1% sodium dodecyl sulfate (0.1 mL), 0.75 mL of 20% acetic acid (pH 3.5), and distilled water (0.3 mL). The mixture was heated at 90℃ for 45 min. After cooling to room temperature, 2.0 mL of a mixture of *N*-butanol and pyridine (15:1, v/v) was added to 2.0 mL of the samples. The mixture was shaken vigorously. After centrifugation at 4000 r/min for 10 min, the absorbance of the organic layer was measured at 540 nm. The MDA level is expressed as nanomoles per milligram of protein[23].

### Evaluation of the adherent colonic mucus

The mucus content of the colon was determined spectrophotometrically by the Alcian blue dye binding method[24]. The colon was excised and immersed for 2 h in 0.1% Alcian blue in 0.16 mol/L sucrose solution buffered with 0.05 mol/L aqueous sodium acetate. The unbound dye was then removed by two subsequent washings for 15 and 45 min in 0.25 mol/L sucrose solution and the mucus-bound dye was eluted by immersing the colon in a 0.5 mol/L $MgCl_2$ solution for 2 h. The solution obtained was centrifuged at 4000 r/min and *A* of supernatant was read at 650 nm. The amount of Alcian blue extracted per one gram of the wet colonic sample was then calculated from standard curves.

### Measurement of vascular permeability

Vascular permeability was measured in the healthy mice two days after a single oral administration of OP or indomethacin as a positive control. Mice were injected intravenously with 4% Evans blue (0.01 mL/g body weight). After injection of the dye, 0.05 mol/L acetic acid (0.01 mL/g body weight) was injected intraperitoneally. Fifteen minutes later, the mice were killed by an overdose of ether and the viscera were exposed after a 1 min period to allow blood to drain away from the abdominal wall. The animal was held by a flap of the abdominal wall and the viscera were irrigated with saline over a Petri dish. The washing was filtered through glass wool and transferred to a test tube. To each tube was added 0.1 mL of 0.05 mol/L NaOH to clear any turbidity due to protein, and *A* was read at 590 nm[25].

### Adhesion of peritoneal leukocytes

The peritoneal cells were harvested from mice by peritoneal lavage with phosphate buffered saline (5 mL). The cells were washed by centrifugation (1500 r/min, 10 min) and then suspended in Hank's medium supplemented with 10% fetal calf serum. The cell suspensions (0.1 mL) were incubated in a 96-well flat-bottom tissue culture plate in the presence of phorbol-12-myristate-13-acetate (PMA, 0.025 mg/L) as a stimulating agent at 37℃ for 15 min. The wells were washed to remove the nonadherent cells and the adherent cells were fixed in ethanol and stained with azure-eosin. The colored material was solubilized in MeOH and *A* of the solution obtained was measured at 650 nm[26].

### Statistical analysis

All data were expressed as the as mean ± SD. Nonparametric statistics were used to evaluate the results. Comparisons between groups were made with the Mann Whitney *U*-test (package "MedCalc" v.9.1.0.1, Mariakerke, Belgium). A value of $P < 0.05$ was considered significant.

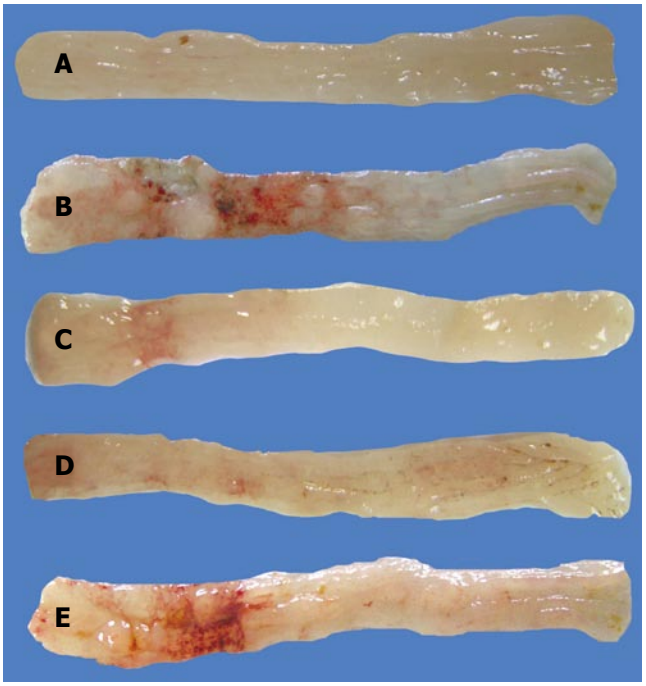

**Figure 1** Macroscopic examination of the colonic mucosa before (**A**) and 24 h after acetic acid injection (**B-E**). Mice were treated two days previously with (**B**) saline (damage score 4, square area of injury 40%); (**C**) prednisolone 5 mg/kg (damage score 2, square area of injury 1%); (**D**) OP, 100 mg/kg (damage score 2, square area of injury 3%); (**E**) apple pectin, 100 mg/kg (damage score 3, square area of injury 25%). The colon without the cecum was removed and opened along the mesenteric border.

## RESULTS

### Effect of OP on colitis severity

All of the mice were found to be sick after a rectal injection of acetic acid and to have diarrhea with blood in the stool and abdominal distention. In comparison with healthy mice (Figure 1A ), the colonic samples from mice with colitis were shown to have severe mucosal damage with edema, deep ulcerations and hemorrhages 24 h after the rectal injection of acetic acid (Figure 1B). A colonic inflammation was biochemically monitored by measuring the level of MPO activity in the colonic tissue taken from the site of inflammation. MPO activity was found to increase from 46 ± 8 to 112 ± 40 U/mg ($P < 0.01$, $n = 7$). Acetic acid infused rectally was shown to reduce the colon-bound mucus from 1.2 ± 0.4 to 0.4 ± 0.17 μg/mL ($P < 0.01$, $n = 7$). Damage of the colon reached the maximum level 24 h after the rectal injection of acetic acid. Signs of healing and regeneration of the mucosa were observed on the 5$^{th}$ d and the mucosa became almost normal on the 8$^{th}$ d after injection of acetic acid.

Oral administration of oxycoccusan OP two days before infusion of acetic acid into the colon was found to prevent the progression of colitis (Figure 1C). In the mice treated with OP, colonic macroscopic scores and the total square area of damage were significantly reduced when

**Table 1 Preventive effect on colon injury of oxycoccusan OP administered orally two days before infusion of acetic acid into the rectum of mice (means ± SD)**

| Pretreatment | Macroscopic damage score | Total square of injury, % |
|---|---|---|
| Vehicle-treated (Colitis) | 2.7 ± 0.8 | 21 ± 7 |
| Oxycoccusan OP | | |
| 25 mg/kg | 2.0 ± 0.4 | 17 ± 9 |
| 50 mg/kg | 2.0 ± 0.8 | 20 ± 9 |
| 100 mg/kg | 1.1 ± 0.4[b] | 10 ± 2[b] |
| Prednisolone 5 mg/kg | 1.3 ± 0.7[b] | 8 ± 3[b] |
| Apple pectin 100 mg/kg | 2.6 ± 0.7 | 23 ± 9 |

[b]$P < 0.01$ *vs* the vehicle-treated colitis group ('Colitis'). $n = 7$.

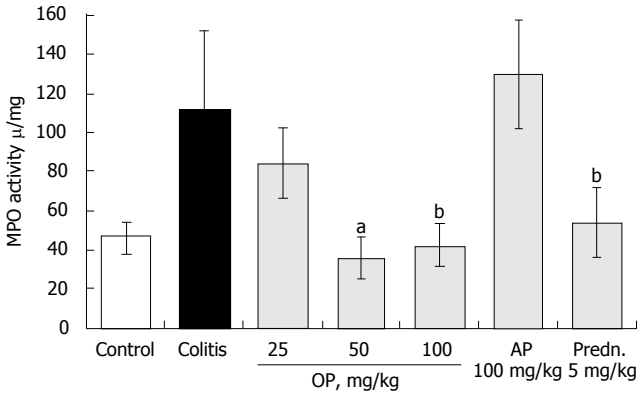

**Figure 2** Effect of oxycoccusan OP on myeloperoxidase (MPO) activity in colonic tissue of mice with acetic acid-induced colitis. Values are means ± SD ($n = 7$), [a]$P < 0.05$, [b]$P < 0.01$ *vs* the colitis group.

compared with the vehicle-treated colitis group (Table 1). The preventive effect of OP was dose-related and comparable with that of prednisolone in a dose of 5 mg/kg, administered p.o. (Figure 1D). The apple pectin used as a reference pectic substance failed to influence the colitis (Figure 1E).

The MPO activities were estimated in the colonic samples as a marker of granulocyte and monocyte influx into the tissue. A peroral pretreatment of mice with OP orally was shown to attenuate the tissue MPO activity in colons as compared with the colitis group (Figure 2).

In the next experiment, the macroscopic score (1.8 ± 0.4 *vs* 2.7 ± 0.6, $P < 0.05$) and square area of damage (7 ± 3 *vs* 28% ± 10%, $P < 0.01$) were also decreased in colitis mice receiving OP pretreatment. Corresponding to morphological alterations, MDA levels were increased in the colonic samples of colitis mice in comparison to healthy mice. MDA levels in the samples obtained from mice that received OP were found to decrease compared to those in the colitis group (Table 2).

In the third experiment, the production of mucus was measured in the colonic samples of healthy, colitis-affected (macroscopic score 2.8 ± 0.9; square area of damage 21% ± 7%) and OP-administered (macroscopic score 1.7 ± 0.5; damage square 8% ± 6%) mice. OP was found to stimulate the production of mucus by colons of colitis-affected mice. The evaluation of Alcian blue recovery from colon-bound mucus in the OP-treated animals with colitis showed that the levels of adherent mucus were comparable with those detected in native mice (Figure 3).

**Table 2 Preventive effects on colonic MDA levels of oxycoccusan OP administered orally two days before infusion of acetic acid into the rectum of mice (means ± SD)**

| Pretreatment | nmol/mg of protein |
|---|---|
| Healthy | 3.6 ± 0.8 |
| Vehicle-treated (Colitis) | 5.1 ± 0.8 |
| Oxycoccusan OP 100 mg/kg | 3.6 ± 0.7[b] |
| Apple pectin 100 mg/kg | 4.2 ± 1.4 |

[b]$P < 0.01$ *vs* vehicle-treated colitis group ('Colitis'). $n = 7$.

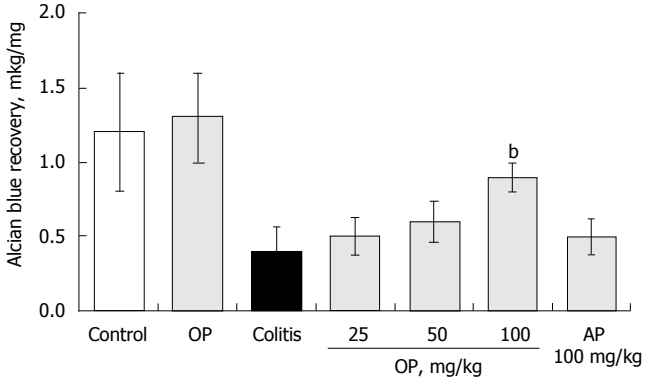

**Figure 3** Effect of oxycoccusan OP (100 mg/kg) on the levels of bound mucus in the colon of mice. Values are means ± SD ($n = 7$), [b]$P < 0.01$ *vs* the appropriate control.

### *Effect of OP on healthy mice*

Vascular permeability, the adhesion of peritoneal leukocytes, and colon-bound mucus were measured two days after oral administration of oxycoccusan to native mice as the initial step to elucidate the mechanism of the preventive effect of oxycoccusan. Oral administration of OP failed to influence the colon mucosa of healthy mice (Figure 3). OP was found to decrease the inflammatory status of mice as was detected by a reduction of vascular permeability (Figure 4). The adhesion of peritoneal neutrophils and macrophages was shown to slightly decrease after the administration of OP (Figure 5). The apple pectin, in comparison with oxycoccusan, failed to possess anti-inflammatory activity and failed to enhance the mucosal layer.

## DISCUSSION

Plant polysaccharides have been previously demonstrated to reduce colon damage in experimental colitis[4,5,27]. The described investigations were performed at an extended exposure (6-21 d) to polysaccharides starting after the induction of colitis. Various effects of polysaccharides are likely to interfuse during this long exposure. In the present study, pectin OP was found to prevent acetic acid-

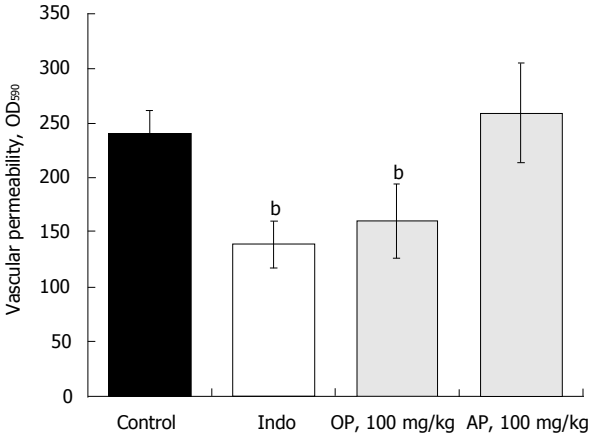

**Figure 4** Effect of oxycoccusan OP on the vascular permeability of the healthy mice. Values are means ± SD ($n$ = 7), $^{b}P < 0.01$ *vs* the control.

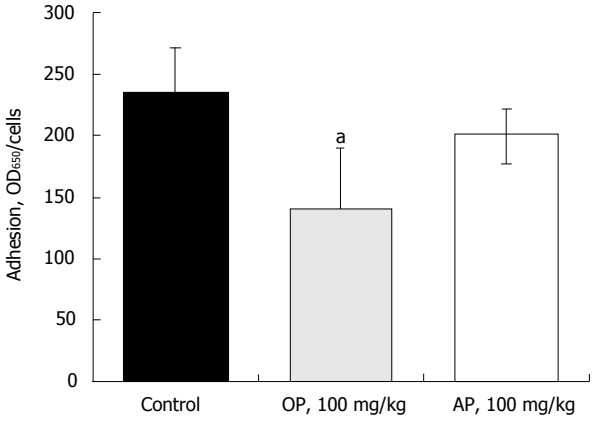

**Figure 5** Effect of oxycoccusan OP on the adhesion of peritoneal leukocytes of the healthy mice. Values are means ± SD ($n$ = 7), $^{a}P < 0.05$ *vs* the control.

induced colitis when given once beforehand at doses of 50-100 mg/kg. The doses of pectin used were chosen to approximate the estimated human intake as dietary fiber[28]. The protective effect of OP was comparable with that of prednisolone, which is a conventional medicine for the treatment of acute episodes of UC.

The exact mechanism of the preventive effect of OP on colitis remains unclear. The suppression of MPO activity by OP indicates that pectin inhibits the accumulation of neutrophils in the colonic mucosa. Indeed, MPO activity has been previously shown to be proportional to a number of infiltrating granulocytes, primarily neutrophils in the model of colonic inflammation[29]. Increasing amounts of transmigrating neutrophils induce significant epithelial disruptions resulting in epithelial discontinuities and erosions[30]. Therefore, it has been suggested that a delay in the influx of neutrophils into the intestinal wall is implicated in the preventive effect of cranberry pectin. A migration of neutrophils from the microvasculature is due to the influx of luminal proinflammatory bacterial products into the *lamina propria,* which results from disruption of the gastrointestinal barrier by oxygen radicals[31]. The role of reactive oxygen species has been stressed in recent years. Increased lipid peroxidation has been identified in the colons of patients with UC[32] as well as in experimental colitis induced by acetic acid[22]. Oxycoccusan was found to prevent an increase in MDA concentration. Plant polysaccharides, including pectins, are assumed to be capable of minimizing free radical-induced damage. A polysaccharide from *Angelica sinensis* has been found to possess a protective effect on immunological colon injury, which is probably due to the mechanism of antioxidation[33]. Ko *et al*[34] showed that colonic damage was significantly reduced by pretreatment of mice with an *Astragalus membranaceus* extract that contains polysaccharides and saponins. A polysaccharide from *Rheum tanguticum* has been shown to protect intestinal epithelial cells against oxidative stress[35]. A significant reduction in mucosal damage has been noted when pectin was administered before the perfusion of rat jejunum with peroxyl and hydroxyl radicals[36]. Therefore, it was proposed that the protective effect of OP against colitis was related to its antioxidant action. However, the presence of flavonoids in the OP preparations should be confirmed before elucidation of the mechanism of antioxidant action of polysaccharides *per se*.

Leukocyte adhesion represents one of the first steps in initiation of the inflammatory response and it is essential for the accumulation of active immune cells at sites of inflammation[37]. In light of this connection, the ability of OP to influence the adhesion of peritoneal leukocytes was determined in order to elucidate the involvement of leukocytes in the mechanism of the antiinflammatory effect. The data on leukocyte adhesion reduction may partially explain the preventive effect of OP on the accumulation of neutrophils in the intestinal wall.

A reduction of vascular permeability by OP indicates the suppression of the release of vasoactive mediators (histamine, serotonin) by competent cells. Sulfated glycosaminoglycan heparin has been shown to inhibit exocytosis in mast cells[38]. Oxycoccusan, as a pectin, possess structural similarity with heparin, which comprises a polyanionic macromolecule with a negative charge density. A possible effect of OP on the activity of basophils and mast cells is under investigation. It is possible that OP exerts its preventive effect on colitis by affecting plasma factors that regulate vascular permeability and cellular trafficking during the process of inflammation.

Thus, a preventive effect of pectin from the common cranberry, namely oxycoccusan OP, on acetic acid-induced colitis in mice was detected. Neutrophil infiltration reduction and antioxidant action may be implicated in the protective effect of oxycoccusan.

## Abstract

**AIM:** To examine the effect of canstatin, a newly discovered endogenous inhibitor of angiogenesis, in the treatment of pancreatic cancer *in vivo*.

**METHODS:** The canstatin cDNA fragment was synthesized and amplified from the total RNA extracted from human placenta tissues by RT-PCR. The resulting product was firstly cloned into pUCm-T vector, then into plasmid pET-22b (+) and transformed into *E. coli* BL21. Isopropyl-1-thio-b-Dgalactopyran-oside (IPTG) was used to induce the expression of canstatin protein and affinity chromatography was used to purify the protein. To determine the activity of purified recombinant human canstatin (rhCanstatin), orthotopic xenograft human pancreatic cancer models were established. Human pancreatic cancer cells (SW1990) were injected into the pancreas of BALB/c nude mice. Twenty-four nude mice with orthotopic xenograft tumor were randomly divided into 3 groups 10 d after the inoculation, and were treated with PBS 0.3 mL, or canstatin 5 mg/kg, or 10 mg/kg per day for 3 wk intraperitoneally. When the experiment was over, all tumors were resected and the effects of rhCanstatin on tumor growth, microvessel density (MVD) were analyzed.

**RESULTS:** After IPTG induction, SDS-PAGE showed a new monomeric 24 kDa protein band. This protein was purified through affinity chromatography and refolded through dialysis with a final concentration of 60 mg/L. In orthotopic pancreatic cancer models, the final tumor volume in groups treated with PBS, canstatin 5 mg/kg, 10 mg/kg were 355.21 ± 39.54 $mm^3$, 112.73 ± 10.47 $mm^3$, and 61.75 ± 6.99 $mm^3$ respectively. The immunohistochemical examination showed that the MVD in tumors treated with canstatin was significantly less than that in other group.

**CONCLUSION:** These findings demonstrate that the rhCanstatin effectively retards the growth of pancreatic cancer in a dose-dependent manner through inhibiting angiogenesis and may be a promising therapeutic agent for pancreatic cancer treatment in the clinic.

**Key words:** Canstatin; Angiogenesis; Pancreatic cancer; Anti-tumor agent

## INTRODUCTION

The prognosis of patients with pancreatic cancer is poor, with or without treatment. The American National Cancer Institute (NCI) reported in its SEER Cancer Statistics Review that there are approximately 27 000 new cases of pancreatic cancer, resulting in around 26 000 deaths each year in the US. It is now the fourth most common cause of cancer deaths in USA and among the top ten common causes of cancer deaths in China. Being extremely aggressive, pancreatic cancer is often far advanced by the time symptoms occur, and a definitive diagnosis is established, with less than 20% resectable chance. The total 5-year survival rate is less than 5% from the time of diagnosis, although combination therapy has been accepted using radiation therapy or chemotherapy with or without surgery. Therefore, it is urgent to develop new treatment strategy for this malignant disease.

Angiogenesis, the formation of new capillary blood vessels, plays an essential role in normal and pathological processes, such as embryogenesis, wound healing and tumor growth[1-2]. Angiogenesis is also essential for the growth of solid tumors and their metastases[3-4]. Solid tumors cannot grow beyond a few millimeters in diameter

without generation of tumor vasculature. Furthermore, the denser the blood vessel formation, the higher the rate of tumor growth and the greater the metastatic potential[5]. Extensive research has led to the identification and isolation of several regulators of angiogenesis, some of which represent therapeutic targets.

Canstatin, a 24-kDa NC1 domain of the $\alpha_2$ chain of type Ⅳ collagen, is a newly discovered endogenous inhibitor of angiogenesis following the discovery of endostatin[6,7]. Previous studies have shown that canstatin efficiently suppresses the growth of human prostate carcinoma and renal cell carcinoma in models, even more potent than endostatin[8]. However, it is still unknown whether canstatin is effective in the treatment of pancreatic cancer. In this study, we cloned canstatin DNA sequence, expressed and purified recombinant human canstatin (rhCanstatin) and detected its anti-tumor effects on pancreatic cancer.

## MATERIALS AND METHODS

### Vectors, host bacteria and reagents

*E. coli* DH5α was preserved in our laboratory. *E. coli* BL21 and plasmid expression vector pET-22b (+) were purchased from the College of Life Sciences of Fudan University. pUCm-T vector was purchased from Shenergy Biocolor. *Bam*HI, *Hin*dⅢ, T4 DNA ligase and DNA molecular weight marker were supplied by New England Biolabs. Protein marker was purchased from Shanghai Sangon Co. Trizol was provided by Jingmei Biotech. One-step reverse transcription polymerase chain reaction (RT-PCR) kit was purchased from Takara. Isopropyl-1-thio-b-Dgalactopyranoside (IPTG), X-gal, plasmid mini kit, gel extraction mini kit and Coomassie Brilliant Blue R250 were purchased from Shanghai Watson. Nickelnitrilotriacetic acid-agarose column was purchased from Qiagen. The placental tissues were kindly provided by a woman who underwent caesarean operation in our hospital with informed consent. A pair of gene specific primers was designed according to canstatin DNA sequence presented in GenBank.

The forward primer (5'-CGGGATCCTGTCAGCAT CGCTACCTC-3') and reverse primer (59-CCCAAGCT TCAGGTTCTTCATGCACAC -3') were synthesized by Shanghai Sangon.

### Cell line, animals and antibody

A human pancreatic cancer cell line SW1990 was preserved in our laboratory. Cells were maintained in culture in DMEM supplemented with 10% fetal bovine serum (FBS) and antibiotics (100 units/mL penicillin and 100 μg/mL streptomycin). BALB/c male nude mice were purchased from Institute of Animal Center of Chinese Academy of Sciences in Shanghai. Rat anti-mouse CD34 monoclonal antibody was purchased from Hbt Biotechnology.

### RNA isolation

The fresh human placental tissues were frozen in liquid nitrogen immediately after dissection. The total RNA was isolated from the tissues using trizol according to the instruction. Pellets of the total RNA were dissolved in diethyl pyrocarbonate-treated water and finally quantitated by measurement of the optical density at 260 nm through spectrophotometer and stored at -80℃ before use.

### Amplification of target sequences by RT-PCR

The sequence encoding canstatin was amplified by RT-PCR from the total RNA. RT-PCR was performed in a 50 μL of reaction system containing 10 × reaction buffer (5 μL), 25 mmol/L $MgCl_2$ (10 μL), 10 mmol/L mixture of four dNTPs (5 μL), 40 MU/L ribonucleases inhibitor 1 μL, 5 MU/L AMV reverse transcriptase XL (1 μL), 5 MU/L AMV-Optimized Taq DNA polymerase (1 μL), 25 μmol/L forward primer (1 μL), 25 μmol/L reverse primer (1 μL), 1.8 g/L total RNA template (1 μL), ribonucleases free double distilled $H_2O$ (24 μL). RT-PCR conditions were: reverse transcription reaction at 50℃ for 40 min, initial denaturation at 94℃ for 2 min, 35 cycles, each cycle consisting of denaturation at 94℃ for 40 s, annealing at 52.6℃ for 40 s and extension at 72℃ for 1 min, and after the cycles a final extension at 72℃ for 5 min. The RT-PCR products were added to 6 × loading buffer, mixed and run on 1% agarose gel (0.5 μg/mL ethidium bromide). After electrophoresis at 100 volts for 40 min, the gel was examined under ultraviolet light and photographed. The PCR products were recovered from the gel following the instruction of gel extraction mini kit.

### Cloning of the PCR products

The ligation mixture included 10 × ligation buffer 1 μL, pUCm-T 1.5 μL, purified PCR products 6.5 μL and T4 DNA ligase 1 μL. After incubated overnight at 16℃, 3 μL of the ligation reactions was used to transform the competent *E. coli* DH5α by electroporation. The transformed cells were gently spread over the surface of the agar plate covered with IPTG and X-gal and containing appropriate ampicillin. The plate was inverted and incubated overnight at 37℃.

### Identification of bacterial colonies containing recombinant plasmids

Six white single bacterial colonies were picked from the agar plate and then inoculated into different LB medium containing ampicillin with the final concentration of 100 mg/L. The cultures were incubated overnight at 37℃ with vigorous shaking. Plasmid DNAs were isolated from each culture by the alkaline lysis method presented in the kit and then analyzed by gel electrophoresis after digestion with *Bam*HI or *Hin*dⅢ.

### DNA sequencing

The positive colony was sequenced on both strands with universal primers M13-/T7 by the Sanger Dideoxy-mediated chain-termination method. The nucleotide sequence was compared with that in GenBank database.

### Construction of prokaryotic expression vector

The recombinant plasmid DNAs were extracted by the method described earlier, digested with both *Bam*HI and *Hin*dⅢ, and finally ligated into predigested pET22b

vector by T4 DNA ligase. Plasmid constructs encoding canstatin were transformed into *E. coli* BL21 through electroporation. The transformed cells were gently spread over the surface of the agar plate containing ampicillin and incubated overnight at 37℃. Seven white single bacterial colonies were picked from the agar plate and grown in small-scale LB medium containing 100 mg/L ampicillin. Plasmid DNAs were isolated from each culture and restriction analysis was performed.

### Expression of rhCanstatin

An overnight bacterial culture was used to inoculate a 200-mL culture into LB medium. This culture was grown for approximately 3.5 h until the cells reached an A600 of 0.6. Then, protein expression was induced by addition of IPTG to a final concentration of 0.5 mmol/L. After a 3-h induction, cells were harvested by centrifugation at 12000 × *g*. The expression level of the protein was assessed by analysis on 12% SDS-PAGE gel followed by staining of Coommassie Brilliant Blue R250.

### Purification and refolding of rhCanstatin

The harvested cells were suspended in 1 mmol/L EDTA, 0.1 mol/L NaCl, 0.05 mol/L Tris-HCl, pH 8.0, sonicated briefly and centrifuged at 5000 g for 20 min at 4℃. The precipitated fraction was washed by 10 mL of 5 mmol/L imidazole, 0.5 mol/L NaCl, 0.02 mol/L Tris-HCl, pH 7.5 and again centrifuged at 5000 g for 20 min at 4℃. The supernatant fraction was discarded. The sediment was lysed in 8 mol/L urea, 0.5 mol/L NaCl, 0.02 mol/L Tris-HCl, pH 7.9 and passed over a 5-mL of nickelnitrilotriacetic acid-agarose column which had been equilibrated and washed with buffer 0 (8 mol/L urea, 0.5 mol/L NaCl, 0.02 mol/L Tris-HCl, pH 8.0) at a speed of 2 mL/min. The column was then stepwisely eluted by 15 mL each of 10, 25, 50, 125 and 250 mmol/L imidazole in buffer 0. The eluted fraction was collected separately and analyzed on SDS-PAGE gel. The eluted protein between 125 and 250 mmol/L imidazole was dialyzed three times against 2 liters of PBS at 4℃. Protein concentration was determined by the BCA assay.

### In vivo tumor studies

Human pancreatic adenocarcinoma cells (SW 1990) were harvested from culture, and $1 \times 10^7$ cells in sterile PBS were injected into the pancreas of 4-wk-old male BALB/c nude mice. The tumors grew for 10 d, after which animals were divided into groups of 8 mice each and treated with PBS 0.3 mL, or canstatin 5 mg/kg, or 10 mg/kg per day for 3 wk. All agents were injected intraperitoneally. When the experiment was over, all tumors were resected. Tumor length and width were measured using a Vernier caliper, and the tumor volume was calculated using the standard formula: length × width squared × 0.5.

### CD34 immunohistochemistry

At the end of treatment, mice were sacrificed, and the tumors were excised. The removed tumors were dissected with a scalpel into several pieces approximately 3-4 mm thick and then fixed in 4% paraformaldehyde for 24 h.

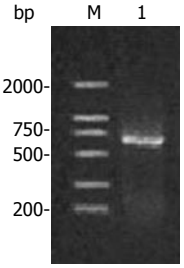

**Figure 1** Amplification products of human canstatin. Lane M: DNA marker; Lane 1: RT-PCR products.

Tissues were then transferred to PBS for 24 h before dehydration and paraffin embedding. After embedding in paraffin, 3-mm tissue sections were sliced and mounted. Sections were deparaffinized, rehydrated, and blocked with 10% rabbit serum. Next, slides were incubated at 4℃ overnight with a 1:50 dilution of rat anti-mouse CD34 monoclonal antibody, followed by two successive incubations at 37℃ for 30 min with 1:50 dilutions of biotin-conjugated secondary antibodies and HRP-conjugated streptavidin. Finally, diaminobenzidine was used as the chromogen. All slides were counterstained with Meyer's hematoxylin and observed under light microscope. Microvessel areas were quantified by manual counting of hotspots in sections, as described by Weidner *et al*[9].

### Statistical analysis

Results were expressed as mean ± SE. Unpaired *t* test was used to compare different groups of data as indicated. A 2-tailed *P* value of $< 0.05$ was considered significant.

## RESULTS

### Amplification of target sequences

The extracted total RNA was separated into three clear bands indicating 28S, 18S, and 5S after agarose gel electrophoresis. When the sample was diluted 50 times by diethyl pyrocarbonate-treated water, the values of $A_{260}$ and $A_{280}$ were 0.879 and 0.410 respectively with a $A_{260}$:$A_{280}$ ratio 2.095 through spectrophotometer. So the concentration of total RNA was 1.8 g/L according to the equation: total RNA concentration = 40 × $A_{260}$ × dilution power/1000. The target sequences were specifically amplified through RT-PCR, showing a clear band near the location of 684 bp DNA on agarose gel (Figure 1).

### Cloning in plasmid vectors and identification of bacterial colonies

After recovered from the gel, the resulting RT-PCR products were ligated into pUCm-T vectors, and the pUCm-T/canstatin constructs were then transformed into *E. coli* DH5α. Both blue and white colonies appeared on the agar plate after an overnight incubation. Six white colonies were selected. Restriction analysis of small-scale preparations of plasmid DNAs showed the plasmid DNAs in one white colony were separated into two bands near the locations of primary plasmid and objective gene fragment after digested by *Hin*dⅢ but only one band near

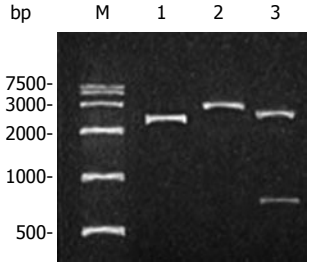

**Figure 2** Restriction analysis of plasmid pUCm-T/canstatin. Lane M: DNA marker; Lane 1: plasmid pUCm-T/ canstatin; Lane 2: pUCm-T/ canstatin digested by *Bam*H Ⅰ; Lane 3: pUCm-T/canstatin digested by *Hin*dⅢ.

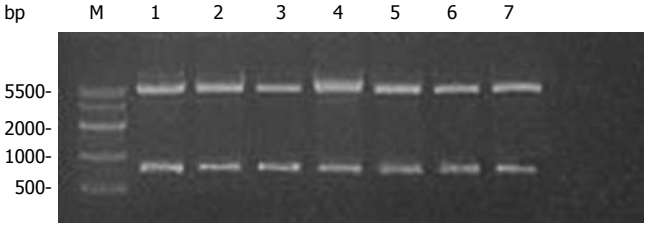

**Figure 3** Restriction analysis of plasmid pET-22b(+)/canstatin. Lane M: DNA marker; Lanes 1 to 7: plasmid DNAs of seven selected colonies digested by both *Bam*H Ⅰ and *Hin*dⅢ.

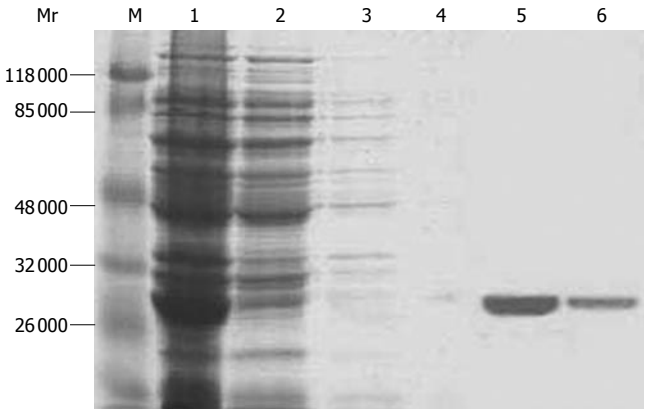

**Figure 4** SDS-PAGE gel electrophoresis of purified protein. Lane M: protein marker; lane 1: total bacterial protein; lane 2: 10 mmol/L imidazole elution; lane 3: 25 mmol/L imidazole elution; lane 4: 50 mmol/L imidazole elution; lane 5: 125 mmol/L imidazole elution; lane 6: 250 mmol/L imidazole elution.

the location of primary plasmid after digested by *Bam*HI (Figure 2). DNA sequencing demonstrated the sequence of this cloned gene was completely homologous to the canstatin gene sequence represented in GenBank.

### *Construction and identification of prokaryotic expression vector*

The canstatin cDNA was cut down from pUCm-T with *Bam*HI and *Hin*dⅢ and ligated into the vector pET-22b (+). The resultant plasmid pET-22b (+)/canstatin was then transformed into *E. coli* BL21. White colonies appeared on LB agar plate after an overnight incubation. Seven of them were picked and restriction analysis showed the plasmids DNA of all selected colonies were separated into two specific bands, one of which was the objective gene fragment (Figure 3).

### *Expression and purification of rhCanstatin*

After IPTG induction, SDS-PAGE analysis revealed a monomeric band at about 24 kDa. The relative quantitative values of expressed products over total bacterial proteins after 3 h of induction were 16.8 with the percentage of total protein 23.0% estimated by densitometry using Quantity One 4.1.1 protein analysis software (Figure 4). RhCanstatin was eluted from the column with two concentrations of imidazole (125 and 250 mmol/L). The concentration of dialyzed rhCanstatin was 60 mg/L.

### *In vivo tumor experiments*

Established orthotopic xenograft tumor models in mice were used to test the effectiveness of canstatin as an inhibitor of angiogenesis-dependent tumor growth. The final tumor volumes in groups treated with PBS, canstatin 5 mg/kg and canstatin 10 mg/kg were 355.21 ± 39.54 $mm^3$, 112.73 ± 10.47 $mm^3$, and 61.75 ± 6.99 $mm^3$ respectively (Figure 5A), and the tumor weights were 0.64 ± 0.08 g, 0.21 ± 0.02 g, and 0.12 ± 0.02 g respectively. The immunohistochemical examination showed that the MVD in tumors treated with canstatin 5 mg/kg (27.4 ± 6.1) or 10 mg/kg (20.2 ± 4.1) was significantly less than that in PBS group (40.2 ± 7.4) (Figure 5B). This decrease in tumor size was consistent with a decrease in CD34-positive vasculature (Figure 5C and D). In all of the *in vivo* studies, mice appeared healthy with no signs of wasting, and none of the mice died during treatment.

## DISCUSSION

Pancreatic cancer is a major cause of morbidity and mortality worldwide. It is an extremely life-threatening neoplasm due to its late diagnosis, rapid progression and resistance to chemo- and radiotherapy. Statistics data show it is the fourth leading cause of cancer death in the USA, with a median survival of less than 6 mo, and a 5-year survival rate of less than 5%[10,11]. Despite the great improvements in conventional therapy, including surgery, chemotherapy and radiotherapy, the mortality of this disease remains almost unchanged. There is, therefore, an urgent need for novel treatment strategies for this deadly disease.

Antiangiogenesis therapy is a new and attractive target for tumor therapy. By interrupting new vessel formation, tumor growth can be effectively arrested[12-16]. Compared to conventional therapy such as chemotherapy, anti-angiogenesis has several advantages theoretically[17,18]. Firstly, it has lower toxicity. Second, tumor vasculature is less mature and more sensitive to inhibiting agents than normal vessels. Third, due to the low mutagenesis rate of normal cell type, the endothelial cell is less likely to counteract therapeutic drugs through development of multi-drug resistance mechanisms. Fourth, drugs have easy access to their therapeutic target. In antiangiogenic therapy the target cells are those which constitute vessel walls, so intravenous antiangiogenic agents act on these cells directly. Fifth, antiangiogenic therapy has an inherent 'amplification' mechanism. Successful interference with only a few endothelial cells may lead to disruption of a whole vessel. Loss of a single vessel may deprive a significant number of tumor cells of essential nutrients, leading to cell death.

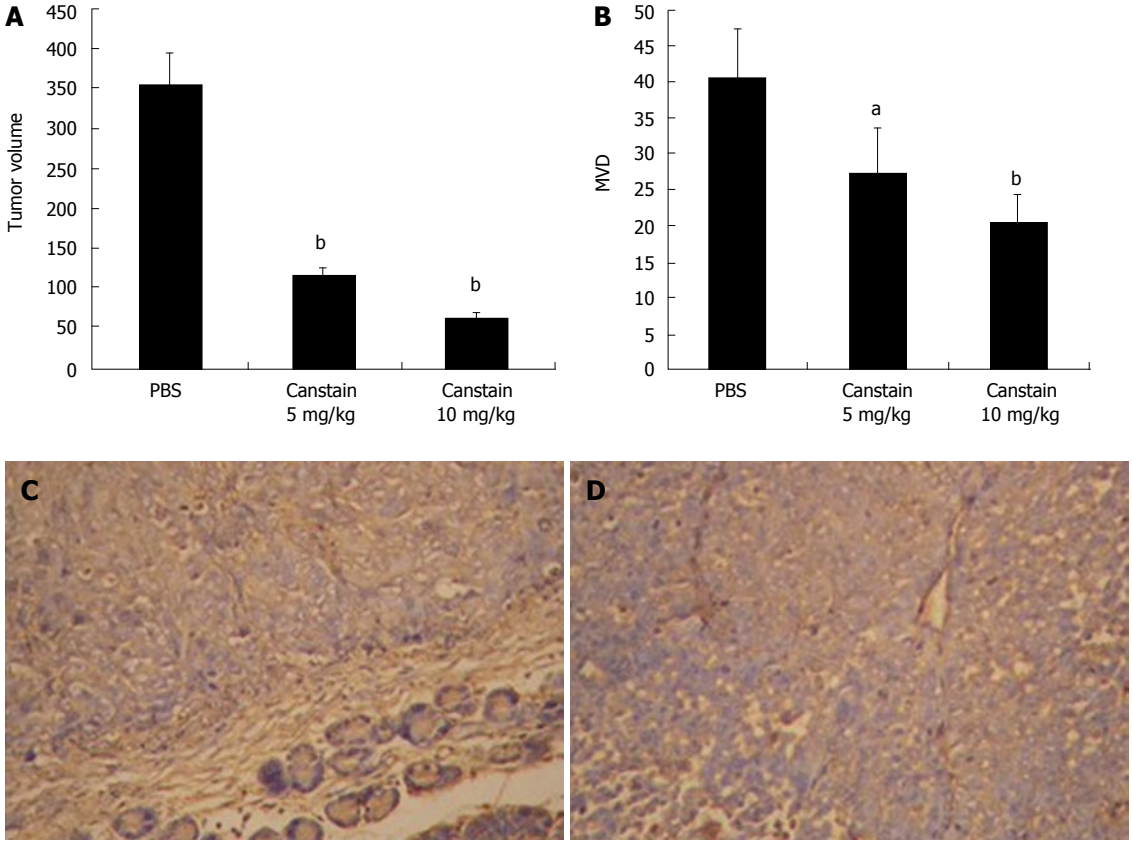

**Figure 5** *In vivo* antitumor effects in a xenograft model. The in vivo antitumor effect of the canstatin was analyzed in a SW1990 human pancreatic cancer cell orthotopic xenograft model. **A**: Tumor volumes in different groups: Canstatin 5 mg/kg or 10 mg/kg treatment showed a significantly stronger anti-tumor effect, compared with the PBS treated group ($^bP < 0.01$); **B**: MVD in xenograft models: significant inhibition of angiogenesis was observed in groups treated with canstatin 5 mg/kg or 10 mg/kg compared with that in the control group ($^aP < 0.05$, $^bP < 0.01$, respectively); **C**: CD34 immunohistochemistry in group treated with PBS (× 200): tumor sections showed extensive angiogenesis; **D**: CD34 immunohistochemistry in group treated with canstatin (× 200): tumor sections showed obviously decreased new vessels with a small focus of necrosis.

In light of these, this new therapy concept has aroused much attention and fueled the development of novel anti-angiogenic agents.

Despite some initial setbacks and negative clinical trial results, major progress has been made over the past few years in targeting angiogenesis for human cancer therapy. In Feb 2004, the US Food and Drug Administration (FDA) approved bevacizumab, a humanized anti-VEGF (vascular endothelial growth factor) monoclonal antibody, for the treatment of metastatic colorectal cancer, following a phase Ⅲ study showing a survival benefit[19]. In Dec 2004, the FDA approved pegaptinib, an aptamer that blocks the 165 amino-acid isoform of VEGF-A, for the treatment of the wet (neovascular) form of age-related macular degeneration (AMD)[20]. Angiogenesis inhibitors for the treatment of cancer have now been approved by the FDA in the US and in 28 other countries, including the European Union. When Avastin was approved in the US, Mark McClellan, the Director of the FDA, stated that: "Angiogenesis inhibitors can now be considered as the fourth modality of cancer therapy."

Canstatin, derived from the C-terminal globular non-collagenous (NC1) domain of the $\alpha_2$ chain of type Ⅳ collagen, is a new endogenous inhibitor of angiogenesis, which has been shown to successfully suppress the growth of implanted human prostate carcinoma and renal cell carcinoma in mice, even more potent than endostatin[21,22].

In the present study, placental tissues with abundant vessels were chosen to extract total RNA. And we successfully constructed a prokaryotic expression system to express rhCanstatin protein. *E. coli* was used as host bacteria because of its ability of rapid growth, well-characterized genetic background, high expression level, and cheapness, which is considered as the most attractive and ideal system for heterologous protein expression. The pET-22b (+) vector, as the expression vector, carries an N-terminal pelB signal sequence plus C-terminal His·Tag® sequence[23,24]. In our study, the resulting cDNA fragment was digested with *Bam*HI and *Hin*dⅢ and ligated into predigested pET-22b (+).This placed canstatin downstream of and in-frame with the pelB leader sequence, allowing for periplasmic localization and expression of soluble protein. The 3' end of the sequence was ligated in-frame with the polyhistidine tag sequence which also facilitated the purification of this target protein. After IPTG induction, SDS-PAGE analysis revealed a 24 kDa monomeric band, demonstrating the successful expression of target protein. Through affinity chromatography and dialysis, the production of rhCanstatin was purified and refolded with a final concentration of 60 mg/L and chick chorioallantoic membrane (CAM) assay demonstrated that rhCanstatin successfully inhibited newly formed blood

vessels in a dose-dependent manner.

Moreover, *in vivo* experiments showed that rhCanstatin successfully inhibited the growth of human pancreatic tumors by 3.15 fold or 5.75 fold at the dose of 5 mg/kg or 10 mg/kg respectively compared with placebo-treated mice. And this decrease in tumor size was consistent with a decrease in CD34-positive vasculature. Our findings demonstrate that rhCanstatin suppressed the growth of pancreatic cancer through inhibition of angiogenesis in a dose-dependent manner and suggest it may be a new potent anti-tumor agent for these patients. These findings add meaningful information to our understanding of the biological activity of rhCanstatin.

In conclusion, our findings verify the viewpoint that angiogenesis is an important target for cancer therapy. Animal tumor experiments demonstrate that the soluble rhCanstatin with antiangiogenic activity is a potential agent for pancreatic cancer therapy. It is meaningful to explore the applications of rhCanstatin in clinical use and study how to achieve the most effective combinations of antiangiogenic agents with chemotherapy or other biological agents in future.

## Abstract

**AIM:** To study the effects of IκBα and its mutants (IκBαM, IκBα243N, IκBαM244C) on NF-κB, p53 and their downstream target genes. The relationship of NF-κB, p53, and IκBα was further discussed.

**METHODS:** pECFP-IκBα, pECFP-IκBαM (amino acids 1-317, Ser32, 36A), pECFP-IκBα243N (amino acids 1-243), pECFP-IκBα244C (amino acides 244-317), pEYFP-p65 and pp53-DsRed were constructed and transfected to ASTC-α-1 cells. Cells were transfected with pECFP-C1 as a control. 30 h after the transfection, location patterns of NF-κB, p53 and IκBα (IκBαM, IκBα243N, IκBα244C) were observed by a laser scanning microscope (LSM510/ConfoCor2, Zeiss). RNA extraction and reverse transcription were performed in cells transfected or co-transfected with different plasmids. Effects of IκBα and its mutants on the transpiration level of NF-κB, NF-κB downstream target gene TNF-α, p53 and p53 downstream target gene Bax were observed by real time QT-PCR. In all experiments β-actin was reference. Results are expressed as the target/reference ratio of the sample divided by the target/reference ratio of the control. Different transfected cells were incubated with CCK-8 for 2 h in the incubator. Then the absorbance at 450 nm was measured by using a microplate reader.

**RESULTS:** Cells that were transfected with p53-DsRed revealed a predominant nuclear localization. YFP-p65 mainly existed in the cytoplasm. Cells were transfected with CFP-IκBα, CFP-IκBαM, and CFP-IκBα243N respectively and revealed a predominant cytosolic localization. However, cells transfected of CFP-IκBα244C revealed a predominant nuclear localization. The mRNA levels of p65, TNF-α, p53 and Bax in CFP-IκBα transfected cells did not change significantly, while in YFP-p65/CFP-IκBα co-transfected cells, IκBα decreased the transcription of p65 downstream gene TNF-α (2.24 ± 0.503) compared with the YFP-p65/CFP-C1 co-transfected cells (5.08 ± 0.891) ($P < 0.05$). Phosphorylation defective IκBα (IκBαM) decreased the transcription levels of all the four genes compared with the control ($P < 0.05$). The N terminus of IκBα (IκBα243N) increased the transcription of NF-κB (1.84 ± 0.176) and TNF-α (1.51 ± 0.203) a little bit. However, the C terminus of IκBα (IκBα244C) increased the transcription of NF-κB, TNF-α, p53 and Bax significantly (8.29 ± 1.662, 14.16 ± 2.121, 10.2 ± 0.621, 3.72 ± 0.346) ($P < 0.05$). The CCK-8 experiment also showed that IκBα244C and p53 synergistically mediate apoptosis.

**CONCLUSIONS:** IκBα and its mutants (IκBαM, IκBα243N, IκBαM244C) have different effects on NF-κB and p53 signaling pathways, according to their different structures. IκBαM bounds with NF-κB and p53 in cytoplasm steadily, and inhibits both of the two signaling pathways. p53 and IκBα244C may be co-factor in inducing apoptosis. The C terminal of IκBα enhanced cell death, which suggests that it may be a pro-apoptotic protein existed in cells.

**Key words:** Nuclear factor-κB; Inhibitor of NF-κB alpha; p53; Real-time QT-PCR

## INTRODUCTION

Nuclear factor κB (NF-κB) is a family of pleiotropic transcription factors[1]. It regulates the transcription of a large number of genes that play key roles in embryonic development, lymphoid differentiation, apoptosis, and immune and inflammatory responses[2-5]. They are characterized by the presence of so called Rel homology domain, RHD, with a length of about 300 amino acids. Their active DNA-binding forms are homodimeric or heterodimeric complexes consisting of combinations of

these protein family members. The most abundant forms of NF-κB are p65/p50 hetero-dimers and p65/p65 homo-dimers[6-7]. In most cells, NF-κB complexes are normally localized to the cytosol as inactive complexes with inhibitory IκBα protein[8]. Activation of NF-κB in response to stimuli involves activation of IκB kinase (IKK), phosphorylation and degradation of IκBα at two serine residues (Ser32 and Ser36), followed by rapid ubiquitin-dependent degradation by the 26S proteosome and release of activated NF-κB[9-11]. Activated NF-κB then translocates to the nucleus, where it binds to its target DNA sequence and activates the transcription of a vast number and wide range of genes[12-15].

RelA, the p65 subunite of NF-κB is constitutively activated in certain neoplastic cells, such as pancreatic cancer cells and acute leukemia cells[16-19]. Approaches to suppress NF-κB activation in malignant cells have been considered as a potential treatment for neoplasia. Studies show that inhibition of NF-κB activation by expression of a dominant-negative mutant form IκBα (Ser 32, 36A) (IκBαM) completely inhibited liver metastasis of a pancreatic cancer cell line, and reduced angiogenesis in an ovarian cancer cell line[20-22].

Recent studies have shown that IκBα is found to inhibit p53 tumor suppressor protein by binding p53 to form a cytoplasmic p53 · IκBα complex, thus it prevents p53 nuclear translocation[23]. On the basis of this data, we hypothesized that when IκBα or its mutants were used to mediate activities of NF-κB in cells, they might affect the p53 signaling pathway simultaneously. In this study, pECFP-IκBα and its three mutants, pECFP-IκBαM (amino acides 1-317, S32, 36A), pECFP-IκBα243N (N terminus of IκBα, amino acides 1-243) and pECFP-IκBα244C (C terminus of IκBα, amino acides 244-317), were constructed. The location patterns of NF-κB, p53 and IκBα (IκBαM, IκBα243N, IκBα244C) were observed by laser confocal scanning microscopy. The effects of IκBα (IκBαM, IκBα243N, IκBα244C) on p53 and NF-κB, as well as the downstream genes of these two signaling pathways, were studied with real time QT-PCR. The relationship of NF-κB, p53, and IκBα activities is further discussed.

## MATERIALS AND METHODS

### Materials

Mammalian cell expression vector pEYFP-p65 was provided by Professor Johannes A. Schmid[24]. A human full-length IκBα cDNA was found in the universal GenBank database (gene number: AY033600) and was obtained from Funeng company (vector: RB01-IκBα). pDsRed-Mit vector was provided by Dr. Fuminori Tsuruta[25]. Wild-type p53 cDNA was provided by Dr. Ye KH (Jinan University, Guangzhou). Dulbecco's modified Eagle medium (DMEM) was purchased from GIBCO (Grand Island, NY). The RNA isolation kit and LightCycler FastStart DNA Master SYBR Green I kit were obtained from Roche. M-MLV Reverse Transcriptase was provided by BBI. Lipofectamine™ Reagent was purchased from Invitrogen. Cell Counting Kit-8 (CCK-8) was purchased from Dojindo Laboratories (Kumamoto, Japan).

### Construction of CFP-IκBα, YFP-p65 and p53-DsRed variants

Four expression constructs were constructed with the pECFP-C1 vector (cloning site, *Eco*RI and *Bam*HI; Clontech): (1) IκBα, the entire coding region (amino acides 1-317)(primers: FW3/RV1); (2) IκBαM, dominant negative IκBα construct made by altering Ser-32 to Ala-32 and Ser-36 to Ala-36, (amino acides 1-317, Ser32A,Ser36A) using primers FW1/RV1, FW2/RV1 and FW3/RV1 in turn; (3) IκBα243N, the N-terminal ankyrin region (amino acides 1-243 ) (primers: FW3/RV2); (4) IκBα244C, the C-terminal domain (amino acids 244-317) (primers: FW4/RV1). Wild-type p53 cDNA were cloned into the *Nhe*I and *Bam*HI sides of pDsRed-Mit vector (primers: p53F/p53R). The synthetic primers used for making these constructs by PCR are FW1: 5'-gag cgg cta ctg gac gac cgc cac gac gcc ggc ctg gac gcc atg aaa gac gag gag ta-3', FW2: 5'-g gag tgg gcc atg gag ggc ccc cgc gac ggg ctg aag aag gag cgg cta ctg gac gac c-3', FW3: 5'-c cgg aat tca ttc cag gcg gcc gag cgc ccc cag gag tgg gcc atg gag ggc c-3', FW4: 5'-gg aat tct aac aga gtt acc tac cag ggc ta-3', RV1: 5'-cgc gga tcc tca taa cgt cag acg ctg gcc tcc aaa cac aca gtc -3',RV2: 5'-cg gga tcc tta tca atg gtg atg gtg atg gtg gac atc agc ccc aca ctt-3', p53F: 5'-c tag cta gcg gaa gct tcc acc atg gag gag ccg cag tca gat-3', p53R: 5'- c ggg atc ccg gtc tga gtc agg ccc ttc tgt-3'. All constructs were verified by restriction and sequence analysis.

### Cell culture and transfections

Cell line, ASTC-α-1, was cultured in DMEM medium, supplemented with HEPES and 100 mL/L new born calf serum, and maintained at 37℃ at an atmosphere of 5% $CO_2$. Transient transfections were performed using the Lipofectamine™ Reagent (Invitrogen). Cells were transfected with CFP-C1 as a control. Microscopy of cells, RNA extraction and RT were performed 30 h after transfection.

### Laser scanning microscopy

YFP-p65, p53-DsRed and CFP-IκBα were visualized by using a laser scanning microscope (LSM510/ConfoCor2, Zeiss, Jena, Germany) with a 37℃ stage incubator. The distribution of YFP-p65 was observed by 514nm laser (HFT458/514, LP530). Cells transfected with p53-DsRed were observed with a 543nm laser and fluorescent images were collected with a 560 nm long-pass filter (HFT700/543, NFT545, LP560nm). CFP-IκBα, CFP-IκBαM, CFP-IκBα243N and CFP-IκBα243C were observed with an Argon-ion laser with 458 nm output and a band pass barrier filter (HFT458 nm, NFT545 nm, BP470-500 nm).

### RNA extraction and RT

Total RNA was isolated by using a high purity RNA isolation kit (Roche) according to the manufacturer's instructions. Total RNA (1 μg) was reverse transcribed with 20 U of M-MLV Reverse Transcriptase, using Oligo(dT)$_{18}$ primers (BBI) according to the manufacturer's instructions.

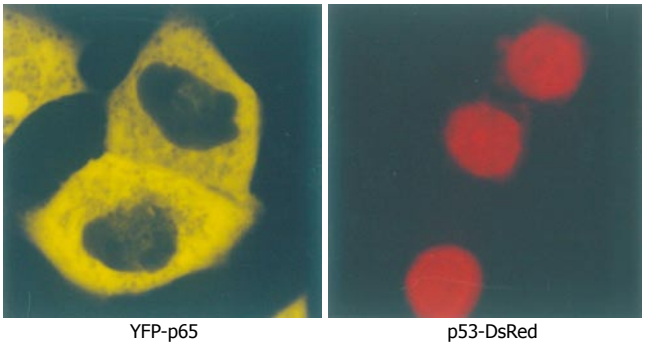

**Figure 1** Microscopy of YFP-p65 and p53-DsRed in living cells.

### *LightCycler real-time QT-PCR*

cDNA amplification by QT-PCR was carried out with the LightCycler FastStart DNA Master SYBR Green I kit (Roche). For QT-PCR, a mastermix of the following reaction components was prepared: 0.8 μL $MgCl_2$ stock solution, (25 mmol/L), 2 μL LightCycler FastStart DNA Master SYBR Green I, 2 μL (0.3 μmol/L) each of the primers, 11.2 μL water. LightCycler mastermix was filled in the glass capillaries and 2 μL of total cDNA temple was added. PCR primers were target gene 1 (p65: forward primer, 5'- GGCTATAACTCGCCTA GTGA -3'; reverse primer, 5'- CGAAG GAGCTGATCTGACTCA -3'), gene 2 (NF-κB downstream gene, TNF-α[26]: forward primer, 5' - CAGAGG GAAGAGTTCCCCAG -3'; reverse primer, 5'- CCTTGGTCTGGTAGGA GACG -3'), gene 3 (p53: forward primer, 5'-AGGTTGGCTCTGACTGTA-3'; reverse primer, 5'- GCAGCTCGTGGTGAGGCTC -3'), and gene 4 (p53 downstream gene, Bax[27]: forward primer, 5'- CTGACA TGTTTTC TGACGGC -3'; reverse primer, 5'-TCAGCCCATCTTCTTCCAGA-3'). In all experiments, β-actin was the reference (forward primer, 5'-GAAAT CGTGCGTGACATTAA-3'; reverse primer, 5'- GGA CTCGTCATACTCCTG-3').

The following LightCycler experimental run protocol was used: denaturation program (95℃ for 10 min), amplification and quantification program repeated 40 times (95℃ for 10 s, 55℃ for 5 s, 72℃ for 10 s), melting curve program (65-95℃ with a heating rate of 0.1℃ per second and a continuous fluorescence measurement) and finally a cooling step to 40℃. For the mathematical model it is necessary to determine the crossing points (CP) for each transcript. CP is defined as the point at which the fluorescence rises appreciably above the background fluorescence. The 'Fit Point Method' must be performed, at which CP will be measured at a constant fluorescence level[28]. Results are expressed as the target/reference ratio of the sample divided by the target/reference ratio of the control.

### *CCK-8 experiment*

Different transfected group cells were cultured in 96-well microplates for 48 h. CCK-8 was added to the cells and incubated for 2 h. OD450, the absorbance value at 450 nm, was read with a microplate reader (DG5032, Hua dong, Nanjing, China). The value is directly proportional to the number of viable cells in a culture medium and the cell proliferation.

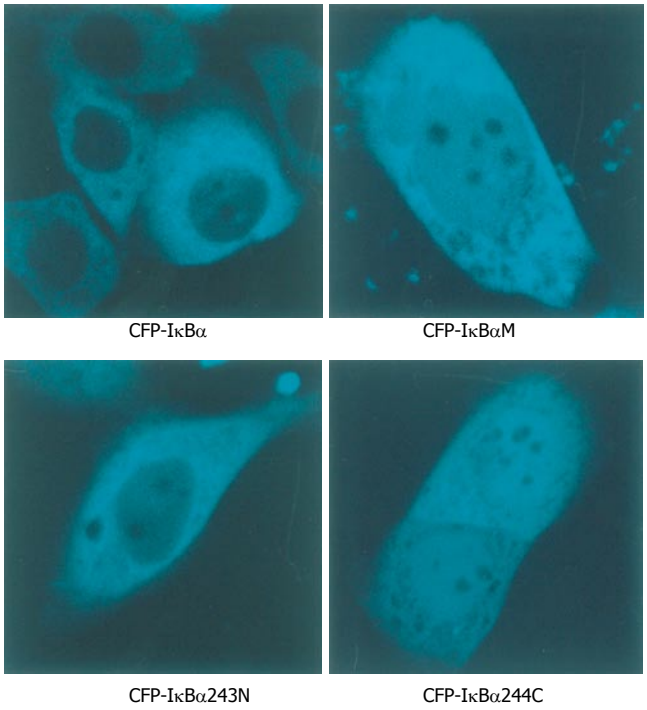

**Figure 2** Localization patterns of CFP-IκBα, CFP-IκBαM, CFP-IκBα243N and CFP-IκBα244C in living cells.

### *Statistical analysis*

Statistical results were obtained using the statistical software SPSS. The significant difference tests were based on analysis of variance with a single factor and two sample *t*-tests were performed.

## RESULTS

### *Localization patterns of p53-DsRed, YFP-p65, CFP-IκBα and its mutants in living cells*

Cells transfected with p53-DsRed revealed a predominant nuclear localization. YFP-p65 mainly existed in the cytoplasm (Figure 1). Cells were transfected with CFP-IκBα, CFP-IκBαM and CFP-IκBα243N respectively, and revealed a predominant cytosolic localization, while cells transfected with CFP-IκBα244C revealed a predominant nuclear localization of CFP-IκBα244C (Figure 2).

### *Standard curve for real time QT-PCR*

The concentration of the standards covers the expected concentration range of all samples. Dilution folds of the cDNA template for the standard curve run were 10ul to 3.20E-3 μL (Figures 3 and 4). The standard curves were analyzed with Real Quant Software to create a coefficient file. The coefficient file was used later in the relative quantification analysis.

### *Effects of IκBα and its mutants on the NF-κB signaling pathway*

Results are expressed as the target/reference ratio of

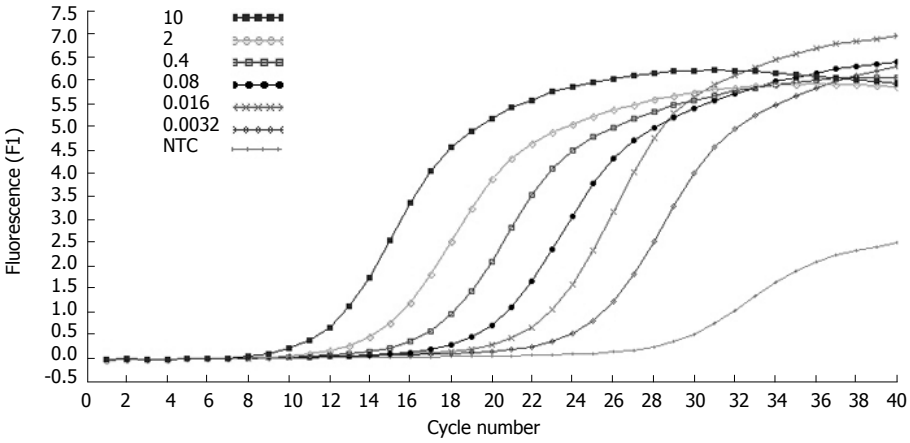

**Figure 3** Amplification plots of five fold serial dilutions of β-actin cDNA. The fluorescence values versus cycle number are displayed.

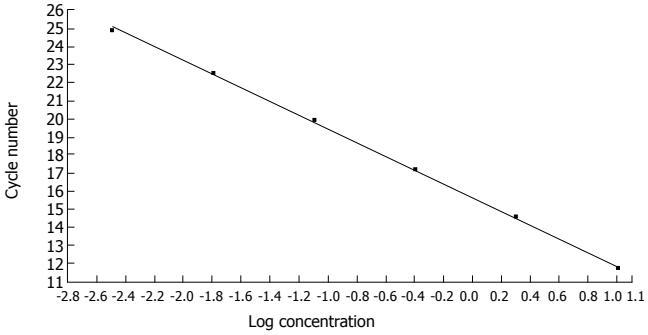

**Figure 4** Standard curve constructed with the β-actin cDNA standards from 1.00E + 1 to 3.20E + 3 by plotting the logarithmic concentration of the standard versus the crossing points (cycle number).

the samples divided by the target/reference ratio of the control ($n$ = 3). In all experiments β-actin cDNA was the reference. Results for the analysis of different transfected cells by QT-PCR showed that the level of p65 cDNA/β-actin cDNA (0.945 ± 0.152) and TNF-α cDNA /β-actin cDNA (1.05 ± 0.106) in CFP-IκBα transfected cells did not change significantly compared with the control(1.000 ± 0.000) (Figure 5), while in YFP-p65/CFP-IκBα co-transfected cells, IκBα decreased the transcription of p65 downstream gene TNF-α (2.24 ± 0.503) compared with the YFP-p65/CFP-C1 co-transfected cells(5.08 ± 0.891) ($^cP$ < 0.05) (Figure 6). In CFP-IκBαM transfected cells, the transcription level of the two genes (0.548 ± 0.086, 0.53 ± 0.056) decreased compared with the control ($^aP$ < 0.05). The level of p65 cDNA /β-actin cDNA and TNF-α cDNA /β-actin cDNA in CFP-IκBα243N transfected cells increased a bit (1.84 ± 0.176, 1.51 ± 0.203) ($^aP$ < 0.05). The most prominent was CFP-IκBα244C. It increased the transcription level of all the genes significantly (8.29 ± 1.662, 14.16 ± 2.121) compared with the control ($^aP$ < 0.05) (Figure 5).

### *Effects of IκBα and its mutants on the p53 signaling pathway*

Results for the analysis of different transfected cells by QT-PCR indicated that the effect of IκBα and its mutants on p53 and its downstream gene, Bax, were different (Figure 7). The level of p53 cDNA /β-actin cDNA and Bax cDNA /β-actin cDNA in CFP-IκBα (0.9 ± 0.126, 1.04 ± 0.109) and CFP-IκBα243N (0.806 ± 0.129, 0.79 ± 0.108) transfected cells did not change very much. In CFP-IκBαM transfected cells, the transcription level of the genes decreased (0.43 ± 0.061, 0.53 ± 0.063) compared with the control ($^aP$ < 0.05), however, CFP-IκBα244C increased the transcription level of p53 and Bax significantly (10.2 ± 0.621, 3.72 ± 0.346) ($^aP$ < 0.05) (Figure 7), which suggested that IκBα244C may play an important role in inducing apoptosis[14].

### *IκBα 244C and p53 synergistically mediates apoptosis*

To study the effect of IκBα244C on cell death, a CCK-8 experiment was performed. As Figure 8 shows, transient expression of p53-DsRed (1.206 ± 0.099 ) or CFP-IκBα244C (1.259 ± 0.072) resulted in enhancement of cell death compared with the control (1.531 ± 0.168) ($n$ = 6, $^aP$ < 0.05). The synergistic effect in mediating apoptosis by p53-DsRed/CFP-IκBα244C (0.805 ± 0.047) ($^dP$ < 0.01) was obtained.

## DISCUSSION

NF-κB and p53 are important transcription factors present in the majority of cells[27-30]. Constitutively activated NF-κB has been associated with increased cell proliferation and survival in cancer cells. Inhibitor of NF-κB alpha, IκBα, participates in both NF-κB and p53 signaling pathways[23,31-33] (Figure 9). The functional NF-κB and p53 activities may modulate each other, which in turn could affect the subsequent responses.

Previous studies demonstrated that IκBα interacts with NF-κB and p53 with different interaction sides[2,8,23]. IκBα and its mutants might have different effects on the transcription of NF-κB, p53 and their downstream genes, according to their different structures. Our studies showed that IκBα did not influence the transcription level of NF-κB, p53 and their downstream target genes in static cells compared with controls, which maybe due to the integrity of IκBα and the self-regulation capability of the cells. IκBα243N (amino acides 1-243), with lack of the PEST domain that regulates basal level protein turnover and is required for inhibition of DNA binding of NF-κB, increased the transcription of NF-κB and TNF-α slightly. Because IκBα243N cannot interact with p53, it has no effect on the transcription of p53 and Bax.

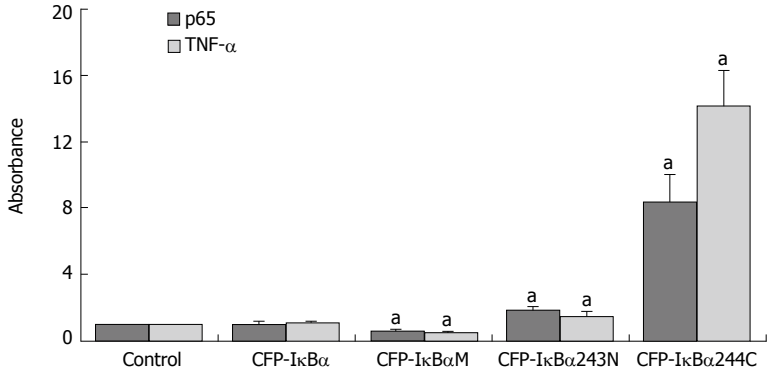

**Figure 5** Effects of IκBα and its mutants on NF-κB and NF-κB downstream gene TNF-α. Abscissa showed different transfected Cells. Y-coordinate expressed the target/reference ratio of the samples divided by the tar = get/reference ratio of the control. In all experiments β-actin cDNA was reference. ([a]*P* < 0.05 *vs* control).

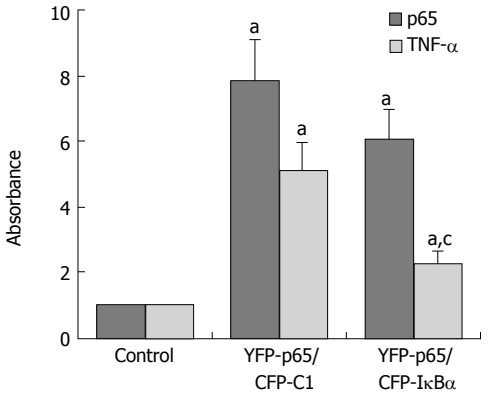

**Figure 6** Effects of IκBα on over expressed NF-κB. ([a]*P* < 0.05 vs control; [c]*P* < 0.05 *vs* YFP-p65/CFP-C1 group).

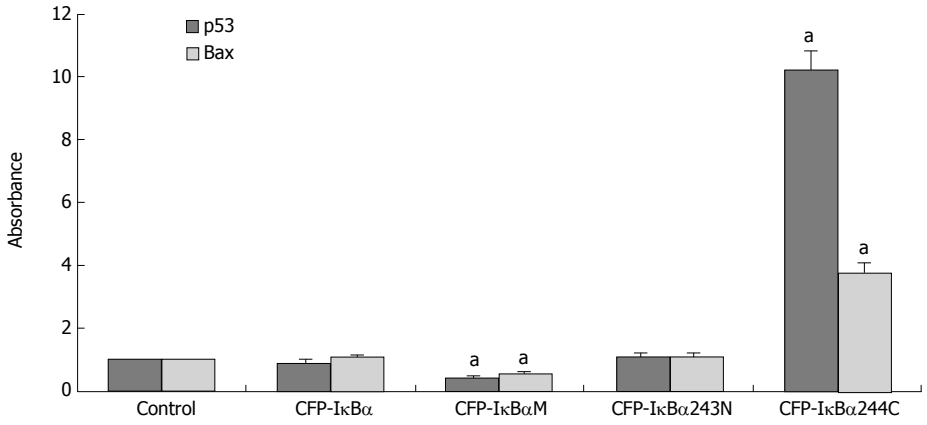

**Figure 7** Effects of IκBα and its mutants on p53 and p53 downstream gene Bax. ([a]*P* < 0.05 *vs* control).

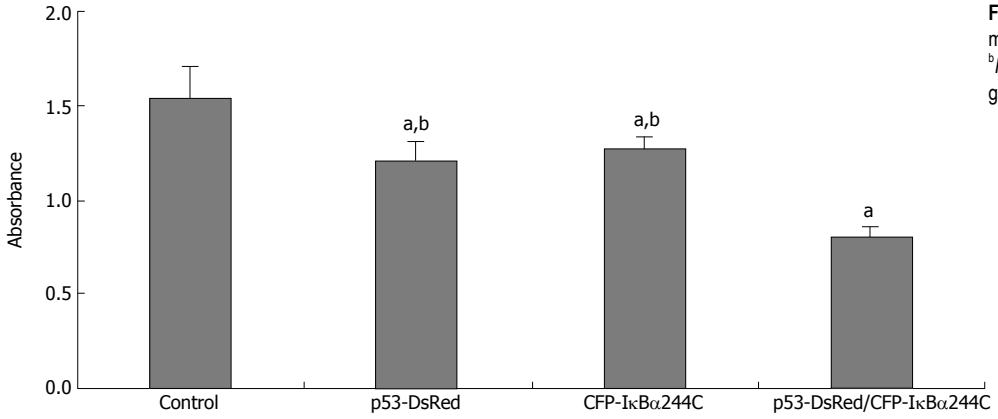

**Figure 8** IκBα244C and p53 synergistically mediates apoptosis. ([a]*P* < 0.05 *vs* control; [b]*P* < 0.01 *vs* p53-DsRed/CFP-IκBα244C group).

Dominant negative IκBα (IκBαM, Ser32, 36A) and the C terminus of IκBα (IκBα244C, amino acides 244-317) are notable because of their significantly different effects. IκBαM has mutations in Ser32 and Ser36. It can not phosphorylate at Ser32 and Ser36 and degradate, so IκBαM bound with NF-κB and p53 in the cytoplasm steadily and inhibited the transcription of their downstream genes, which is consistent with the report that IκBαM has been found to represses p53-dependent apoptosis in acute lymphoblastic leukemia cells[34]. In particular, transfection of IκBαM in human colon carcinoma and breast cancer cell lines did not increase sensitivity to daunomycin or Taxol[35,36]. IκBαM may repress p53 expression in two ways: (1) A portion of IκBαM directly interacts with p53 in cytoplasm and inhibits p53 translocate to the nucleus; (2) IκBαM binds to NF-κB in the cytoplasm and NF-κB·IκBαM complex is formed, which in turn inhibits the NF-κB activity and the NF-κB dependent p53 activity, for the NF-κB signaling cascade is a potential modulator of p53 activity, and NF-κB is a co-factor of p53 in mediating cell death[37-39].

IκBα244C does not have the ARD (ankyrin repeat domain) and NES in N terminus. It could not prevent NF-κB from translocating to the nucleus, and IκBα244C itself

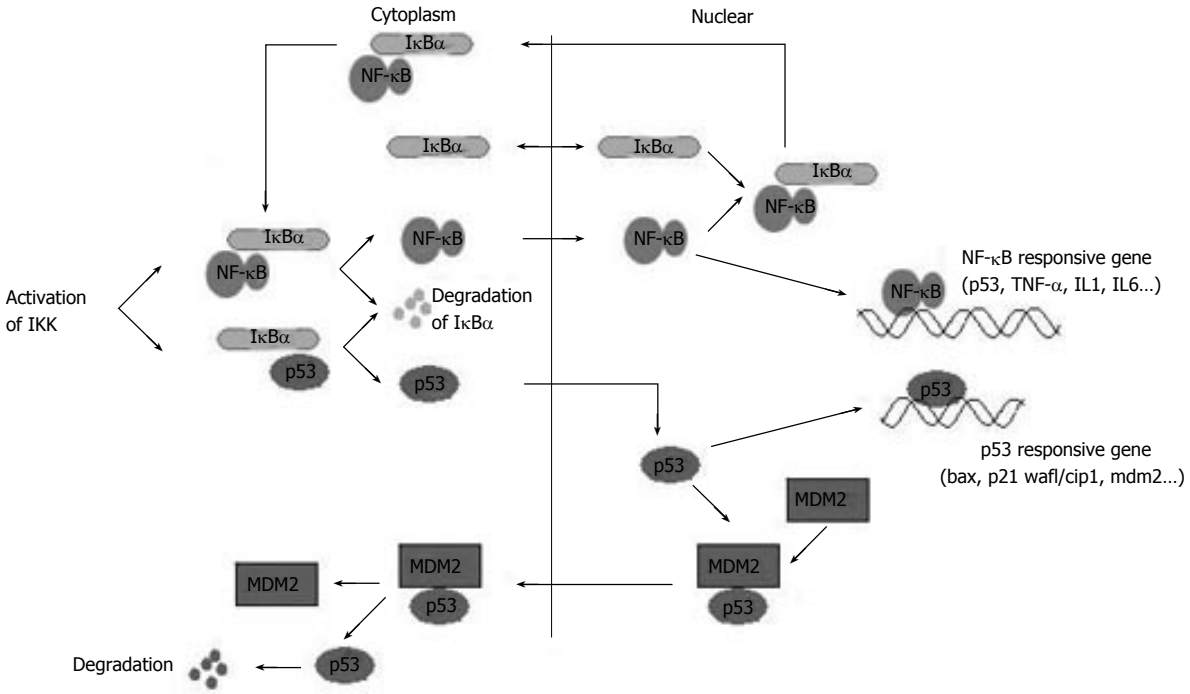

**Figure 9** IκBα participates in NF-κB and p53 signaling pathways.

mainly existed in the nucleus. IκBα244C enhanced the transcription level of p53, NF-κB and their downstream genes. The CCK-8 experiment showed that co-expression of p53 with IκBα244C resulted in enhancement of p53-mediated cell death. p53 and IκBα244C are possibly co-factors in inducing apoptosis, and the C terminus of IκBα may serve as a pro-apoptotic protein in living cells.

NF-κB has been considered a target for cancer treatment[17,40]. The function of IκBα as an inhibitor in regulating NF-κB activation has been well studied. Findings from the present study suggest that mutants of IκBα have different effects on NF-κB and p53 signaling pathways, and may result in different therapy results. The inhibition effect of IκBαM indicates drugs that induce apoptosis by a p53-dependent mechanism may be inhibited by the use of IκBαM constructs through inhibition of p53 function by these agents. The C terminal of IκBα enhanced cell death, which suggests that it may be a pro-apoptotic protein existing in cells, but the mechanism remains to be determined and there may exist NF-κB and p53 independent pathways.

## ACKNOWLEDGMENTS

We thank Dr. Johannes A Schmid for providing pEYFP-p65 vector. Also say thanks to Dr. Fuminori Tsuruta for providing pDsRed-Mit vector, and Dr. Kaihe Ye for providing p53 cDNA.

## Abstract

**AIM:** To review all studies in the literature that have assessed Hematopoietic cell transplantation (HCT) and Crohn's disease (CD) with the ultimate aims of determining if this is a viable treatment option for those with CD. A secondary aim was to review the above literature and determine if the studies shed further light on the mechanisms involved in the pathogenesis of CD.

**METHODS:** An extensive Medline search was performed on all articles from 1970 to 2005 using the keywords; bone marrow transplant, stem cell, hematopoietic cell, Crohn's disease and inflammatory bowel disease.

**RESULTS:** We identified one case in which a patient developed CD following an allogeneic HCT from a sibling suffering with CD. Evidence for transfer of the genetic predisposition to develop CD was also identified with report of a patient that developed severe CD following an allogeneic HCT. Following HCT it was found that the donor (that had no signs or symptoms of CD) and the recipient had several haplotype mismatches in HLA class Ⅲ genes in the IBD3 locus including a polymorphism of NOD2/CARD15 that has been associated with CD. Thirty three published cases of patients with CD who underwent either autologous or allogeneic HCT were identified. At the time of publication 29 of these 33 patients were considered to be in remission. The median follow-up time was seven years, and twenty months for allogeneic and autologous HCT respectively. For patients who underwent HCT primarily for treatment of their CD there have been no mortalities related to transplant complications.

**CONCLUSION:** Overall these preliminary data suggest that both allogeneic and autologous HCT may be effective in inducing remission in refractory CD. This supports the hypothesis that the hemolymphatic cells play a key role in CD and that resetting of the immune system may be a critical approach in the management or cure of CD.

**Key words:** Crohn's disease; Inflammatory bowel disease; Bone marrow transplant; Stem cells; Hematopoietic cell transplantation

## INTRODUCTION

Crohn's disease (CD) is a chronic inflammatory disease of the gastrointestinal tract which commonly affects young adults. It follows a relapsing and remitting course and there is no known cure. However, approximately 10% to 15% have chronic unremitting active disease, with only 10% remaining in remission over many years[1]. A recent systematic review of population based cohorts estimated the prevalence of CD to be 26.0 to 198.5 cases per 100 000 persons and the incidence to be 3.1 to 14.6 cases per 100 000 person-years in North America[1]. In Europe the overall incidence per 100 000 person-years was 5.6[2]. Health related quality of life and general quality of life is lower in Crohn's disease patients compared to the normal population[3] and quality of life is inversely related to active disease, hospitalization and surgery[4-7]. Achieving disease remission improves overall health related quality of life, employment rate, mental and physical functioning[8,9]. In three trials patients with CD have increased mortality compared to the normal population. Standardized mortality ratios were 1.4, 1.51 and 1.3 respectively[10-12]. Loftus *et al*[13] also showed that 20 year survival was 79% for those with CD versus 86% in the normal population. A recent study revealed that up to 32% of all deaths in patients with CD are directly related to complications of their disease[14].

Economic consequences for CD relates both to the loss of productivity, as CD most commonly affects adults in their working years, and the costs of hospitalization, medical and surgical treatment. Longobardi *et al*[15]

estimated the cost of non participation in the labour force in 1998 to be 104.2 million dollars in Canada for patients with inflammatory bowel disease. A study of Crohn's disease patients in the United States found that surgery accounts for the majority of hospitalization and 40% of the total cost of hospitalization[16]. Crohn's disease patients who suffer an acute exacerbation requiring hospitalization in the United Kingdom have a 20 fold increase in healthcare costs compared to patients with stable disease[17].

Present therapy is aimed at relieving inflammation and treating signs and symptoms. Therapy consists of non-specific anti-inflammatory agents such as 5-ASA, glucocorticoids, immunomodulators, and anti-tumor necrosis factor therapy. The goals of therapy should include the induction and maintenance of remission and an attempt to heal mucosa with the ultimate goal being restitution of normal intestinal function. Despite the growing use of immunomodulators and new biologic agents the need for intestinal resection has remained stable[18]. Within five years of diagnosis of CD up to 43% of patients require surgical intervention[19]. The impact of infliximab, a monoclonal antibody to tumor necrosis factor has been substantial in treating patients with CD who were previously refractory to standard treatment. In our center response rates to infliximab are 75%-78%. However, the use of infliximab is often limited by its cost. In Canada the median cost of one year of infliximab maintenance is $27 000. For those patients who do not respond to infliximab currently there is no standard medical therapy. The goal of this review is to discuss one current area of research in hematopoietic cell transplantation and Crohn's disease.

## HEMATOPOIETIC CELL TRANSPLANTATION (HCT) IN OTHER AUTOIMMUNE DISEASES

HCT includes conditioning (high dose chemotherapy, total body irradiation and/or anti-lymphocyte antibodies) followed by the infusion of the hematopoietic cells. The hematopoietic cells are either directly harvested from the marrow or mobilized from marrow to blood (for e.g. by filgrastim) and harvested by apheresis. In case of autologous transplantation for autoimmune diseases, the graft is typically depleted of T cells (e.g. by immunomagnetic selection of CD34 cells) to reduce the likelihood of reinfusing presumed disease-causing T cells. In spite of this, a small number of T cells may be reinfused and some T cells may survive the conditioning. Allogeneic HCT should theoretically be associated with a higher likelihood of cure of an autoimmune disease than autologous HCT, as typically there is a graft-*vs*-host reaction that eliminates the presumed disease-causing T cells that survived conditioning. On the other hand, due to graft-vs.-host disease (GVHD), allogeneic transplantation is typically associated with higher transplant-related morbidity and mortality. For this reason, far more autologous than allogeneic transplants have been performed for various autoimmune diseases, in an attempt to "reset the immune system".

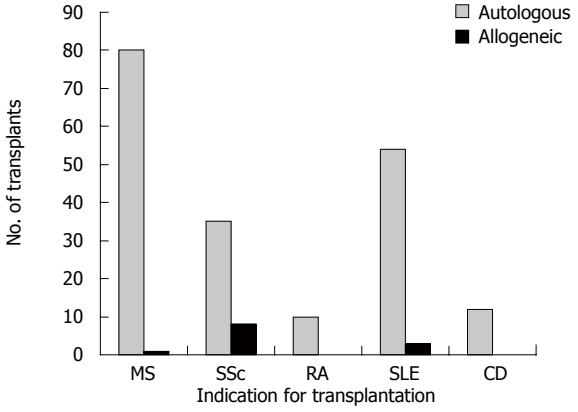

**Figure 1** Number of hematopoietic cell transplants for multiple sclerosis (MS), scleroderma/systemic sclerosis (SSc), rheumatoid arthritis (RA), systemic lupus erythematosus (SLE) and Crohn's disease (CD) registered to the Center for International Blood and Marrow Transplant Research (CIBMTR) by 30 teams in North America, by September, 2005.

HCT has been performed in more than 700 patients with autoimmune diseases[20]. The most frequent indications have been systemic sclerosis (SSc), multiple sclerosis (MS), rheumatoid arthritis (RA), and systemic lupus erythematosus (SLE) (Figure 1). The results are reviewed below. For MS, the European Blood and Marrow Transplant (EBMT) registry reported data on autologous transplantation in 85 patients with severe progressive disease given cyclophosphamide and/or growth factors for stem cell mobilization, then combination chemotherapy ± total body irradiation (TBI) and anti-lymphocyte globulin. Transplant related mortality at three years was 6% with progression free survival of 74% and overall survival 90%[21]. Marked improvement in gadolinium-enhancing MRI lesions was seen. Unfortunately, filgrastim-induced neurological deterioration was seen in 22 patients; this was typically transient but six patients had persistent deficits. Recently updated analysis of 183 patients reported to the EBMT registry reveals 5.5% treatment-related mortality[20].

Several single-center Phase Ⅰ/Ⅱ studies with 15 or more patients have been completed in Europe and show a progression-free survival at one to three years ranging from 70% to 80% with transplant-related mortality ranging from 0%-3%[22]. A US multicenter Phase Ⅰ/Ⅱ study of 26 MS patients who received autologous stem cell transplant after conditioning with cyclophosphamide, TBI and anti-thymocyte globulin (ATG) conditioning and granulocyte colony stimulating factor (G-CSF) mobilization demonstrated a three year projected survival of 91% and disease progression of 27% at 24 mo median follow-up[23]. One patient had a neurological flare during filgrastim therapy and one deteriorated during transplant; prophylactic steroid use may have prevented this in further patients. A Phase Ⅲ randomized trial is underway in Europe (ASTIMS trial) comparing autologous HCT using high dose chemotherapy (carmustine, etoposide, araC and melphalan) and ATG *vs* low dose chemotherapy (mitoxantrone) alone.

Systemic sclerosis (SSc) is a debilitating multiorgan disease with a mortality rate of 40% to 50% at five years

in high risk patients with high skin scores and involvement of the heart, lung or kidney[24-26]. Per the EBMT/EULAR (European League Against Rheumatism) registry, of the first 57 patients transplanted for SSc, 50 have been followed up for more than 6 mo (median 22.9 mo) and had an overall functional response rate of 92% (14 complete responses, 35 partial responses) and no response in 8%[27]. Skin score improvement > 25% was durable at two years in 79% of patients and lung function remained stable overall. Of responding patients, 35% showed evidence of relapse at nine months with projected 48% disease progression at five years and 72% survival at one year. Treatment-related mortality was 8.7%. In a US study of 30 SSc patients of autologous HCT using conditioning with cyclophosphamide, TBI and anti-thymocyte globulin (ATG) resulted in 75% of patients surviving at median follow-up of 36 mo with 12 of 12 assessable patients showing significant improvement in skin scores or the Health Assessment Questionnaire (HAQ) disability index at 12 mo[28]. Two of the first eight patients died of pulmonary toxicity, prevented in subsequent patients by lung shielding during TBI, two other patients died of treatment-related causes and two of progressive disease. In 19 assessable patients major organ function (lung, cardiac, renal) was stable. A French study showed response in 8 of 11 patients given autologous transplant with 36% of patients deceased at 18 mo follow-up (three of disease, one of treatment-related mortality)[26]. Four other patients had active SSc requiring treatment 6-12 mo post transplant. A phase Ⅲ trial is now accruing patients in Europe (ASTIS trial), comparing monthly pulse IV cyclophosphamide 750 mg/m$^2$ for 12 mo *vs* autologous HCT using mobilization with cyclophosphamide/filgrastim and conditioning with cyclophosphamide/ATG. No deaths have been seen in the first 42 patients. Another Phase Ⅲ trial has been recently opened in the US (SCOT trial), comparing monthly pulse Ⅳ cyclophospamide (also 750 mg/m$^2$ for 12 mo) versus autologous HCT using cyclophosphamide/filgrastim mobilization and conditioning with cyclophosphamide, ATG and total body irradiation.

For RA treated with autologous HCT, EBMT registry data revealed no treatment-related mortality in 76 patients who had failed a median of five disease-modifying anti-rheumatic drugs (DMARDS) at a mean follow-up of 16 (3-55) mo[29]. Two thirds of patients obtained American College of Rheumatology score improvements of 50% or better (ACR50), improved function on the HAQ, and tender joints improved for at least 18 mo despite the need for 73% of patients to restart DMARDs within 1 year. In a small study of 14 Dutch patients, 8 of 12 patients responded although 57% required reintroduction of DMARDS at a median of 105 d; three of these heavily treated and refractory patients then responded to DMARDS[30]. Thirty three Australian patients revealed no treatment related mortality with an ACR20 in 70% of patients and ACR20 in 39%, but disease recurred in 29 patients, at a mean of 180 d[31]. Further studies may clarify the role of HCT in rheumatoid arthritis in the context of newer biologic therapies.

Systemic lupus erythematosus has diverse clinical manifestations and an overall survival at ten years of 90%, with a subset of patients refractory to standard immunosuppressive therapy. In a study of 17 patients with refractory SLE given cyclophosphamide for stem cell collection, followed by cyclophosphamide, ATG, and methylprednisolone, 11% died after mobilization of treatment-related toxicity[32]. Follow up at 2 to 66 mo, revealed no deaths in the other 15 patients, with significant reductions in autoantibody titers, prednisone requirements, proteinuria and improved serum complement levels. Two of seven patients followed more than 30 mo relapsed and required further treatment. In the EBMT database, 27 of 51 patients improved, another 14 improved with subsequent relapse, and 7 patients (11%) died[33].

Across all disease groups, mobilization regimens have been associated with toxicity - in the EMBT registry database there was a mortality rate of 1.5%, largely from cyclophosphamide cardiotoxicity and filgrastim- induced disease flares[34].

Treatment-related mortality in the first 470 patients of the EBMT registry who received an autotransplant was 7 to 8% with marked differences between disease groups; although there was a rate of 12.5% in scleroderma patients, only 1 of 70 patients with rheumatoid arthritis died[34]. Death rates are likely related to severity of underlying illness/organ dysfunction and in SSc is associated with pulmonary artery pressure > 50 mm Hg and total body irradiation without lung shielding[35]. Patient selection is key; there have been no deaths in the last 2 years in MS and SSc trials.

## BONE MARROW DERIVED CELLS PLAY A CRITICAL ROLE IN IBD

Genetic studies suggest that in patients with inflammatory bowel disease (IBD) there may be several defects in the hemolymphatic ("inflammatory", hematopoietic cell-derived) cells[36]. Mutations in the NOD2/CARD15 gene increase the risk of developing Crohn's disease. NOD2/CARD15 is expressed in intestinal epithelial cells and monocytes/macrophages[37,38]. Recognition of intracellular bacteria in intestinal epithelial cells is impaired in 2030insC mutant NOD2[39]. Interestingly presence of NOD2 gene polymorphism, has also been associated with risk of gut GVHD[40,41]. Holler *et al*[41] found that the presence of single nucleotide polymorphisms of the NOD2/CARD15 gene in both the recipient and donor increased the incidence of GVHD to 56% compared to 18% in cases with no mutations from either recipient or donor.

Interestingly, a 37 years old patient developed CD after receiving an allogeneic marrow transplant from a sibling that had CD[42]. Furthermore, genetic studies showed that another patient that developed severe CD following an allogeneic bone marrow transplant may have developed the disease due to the transfer of known susceptibility genes[43]. In this case, CD developed following receiving marrow from a donor (that did not exhibit CD) but had several haplotype mismatches in HLA class Ⅲ genes in the IBD3 locus including a polymorphism of NOD2/CARD15 that has been associated with CD[43].

The role of bone marrow-derived cells in the intestine following transplant is presently unclear. Both in animal

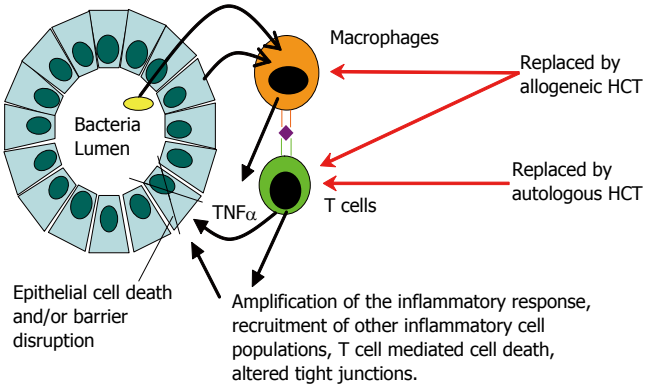

**Figure 2** Pathogenesis of CD and proposed mechanism of action of HCT. See text for details.

models as well as in patients it appears that bone marrow derived cells are involved in the healing process following intestinal injury and may contribute to various components of the mucosa including myofibroblasts, endothelium as well as possibly the epithelium[44,45].

Given the above evidence for hematolymphatic cell playing an important role in IBD pathogenesis, a hypothesis has been put forth that HCT may induce remission of IBD. See Figure 2 for the proposed (speculative) mechanism of action. In this scenario macrophages (orange) present peptides (purple diamond) derived from patient cells or intestinal microorganisms (yellow) to T cells (green). The T cells become stimulated and secrete cytokines like tumor necrosis factor alpha (TNF-α) which can directly damage enterocytes and/or amplify the inflammatory response. The macrophages present the peptide by major histocompatibility complex (MHC) class Ⅱ (e.g., HLA-DR) and the T cells recognize the MHC-peptide complex through T cell receptors. Only macrophages and T cells are depicted here for simplicity, though other hematolymphatic cells (cells derived from hematopoietic stem cells) may participate in the pathogenesis, including neutrophils, eosinophils, dendritic cells and mast cells. Likewise, only enterocytes are depicted here despite other intestinal non-hematolymphatic cells like fibroblasts may participate in the pathogenesis. Genetic predisposition to CD may involve non-hematolymphatic cells (e.g., altered genes needed for the healing of epithelial cells from injury may be missing or altered) or hematolymphatic cells (e.g., altered genes needed for T cells to undergo apoptosis). The latter mechanism may prevail given the ability of HCT to induce durable remission of CD. The genetic predisposition to CD involving the hematolymphatic cells may be due to inherited DNA sequences (e.g., coding for HLA-DR type capable of presenting the pertinent peptide) or DNA sequences generated during ontogeny (e.g., coding for T cell receptor capable of recognizing the peptide). Allogeneic HCT may cure CD by replacing all recipient hematolymphatic cells with donor hematolymphatic cells harboring DNA sequences that do not predispose to CD. Autologous HCT may cure CD by replacing the hematolymphatic cells which (or the ancestors of which) generated the predisposing DNA sequence in ontogeny (e.g., the T cell clone capable of recognizing the peptide) with healthy autologous hematolymphatic cells (e.g., T cell clones generated de novo in the thymus after the HCT that cannot recognize the peptide). The cells that are thought to be replaced by the allogeneic or autologous HCT are pointed out by the red arrows. The pathogenesis of CD is based in part on the following references; [1-4].

## ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION (HCT) IN CROHN'S DISEASE

To date there are no reported cases of allogeneic bone marrow or HCT performed for the primary treatment of CD. There are 14 patients reported in the literature that had CD and underwent allogeneic HCT for hematological disorders (Table 1). Ditschkowski *et al*[46] reported a case series in which 10 out of 11 patients remained free of inflammatory bowel disease following allogeneic HCT for hematological malignancy with a median follow-up time of 34 mo. Seven out of the eleven patients had Crohn's disease. All patients received cyclophosphamide as part of different conditioning regimens. All patients except for two received total body irradiation. The one patient with recurrent IBD symptoms after transplant failed to demonstrate any endoscopic or radiological recurrence of IBD. There was one transplant-related mortality reported at ten months from opportunistic infection. The usefulness of this study for the determination of whether allogeneic HCT may cure CD is limited by the fact that at the last follow up only two patients were off of immunosuppressive drugs.

Lopez-Cubero *et al*[47] reported a case series of six patients with Crohn's disease who underwent allogeneic marrow transplantation for leukemia. Five of these patients had active CD at the time of transplant. All patients received cyclophosphamide and total body irradiation as conditioning therapy. Two patients had sclerosing cholangitis. One patient died of sepsis at 3 mo post-transplant. The remaining five patients were free of CD related symptoms more than one year post transplant. Four of these five patients had sustained remission of CD at 54 to 183 mo post-transplant. One patient had relapse of CD at d 545 post transplant. Interestingly, the relapsed patient had mixed donor-host hematopoietic chimerism, whereas the four patients who achieved sustained remission were assumed to be complete chimeras as they had GVHD in the first two years after HCT. Immunosuppressive drugs were discontinued at least six months prior to the last follow up in the four patients with sustained CD remission.

An additional case has been reported involving a 35 year old male with CD who was transplanted for AML and at eight years post transplant was free of symptoms and signs of CD[48]. In summary of the 14 published cases of allogeneic bone marrow or stem cell transplant in patients with CD, 11 patients have achieved remission (Table 2). The median follow up time was seven years. Of seven patients followed for CD after they have discontinued immunosuppressive drugs, six patients are in remission of

CD. There have been two transplant-related deaths among the 14 cases.

## AUTOLOGOUS HEMATOPOIETIC CELL TRANSPLANTATION IN CROHN'S DISEASE

To date there have been 19 patients who have been reported to have both Crohn's disease and autologous HCT. Patients who underwent transplantation for the primary treatment of Crohn's disease had previously failed standard medical treatment including infliximab. The first case was published in 1993. A 41 year old female with non-Hodgkin's lymphoma and CD underwent an autologous bone marrow transplant. The follow-up period was short. However the patient was symptom free at six months[49]. Three additional cases who underwent transplant for malignancies have also remained in clinical remission[50-52].

Recently, Oyama *et el*[53] and colleagues reported a study in which 12 patients with refractory CD underwent autologous hematopoietic cell transplantation. All of their patients had failed traditional medical treatment including infliximab with a minimal CDAI $\geqslant$ 250. Majority of these patients had a history of surgery. Mobilization was with cyclophosphamide and filgrastim, and conditioning with cyclophosphamide and equine ATG. The peripheral blood stem cells were T-cell depleted. There was sustained

remission (CDAI $\leqslant$ 150) in 11 of 12 patients after a median follow-up of 18.5 mo. One patient experienced CD relapse at 15 mo post-transplant. All patients tolerated the BMT well and there were no transplant-related deaths. One patient died of accidental cause at 37 mo post HCT. Follow-up was at 6 and 12 mo post HCT and then yearly, and included at each visit small bowel radiograph and colonoscopy.

Collectively, 18 out of 19 patients have achieved clinical remission over a median follow up time of 20 mo (Table 3). Only two of these patients are on any ongoing medications again suggesting that HCT may result in CD remission without any need for ongoing medications. Fourteen of these patients underwent autologous HCT for primary treatment of their CD. The majority of these 18 patients had active disease prior to HCT with a history of CD complications including surgery and failure of infliximab therapy in patients where the primary indication for HCT was CD. There has been no mortality related to transplant complications.

## HCT VERSUS IMMUNOSUPPRESSION/ GCSF ALONE

Cyclophosphamide and GCSF were used as the mobilization regimen in the study by Oyama *et al*[54]. Arguably these two agents may explain part of the success of the HCT as cyclophosphamide has been shown to be effective in achieving remission in Crohn's disease and GCSF may shift the Th1/Th2 balance toward Th2 (whereas Th1 cells predominate in CD)[55]. In pediatric patients with IBD, IBD improved during treatment of glycogen storage disease with GCSF[56]. More recently a randomized placebo control trial showed an improvement in CDAI score and rates of remission with GCSF in CD[57].

However, three cases suggest that sustained clinical remission with HCT is likely not due just to cyclophosphamide and GCSF. Scime *et al*[58] reported a case of a 55 year old male who underwent HCT for primary treatment of CD. He showed no improvement in colonic lesions one month after mobilization therapy with cyclophosphamide and GCSF. He subsequently achieved both significant endoscopic and histological improvement after autologous HCT. Five months after HCT the patient remains in clinical remission. Kreisel *et al*[59] describe a 36 year old male who also underwent HCT for the primary treatment of CD. He continued to have persistent histological changes and recurrent CD nine months after mobilization therapy with cyclophosphamide and GCSF (before HCT). Ten mo after HCT the CD was improved,

in clinical remission with minimal histological changes. A third case involved a 30 year old male who underwent an autologous transplant for Hodgkin's lymphoma. He had partial improvement of his CD after mobilization therapy, however, required persistent steroid therapy. At 38 mo after HCT he remains in clinical remission[60].

In Europe a randomized Phase Ⅲ trial of autologous stem cell transplantation in Crohn's disease (ASTIC) has been established that should answer the question of whether the autologous transplantation adds significantly to the effect of immunosuppression/GCSF alone. Patients are randomized into those receiving mobilization chemotherapy with GCSF only versus mobilization chemotherapy with GCSF followed by autologous transplantation[61].

## SUMMARY OF HCT CASES IN CD

In total there are now 33 cases published of patients with CD who underwent either autologous or allogeneic bone marrow or hematopoietic stem cell transplantation. Twenty nine out of these thirty three patients are considered in remission. There were two cases of transplant related mortality. Importantly of the fourteen cases transplanted primarily for treatment of CD there have been no mortalities related to the transplant. Overall these preliminary data suggest that both allogeneic and autologous HCT may be effective in inducing remission in refractory CD. This supports the hypothesis that the hematolymphatic (inflammatory, bone marrow-derived) cells play a key role in CD and that resetting of the immune system may be a critical approach in the management or cure of CD.

The course of many autoimmune diseases including CD is by nature relapsing and remitting, underscoring the need for control populations with comparable severity of disease to evaluate outcomes in HCT. There is a need for objectively validated disease severity scoring, and for establishing prognostic indicators to identify candidates at high risk for poor disease outcome who might benefit from aggressive treatment. Of the cases where transplant was the primary treatment for CD, there have been no transplant related mortalities. However HCT for CD has to be approached with caution as transplantation for other autoimmune diseases has been associated with a transplant-related mortality of 0 to 25% (Passweg, personal communication on the ASTIS trial)[21,22,26-28, 33, 34].

Potential candidates for phase Ⅱ/Ⅲ trials would include patients who have failed standard medical treatment including infliximab (or can not tolerate it), who are unlikely to benefit from further surgery, and those with severe fistulizing disease not responding to conventional treatment.

## Abstract

**AIM:** To investigate the incidence and risk factors of late-onset acute rejection (LAR) and to clarify the effectiveness of our immunosuppressive regime consisting of life-long administration of tacrolimus and steroids.

**METHODS:** Adult living donor liver transplantation recipients ($n$ = 204) who survived more than 6 mo after living donor liver transplantation were enrolled. Immunosuppression was achieved using tacrolimus and methylprednisolone. When adverse effects of tacrolimus were detected, the patient was switched to cyclosporine. Six months after transplantation, tacrolimus or cyclosporine was carefully maintained at a therapeutic level. The methylprednisolone dosage was maintained at 0.05 mg/kg per day by oral administration. Acute rejections that occurred more than 6 mo after the operation were defined as late-onset. The median follow-up period was 34 mo.

**RESULTS:** LAR was observed in 15 cases (7%) and no chronic rejection was observed. The incidence of hyperlipidemia, chronic renal failure, new-onset post-transplantation diabetes, and deep fungal infection were 13%, 2%, 24%, and 17%, respectively. Conversion from tacrolimus to cyclosporine was required in 38 patients (19%). Multivariate analysis revealed that a cyclosporine-based regimen was significantly associated with LAR.

**CONCLUSION:** Both LAR and drug-induced adverse events happen at a low incidence, supporting the safety and efficacy of the present immunosuppression regimen for living donor liver transplantation.

**Key words:** Living donor liver transplantation; Steroid; Acute rejection

## INTRODUCTION

Standard regimens for immunosuppressive therapy after liver transplantation include calcineurin inhibitors and steroids, which result in a reduced incidence of acute rejection and improved recipient survival[1]. The long-term complications of chronic immunosuppression, such as diabetes mellitus, renal toxicity, hyperlipidemia, and opportunistic infections, however, are a great concern with regard to improved survival.

Because the majority of acute rejections occur within the first few months after liver transplantation, most centers try to taper off steroids and minimize maintenance trough levels of calcineurin inhibitors within the first 6 mo after liver transplantation[2,3]. Recently, more rapid steroid withdrawal programs (within 2 wk) were introduced[4,5]. The shorter steroid regimen increases the possibility of late-onset acute rejection (LAR), which might result in graft loss and serious morbidity[6].

The appropriate doses of immunosuppressive drugs over the long-term should be balanced against the incidence of LAR and drug complications. Our immunosuppressive regimen after adult living donor liver transplantation (LDLT) consists of life-long administration of steroids and tacrolimus strictly controlled with therapeutic drug monitoring. In the present study, we retrospectively investigated the incidence and risk factors of LAR to clarify the safety and efficacy of our immunosuppressive regime.

## MATERIALS AND METHODS

### Patients

A total of 247 LDLTs were performed in adult patients at the University of Tokyo Hospital between January 1996 and March 2005. Among the 224 recipients, 18 patients were excluded because of death within the 6 mo. Moreover, another two cases were excluded, one who received the graft from his identical twin and another who received auxiliary partial orthotopic liver transplantation. The remaining 204 patients (102 men and 102 women; age range: 18-67 years) were enrolled in the study. The median postoperative follow-up period was 34 mo (range, 6-114). The most common indication for LDLT was viral cirrhosis ($n$ = 77) followed by primary biliary cirrhosis ($n$ = 46).

Pre-operative aspartate transaminase, total bilirubin levels, and serum creatinine were 19-308 IU/L, 4-400 mg/L, and 2-44 mg/L, respectively. The median score for model for end-stage liver disease was 14 (range, 4-34).

### Immunosuppression

Our surgical technique for recipient and donor surgery is described elsewhere[7]. All the patients received the same immunosuppressive regimen (Table 1) consisting of tacrolimus (FK, Prograf, Astellas Pharma Inc., Tokyo, Japan) and methylprednisolone. If adverse effects occurred with FK, the patient was switched to cyclosporine (CsA). The indications for conversion are described elsewhere[8]. More than 6 mo after LDLT, FK and CsA were maintained at 5 to 10 μg/L and 100 to 150 μg/L, respectively, with therapeutic drug monitoring at least once a month. A trough level of less than 5 μg/L FK or less than 100 μg/L CsA was regarded as sub-therapeutic. Methylprednisolone was maintained at 0.05 mg/kg per day by oral administration for lifetime of the recipients after the initial 6 mo.

### Postoperative care

Diagnosis of acute rejection was based on internationally accepted histologic criteria[9]. Acute rejection occurring more than 6 mo after LDLT was regarded as LAR. Biopsy-proven acute cellular rejection scored more than 3 in Banff classification was treated with high-dose methylprednisolone (20 mg/kg per day) followed by recycling. Patients with steroid-resistant cellular rejection were treated with mycophenolate mofetil and anti-T-cell monoclonal antibody (OKT3, Ortho-Biotech Corporation, Raritan, NJ).

The cytomegalovirus status of the patient was monitored by pp65 antigenemia assay once a week for 3 mo postoperatively. When there were more than 5 antigen-positive cells/50 000 white blood cells, antiviral therapy was started until the antigenemia assay was negative. Details of antibacterial and antifungal prophylaxis are described elsewhere[10].

Hyperlipidemia was diagnosed when the serum cholesterol level was over 2300 mg/L in two successive examinations. Chronic renal failure was defined as serum creatinine of more than 25 mg/L on at least two successive determinations more than 6 mo after LDLT. Patients with normal glucose tolerance preoperatively, who required pharmacologic assistance to control blood sugar more than 6 mo after the transplantation, were diagnosed with new-onset post-transplantation diabetes.

**Table 1 Target trough levels of calcineurin inhibitors and steroid dosage**

| Postoperative time (d) | Tacrolimus (μg/L) | Cyclosporine (μg/L) | Methylprednisolone (mg/kg daily) |
|---|---|---|---|
| 1-7 | 15-20 | 300-350 | 20-0.75 |
| 8-14 | 14-16 | 250-300 | 0.5-0.3 |
| 15-90 | 10-15 | 200-250 | 0.3-0.12 |
| 91-180 | 8-10 | 150-200 | 0.08-0.12 |
| 180- | 5-10 | 100-150 | 0.05 |

### Statistical analysis

The incidence of acute rejection and post-transplantation complications more than 6 mo after LDLT was examined. Preoperative factors included age, gender, disease, serum total bilirubin levels, model for end-stage liver disease score, donor/recipient blood type, gender match, donor age, and the result of donor/recipient human leukocyte antigens (HLA) and the lymphocytotoxic crossmatch. Intraoperative factors included anhepatic phase duration, blood loss, and graft weight/standard liver volumes[11]. Postoperative factors were initial immunosuppressive regimen (FK or CsA), cytomegalovirus infection, and episodes of early acute rejection.

Categorical data were compared using chi-square or Fisher's exact tests. Continuous data were compared using the t-test or Mann Whitney U test. Multiple regression analysis was performed using the proportional hazards models to identify factors that were independently associated with LAR. The trough levels of the calcineurin inhibitors 6 mo after LDLT were recorded and compared between patients with LAR and those without. LAR-free survival was stratified by immunosuppressive regimen using the log-rank test. A $P$ value of less than 0.05 was considered statistically significant. Values of measured variables were expressed as median and range.

## RESULTS

### Clinical outcome

None of the patients experienced immediate graft non-function or chronic rejection. Postoperative vascular, hemorrhagic, and biliary complications that required re-operation within 6 mo, occurred in 75 patients (37%). Conversion from FK to CsA was required in 38 patients (19%) during the initial 6 mo after surgery. The most common reason for conversion was neurotoxicity ($n$ = 15), followed by hematopoietic disorder ($n$ = 7), diabetes mellitus ($n$ = 6), gastrointestinal intolerance ($n$ = 4), hepatotoxicity ($n$ = 3) and cardio-pulmonary disorder ($n$ = 3). The median time to conversion was 16 d (range: 6-165). The cumulative 1- and 3-year patient survival rates were 90% and 87%, respectively.

**Table 2 Incidence of LAR for selected baseline factors**

| Factors | Variables (*n*) | % LAR | *P* |
|---|---|---|---|
| Preoperative | | | |
| Age (yr) | < 40 (53) *vs* ≥ 40 (151) | 12 *vs* 6 | 0.03 |
| Gender | Men (102) *vs* women (102) | 8 *vs* 8 | 0.79 |
| Disease: Viral | Yes (77) *vs* No (127) | 9 *vs* 6 | 0.41 |
| Total bilirubin (mg/L) | < 50 (100) *vs* ≥ 50 (104) | 8 *vs* 7 | 0.72 |
| MELD score | < 10 (123) *vs* ≥ 10 (81) | 7 *vs* 9 | 0.57 |
| Blood type match | Identical (163) *vs* compatible (41) | 8 *vs* 5 | 0.5 |
| Gender match | Yes (91) *vs* No (113) | 9 *vs* 6 | 0.48 |
| Donor age (yr) | < 40 (84) *vs* ≥ 40 (120) | 10 *vs* 6 | 0.32 |
| HLA-A mismatch (*n*) | 0 (75) *vs* 1 or 2 (128) | 9 *vs* 6 | 0.64 |
| HLA-B mismatch (*n*) | 0 (38) *vs* 1 or 2 (166) | 11 *vs* 7 | 0.41 |
| HLA-DR mismatch (*n*) | 0 (43) *vs* 1 or 2 (161) | 5 *vs* 8 | 0.44 |
| T-LCX | Negative (195) *vs* positive (9) | 8 *vs* 0 | 0.39 |
| B-LCX | Negative (116) *vs* positive (88) | 5 *vs* 7 | 0.71 |
| Operative | | | |
| Anhepatic time (min) | < 150 (116) *vs* ≥ 150 (88) | 8 *vs* 7 | 0.8 |
| Blood loss (mL/kg) | < 100 (88) *vs* ≥ 100 (116) | 7 *vs* 8 | 0.8 |
| Graft weight/SLV (%) | < 50 (69) *vs* ≥ 50 (135) | 7 *vs* 7 | 0.97 |
| Postoperative | | | |
| Immunosuppressive regimen | FK (166) *vs* CsA (38) | 32 *vs* 2 | < 0.0001 |
| Proceeding CMV infection | Yes (82) *vs* No (116) | 7 *vs* 8 | 0.91 |
| Early acute rejection | Yes (61) *vs* No (143) | 11 *vs* 6 | 0.14 |

LAR: Late onset acute rejection; MELD: Model for end stage liver disease; HLA-n: Human leukocyte antigen n allele; LCX: Lymphocytotoxic crossmatch; SLV: Standard liver volume; CMV: Cytomegalovirus.

### *Postoperative complications*

Serum cholesterol and serum creatinine levels were 1130 mg/L (range, 560-2110) and 10 mg/L (range, 2-44) preoperatively, and 1850 mg/L (range, 900-3760) and 8.6 mg/L (range, 3-31) at 6 mo after transplantation, respectively. The incidence of hyperlipidemia, chronic renal failure, and new-onset post-transplantation diabetes was 13% ($n$ = 27), 2% ($n$ = 3), and 24% ($n$ = 48), respectively. To date, none of the patients has developed symptomatic cardiovascular diseases or end-stage renal disease that required hemodialysis or kidney transplantation.

Positive cytomegalovirus antigenemia occurred in 40% (82/204), all within 6 mo of surgery. The incidence of deep fungal infection that occurred more than 6 mo after surgery was 17% (35/204), which included candidiasis ($n$ = 20), aspergillosis ($n$ = 5), Pneumocystis carinii pneumonia ($n$ = 3), and cryptococcosis ($n$ = 2). The median time to the diagnosis was 192 d (range: 181-326). These deep infections were all successfully treated, except for one patient who died due to cryptococcosis.

### *Late-onset acute rejection*

LAR was observed in 15 cases (7%, Table 2). The median time to LAR was 302 d (range: 182-1490). All LAR cases were on a maintenance dose of steroid (methylprednisolone 0.05 mg/kg per day), except for one patient who had undergone steroid withdrawal 10 mo before LAR because of aseptic necrosis of the femoral head. Univariate analysis revealed that CsA-based immunosuppressive regimen at the onset of LAR and lower recipient age were significantly associated with LAR (Table 2). Multivariate analysis revealed that only the CsA-based regimen was an independent predictor (Hazard ratio, 0.033; range, 0.007 to 0.142; $P < 0.0001$).

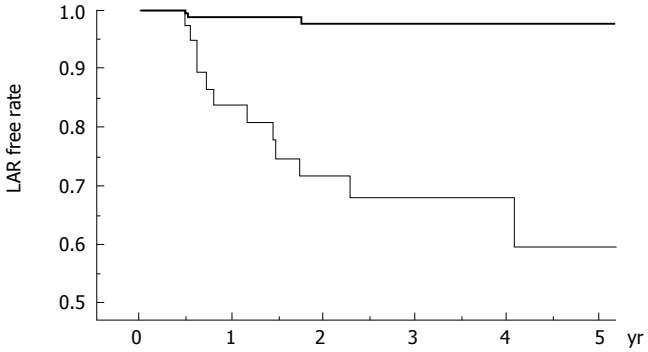

**Figure 1** Kaplan-Meier plot of LAR-free survival based on immunosuppression. Thick line: patients with tacrolimus ($n$ = 166); thin line: those with cyclosporine ($n$ = 38). $P < 0.0001$ comparison between patients with tacrolimus and cyclosporine.

**Table 3 Actual trough levels of calcineurin inhibitors six months after transplantation**

| Group | All | LAR | No LAR | *P* |
|---|---|---|---|---|
| | Mean (range) | Mean (range) | Mean (range) | |
| Tacrolimus (μg/L) | 7.0 (4.5-11.3) | 7.4 (6.5-9.2) | 7.0 (4.5-11.3) | 0.47 |
| Cyclosporine (μg/L) | 133 (70-210) | 135 (79-210) | 128 (70-190) | 0.35 |

LAR: Late onset acute rejection.

LAR-free survival stratified by immunosuppression regimen (FK-based or CsA-based) is shown in Figure 1. In those who developed LAR, only one patient in the CsA group had a sub-therapeutic level at least once during the preceding 8 wk. The trough levels more than 6 mo after transplantation were properly maintained within the target range in both FK-based and CsA-based recipients and were not related to LAR (Table 3). All LAR patients were successfully treated with steroid recycle therapy only, except for two who required additional mycophenolate mofetil and anti-T-cell monoclonal antibody administration. None of them developed chronic rejection.

## DISCUSSION

In the present study, there was a 7% incidence of LAR, which is an acceptable rate compared with previous studies (7%-23%)[12-16]. The incidence of early acute rejection in this population was 30% (61/204), and HLA-DR mismatching and positive T-lymphocytotoxic crossmatch had been proved to be independent significant predictors of early acute rejection[17]. Neither HLA compatibility nor lymphocytotoxic crossmatch was associated with LAR. Episodes of early acute rejection were not related to LAR, as reported previously[12,15]. The present study indicated that a CsA-based immunosuppressive regimen and lower

recipient age were significant risk factors for LAR, which is consistent with previous studies[18].

Whether FK or CsA is the primary immunosuppressant depends on the transplant center, although FK is currently prescribed for nearly 90% of new liver transplantation recipients[1]. In recent randomized trials in adults, there was no difference in the incidence of acute rejection over 1 to 30 mo[19]. It indicates that CsA and FK are equivalent immunosuppressants when maintained at high therapeutic levels. Previous reports emphasized that sub-therapeutic levels of calcineurin inhibitors are related to LAR[12-15], which was not supported by the present data (Table 3). Based on the properly maintained trough level of FK and CsA in our series, the patient drug-compliance bias is negligible and the higher LAR incidence in the CsA group might represent incomplete immunosuppression in the present CsA-based regimen especially for young recipients.

Steroid withdrawal after liver transplantation is still controversial. There are reports of successful steroid withdrawal in randomized studies[2,5]. In contrast, Pageaux *et al*[4] reported a higher incidence of rejection in a steroid withdrawal group. Yoshida *et al*[14] reported that low-dose steroids increased the incidence of LAR. The aim of steroid withdrawal is to reduce long-term complications, such as diabetes mellitus, hyperlipidemia, and opportunistic infections. When compared to steroid free protocols our results with steroid maintenance showed comparable incidence in opportunistic infection, normal serum creatinine and cholesterol level (6-12 mg/L and 1290-2320 mg/L, respectively) although incidence of postoperative diabetes mellitus (24%) seemed higher. Our protocol of life-long steroid maintenance might be justified by the lower incidence of LAR without increased risk of opportunistic infections and metabolic complications.

In conclusion, an FK-based regimen with life-long steroid maintenance (0.05 mg/kg per day) is safe and effective after liver transplantation. In young (< 40 years of age) recipients who require conversion from FK to CsA, careful observation for LAR is necessary.

## Abstract

**AIM:** To utilize transcatheter arterial steroid injection therapy (TASIT) *via* the hepatic artery to reduce hepatic macrophage activity in patients with severe acute hepatic failure.

**METHODS:** Thirty-four patients with severe acute hepatic failure were admitted to our hospital between June 2002 to June 2006 providing for the possibility of liver transplantation (LT). Seventeen patients were treated using traditional liver supportive procedures, and the other 17 patients additionally underwent TASIT with 1000 mg methylprednisolone per day for 3 continuous days.

**RESULTS:** Of the 17 patients who received TASIT, 13 were cured without any complications, 2 died, and 2 underwent LT. Of the 17 patients who did not receive TASIT, 4 were self-limiting, 7 died, and 6 underwent LT. Univariate logistic analysis revealed that ascites, serum albumin, prothrombin time, platelet count, and TASIT were significant variables for predicating the prognosis. Multivariate logistic regression analysis using stepwise variable selection showed that prothrombin time, platelet count, and TASIT were independent predictive factors.

**CONCLUSION:** TASIT might effectively prevent the progression of severe acute hepatic failure to a fatal stage of fulminant liver failure.

## INTRODUCTION

Although it is accepted that severe acute hepatic failure is self-limiting in most patients, it progresses to fulminant liver failure with a high mortality rate in some patients[1]. Liver transplantation (LT) is the only effective treatment for patients with fulminant liver failure[2]. It seems that early treatment for severe acute hepatic failure could effectively reduce the mortality, but it is challenged with several reasons. First, it is difficult to determine the likelihood of progression from severe acute hepatic failure to fulminant liver failure. Although studies have proposed several predictive parameters, such as coagulopathy, jaundice, etiology, and aging[3-7], a reliable and widely accepted procedure for distinguishing self-limiting cases from fatal cases has not been established. Second, even if it might be possible to predict the prognosis of severe acute liver failure, no effective procedures exist for preventing the progression from severe acute hepatic failure to fulminant liver failure. Plasma exchange and hemodiafiltration have been used as artificial liver support systems, but they are only partially effective[8-11].

The development of methods for inhibiting the progression of severe acute hepatic failure to fulminant liver failure has been hampered by a lack of understanding of the mechanisms of fulminant liver failure. The reason why the condition is fatal in some patients but remits spontaneously in others even among cases sharing a common etiology remains unclear. Several recent studies

indicate that activated macrophages in the liver might play a key role in the development of fulminant liver failure[12-15]. If this hypothesis is correct, then suppressing intrahepatic macrophage activity might be a useful treatment.

It is well known that macrophage activity is suppressed by corticosteroids[16,17], which have been used in the past as a treatment for severe acute hepatic failure, but their effectiveness has not been definitively established[18-20]. We speculated that the disappointing results might be due to an insufficient concentration of corticosteroids in the hepatic circulation, and therefore injected corticosteroids *via* the hepatic artery as a treatment for patients with severe acute hepatic failure. Selective arterial injection has been used for the treatment of hepatocellular carcinoma[21,22]. Infusion of 5-flourouracil or cisplatin *via* the hepatic artery is effective while peripheral intravenous injection *via* the hepatic artery is not effective against hepatocellular carcinoma. In this study, patients with severe acute hepatic failure were enrolled and prognostic factors, including arterial steroid injection therapy, were analyzed.

## MATERIALS AND METHODS

### Patients

The patients enrolled between June 2002 to June 2006 in this study were admitted to our hospital with a diagnosis of severe acute hepatic failure and fulfilled at least one of the following criteria: progressive and sustained prothrombin time (PT) (PT-international normalized ratio (INR) > 1.5 for more than 3 d), presence of ascites, and presence of hepatic encephalopathy. When obvious liver atrophy and hepatic coma were observed on admission, the patient was immediately prepared for liver transplantation and excluded from the study. Transcatheter arterial steroid injection therapy (TASIT) was administered with the consent of the patient or in cases of severe encephalopathy greater than grade Ⅱ, with the written informed consent of the patient's family. When consent was not obtained, traditional supporting treatments were continued. Therefore, this study was not a randomized trial. Plasma exchange was repeated to keep PT-INR lower than 1.7, and hemodiafiltration was performed if necessary. Regardless of the method of treatment, LT was implemented in cases whose liver insufficiency progressed when an appropriate donor could be found.

### Arterial steroid injection protocol

A 5-frame catheter was inserted from the right femoral artery to the common hepatic artery. Before the steroid injection, angiography was performed to determine whether an anomaly of the hepatic artery existed. When no replaced hepatic artery was found, the tip of the catheter was set at the proper hepatic artery. When the liver blood was supplied from two hepatic arteries, the branch that showed the widest feeding area was selected for positioning of the catheter. After insertion of the catheter, 1000 mg methylprednisolone was infused for 2 h per day. The arterial steroid injections were continued for 3 d, and the catheter was removed just after injection on the third day. When a bleeding tendency was observed during this protocol, once-daily plasma exchange was added to the regimen.

The details of the informed consent statement and the arterial steroid injection protocol were approved by the Ethics Committee of Kyushu University.

### Statistic analysis

Differences in clinical backgrounds, symptoms, and laboratory data between patients who did or did not receive TASIT were analyzed using $\chi^2$ test and Student *t*-test. Factors potentially associated with the prognosis of severe acute hepatic failure were analyzed by univariate analysis followed by multivariate logistic regression analysis using stepwise variable selection. Factors with a *P* value > 0.10 were removed from the multivariate analysis.

## RESULTS

Between June 2002 to June 2006, 34 patients (21 males and 13 females) were enrolled in this study. Seventeen patients gave their consent to receive TASIT and underwent the treatment. The characteristics of the patients on admission are shown in Table 1. The overall outcome was as follows: 17 patients were conservatively cured, 9 died, and 8 underwent LT. Since it is difficult to find donors for orthotopic transplantation in Japan, living donor LT was performed if necessary. All patients who underwent LT survived the procedure. Pathological examination of liver samples resected during LT showed that the injured liver was markedly atrophic and wholly necrotized in each case, indicating that the cases selected for LT were correctly identified as candidates for LT.

Patient backgrounds on admission did not differ significantly except for the encephalopathy-grading, serum albumin and LDH concentration between patients who did or did not undergo TASIT. In patients who did not receive TASIT, 4 were conservatively cured, 7 died, and 6 underwent LT. In patients who received TASIT, 13 were conservatively cured, 2 died, and 2 underwent LT. All deaths among patients who did not receive TASIT were due to progression to liver failure, while in the TASIT group, one patient died of liver failure and the other died of pneumonia seven days after initial recovery from hepatic insufficiency.

Rapid improvement of liver function was observed in the conservatively cured 13 survivors who received TASIT during the 3-d protocol. Encephalopathy was observed in 9 of the conservatively cured survivors on admission, and completely disappeared on the second day of the TASIT protocol. As shown in Figure 1, serum ALT concentrations decreased remarkably and coagulopathy rapidly improved. Serum ALT concentrations rebounded slightly for a few days in most of the survivors just after the end of the TASIT protocol, and subsequently decreased and normalized within 3 wk after TASIT in all but 1 patient. Even in 1 exceptional case showing prolonged serum ALT elevation after TASIT, the ALT level was much lower compared to that on admission and PT stayed within the normal range. The hepatic function of the patient normalized five weeks after TASIT, but the

*P*-values were calculated to compare the patients treated with and without TASIT.

etiology remained unknown.

To determine prognostic factors, patients were assigned to 2 groups based on their clinical outcomes: one group consisted of conservatively cured survivors who did not receive LT and the other included fatal cases and LT recipients who were judged to have a poor prognosis without LT, based on pathological findings of the injured liver. Univariate logistic analysis was performed for age, sex, etiology of hepatitis, administration of TASIT, laboratory data, and symptoms on admission (Table 2). Among these parameters, presence of ascites, concentration of serum albumin (> 3.3 g/dL), PT-INR (> 2.0), platelet count (> 12 × $10^4/\mu L$), and TASIT were significant factors ($P < 0.05$). Stepwise multiple regression analysis was performed using variables with *P* values ⩽ 0.1, which revealed that PT-INR, platelet count, and TASIT were independent prognostic factors (Table 3). The *P* value of the prediction equation was < 0.0001.

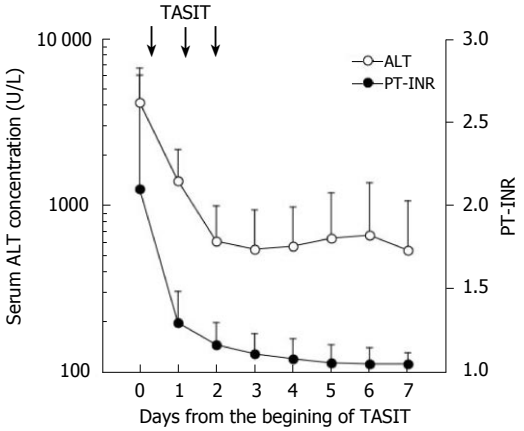

**Figure 1** Improvement of serum ALT concentrations (open circle) and PT-INR (closed circle) in the conservatively cured survivors after TASIT (mean ± SD).

## DISCUSSION

It is difficult to predict whether an individual patient with acute hepatitis develops fulminant liver failure because the condition often resolves spontaneously without any aftereffects. Severe acute hepatic failure has been generally defined as a clinical continuum between acute hepatitis without serious coagulopathy (PT > 50%) and acute liver disease complicated by clinical encephalopathy[1], which is considered a transient stage giving warning of fulminant liver failure. However, according to this definition of severe acute hepatic failure, two-thirds of patients spontaneously recover without developing encephalopathy[3]. Since such a high rate of conservative recovery is inappropriate for evaluating the effects of treatments designed to prevent progression of severe acute hepatic failure to fulminant liver failure, we established a more stringent criterion as a pre-stage of fulminant liver failure, namely acute severe hepatitis that has any of the following conditions: progressive and sustained PT

(PT-INR > 1.5 more than 3 d), presence of ascites, and presence of hepatic encephalopathy. We speculated that PT at a point could not predict progression of severe acute hepatic failure to fulminant liver failure since a transient severe decrease of PT-INR is often observed even in self-limited acute hepatitis. Therefore, coagulopathy should be present for a specific period of time to enroll the patients close to fulminant liver failure. In this study, only 4 of 17 patients (23.5%) who were not treated with TASIT were conservatively cured. The remaining 13 patients died or underwent LT, which led to a markedly poorer prognosis than that reported in previous investigations in patients with severe acute hepatic failure[3,6]. The fatal outcomes indicate that our method for assessment of severe acute hepatic failure can identify patients who have a high risk of developing fulminant liver failure.

Multivariate logistic analysis revealed that TASIT could effectively prevent the progression of severe acute hepatic failure to fulminant liver failure. In light of past reports showing that corticosteroids have no effect on severe acute hepatic failure[18-20], we suggest that the effectiveness of TASIT may be due to the high concentrations of corticosteroids achieved in the hepatic circulation. However, we have not yet elucidated the mechanisms by which high concentrations of corticosteroids affect hepatic macrophages or damage hepatocytes. Furthermore, the role of macrophages in severe acute hepatic failure needs to be further clarified.

We believe that our protocol is safe and effective, but the ideal dose and duration of corticosteroid treatment should be verified. Although excessive use of corticosteroids generally induces infections that would hinder LT, 2 patients in this study who underwent LT after TASIT recovered without any complications, suggesting that our protocol does not seem to influence the outcome of LT. However, lower corticosteroid doses might be sufficient to prevent the progression of the disease. Randomized, controlled studies are needed to confirm this possibility.

**Table 3 Multivariate logistic regression analysis using stepwise variable selection**

| Variables | Estimate | *P* | Lower 95% | Upper 95% | Odds ratio |
|---|---|---|---|---|---|
| TASIT (done) | 1.6535 | 0.0076 | 0.6220 | 3.2312 | 27.3009 |
| Platelet (< 12 × $10^4$/μL) | 2.6871 | 0.0261 | 0.6450 | 5.7805 | 14.6895 |
| PT-INR (< 1.0) | 1.8711 | 0.0687 | -0.0119 | 4.1505 | 6.4953 |

Among the patients who received TASIT, 4 were not conservatively cured, 2 underwent LT and 2 died without LT. Since one of the deaths resulted from pneumonia after recovery from hepatic failure, TASIT was found to be ineffective for severe acute hepatic failure in 3 patients. A common finding in the 3 patients was rapid atrophy of the liver, showing an obvious decrease in liver volume within 24 h of admission, indicating that TASIT is not effective for patients who are at the later stage of fulminant liver failure. Therefore, TASIT should be performed when possible warning signs of the progression of severe acute hepatic failure to fulminant liver failure are observed. However, early administration of TASIT would involve patients who might otherwise recover following traditional supportive measures. Thus it is possible that some of the patients treated with TASIT in this study may have been cured without the treatment. Nonetheless, considering the results of multivariate logistic analyses and the high cost of LT, we believe that TASIT is advantageous over the traditional liver supportive procedures.

In this study, we demonstrated a new treatment strategy for preventing the progression of severe acute liver failure to fulminant liver failure. Our results indicate that TASIT is a safe and effective treatment for severe acute hepatic failure. However, its effect is insufficient in patients showing marked and rapid progression of liver atrophy. Therefore, the option of LT should be considered simultaneously. Randomized, controlled trials are needed to further evaluate this treatment strategy.

## Abstract

**AIM:** To profile the immunogenic proteins of *Shigella flexneri* (*S. flexneri*) expressed during human infection using a proteomic approach.

**METHODS:** Soluble and membrane protein extractions of *S. flexneri* 2457T were separated by two-dimensional gel electrophoresis (2-DE). Proteins were transferred to PVDF membrane and immunoblotted with sera from shigellosis patients. Reactive protein spots were matched to Coomassie stained gels run in parallel, cut out and trypsin digested. Matrix-assisted laser desorption/ionization time of flight-mass spectrometry (MALDI-TOF-MS) was used to determine the peptide mass fingerprints, which were searched in the MASCOT database to identify the protein.

**RESULTS:** A total of 8 immunoreactive proteins were successfully identified from the Coomassie stained gels in three repeats. Six of these proteins have not previously been reported as immunogenic in *S. flexneri*. These proteins could be potential candidates for vaccine or attenuation studies.

**CONCLUSION:** Soluble and membrane proteins of *S. flexneri* 2457T have been screened by 2-DE and immunoblotting with sera from shigellosis patients. Eight proteins are identified as immunogenic.

**Key words:** *Shigella flexneri*; Immunogenetics; Vaccine antigen; Immunoblotting

## INTRODUCTION

Shigellosis is a public health concern in developing countries, particularly for young children who make up 69% of all cases. The majority of shigellosis cases in the Asian, African and Central American regions are caused by *Shigella flexneri* (*S. flexneri*)[1]. Bacteria are transmitted *via* the fecal oral route and require as little as 100 organisms to cause the disease. *S. flexneri* penetrates the epithelial layer of the large intestine, invading and spreading throughout the intestinal epithelial cells. A number of proteins are known to be important for these invasion steps, particularly the products of the *mxi-spa* and *ipa* loci located on the virulence plasmid[2,3].

The immune response against *S. flexneri* appears to be predominantly a humoral response and it still remains unclear whether the host's cellular immunity plays any protective role[4]. The humoral immunity appears to be protective against reinfection, generally against the homologous serotype[5-7]. This is because both the mucosal and systemic immune responses seem to be primarily directed against the lipopolysaccharide (LPS), the structure of which differs between the serotypes. Besides the LPS, *S. flexneri* proteins, which do not show serotype-specificity, have been identified as immunogenic during *S. flexneri* infection of higher primates. The invasion plasmid antigens (Ipa) are antigenic in monkey and human studies, and capable of inducing a protective immune response in mice and guinea pigs when delivered as a multiprotein complex[8-11]. Additionally, some major outer membrane proteins of 30-35 kDa are recognized by the mucosal immune response of *Shigella* patients and are protective in guinea pigs, mice and rabbits[8,12,13].

The escalation in antibiotic resistance in *S. flexneri* isolates is adding increased strain to the limited health services of developing countries. Consequently, the World Health Organization has prioritized the development of a safe and effective vaccine against *S. flexneri*[1]. However, despite promising results with attenuated live vaccine strains, the current vaccine candidates are either not sufficiently attenuated or immunogenic enough[14,15], suggesting that the identification of additional attenuation or protective antigens is warranted.

In order to identify such targets in *S. flexneri*, a profile of immunogenic proteins would be a useful tool. To

date, a proteomic study of detectable immunoreactive proteins from natural *Shigella* infection of humans has not been reported. It is possible to identify antigens from two-dimensional gels using immunoproteomics, where proteins of a particular pathogen are separated by two-dimensional electrophoresis (2D-E) and blotted onto membranes and probed with patients' sera. Subsequent matching and identification of any reactive protein spots generates an immunoproteome for the organism in question. This technique was initially used to visualize the antigens of *Borrelia garinii* and has since been used for a number of microorganisms including *S. aureus*, *H pylori* and *C. albicans*[16-19]. Similar studies have recently been performed with *S. flexneri* protein probed with sera from immunized mice or rabbits[20-22]. However, shigellosis is not a natural disease of mice or rabbits and it remains unclear what use immunoproteome data from laboratory animals will be in the study of human *Shigella* infection. Consequently the generation of an immunoproteome for *S. flexneri* with sera from human shigellosis patients would ultimately be a desirable tool for future vaccine and virulence research.

In this paper, we report the use of immunoproteomics to visualize and identify immunogenic *S. flexneri* 2457T serotype 2a soluble and membrane proteins, which are reactive to sera from *S. flexneri* infected patients.

## MATERIALS AND METHODS

### Bacterial cell culture

*S. flexneri* 2457T was grown in Luria Bertani broth overnight at 37℃ in a shaking incubator. Overnight cultures were diluted 1:100 and shaken at 140 rpm until an $OD_{600}$ of 0.5 was reached.

### Isolation of soluble proteins

Cultures at $OD_{600}$ 0.5 were pelleted by centrifugation at 14 000 *g*, 4℃ for 10 min. Pellets were washed in wash buffer (68 mmol/L NaCl, 2 mmol/L KCl, 1.5 mmol/L $KH_2PO_4$, 9 mmol/L $NaH_2PO_4$) and pelleted again. The pellet was resuspended in lysis buffer (8 mol/L urea, 4% w/v CHAPS, 1% w/v DTT, 0.8% 3/10 ampholytes, 35 mmol/L Trizma, 5 mmol/L EDTA, 1 mmol/L PMSF) and sonicated on ice at constant duty and an output of 8 for 10 × 10 s with 20 s breaks by a Branson 450 Sonifier (Branson Ultrasonics Corporation, Danbury, CT, USA). Unbroken cells and debris were removed by centrifugation at 100 000 × *g* for 1 h at 10℃. The supernatant was collected and stored at -80℃ until required. The protein concentration of the remaining supernatant was determined by Bradford assay using BSA suspended in lysis buffer as the standard.

### Isolation of outer membrane proteins

For the extraction of membrane proteins the method was modified from Molloy *et al*[23], with the following changes. Cultures at $OD_{600}$ of 0.5 were collected by spinning at 1400 × *g* for 10 min. Harvested cells were resuspended in wash buffer (68 mmol/L NaCl, 2 mmol/L KCl, 1.5 mmol/L $KH_2PO_4$, 9 mmol/L $NaH_2PO_4$) and spun again. The pellet was resuspended in 50 mmol/L Tris-HCl pH 7.3 containing 0.2 g/L DNase I. The cells were disrupted by sonication as described above and unbroken cells and cell debris were removed by centrifugation at 6000 *g* for 10 min. The supernatant was collected and the pellet was resuspended in 50 mmol/L Tris-HCl pH 7.3 and submitted to sonication and centrifugation again. The supernatants were pooled, carbonate treated and collected as described by Molloy *et al*[23]. The collected membrane proteins were resuspended in 2% ASB-14, 1% DTT, 7 mol/L urea, 2 mol/L thiourea, 0.5% 3/10 ampholytes and stored at -80℃.

### Two-dimensional electrophoresis

For the first dimension isoelectric focusing, 11 cm Immobiline Dry Strips with the pH gradient 4-7 were used (Amersham Pharmacia Biotech, Uppsala, Sweden). Strips were rehydrated for 16 h in 200 μL of rehydration solution (8 mol/L urea, 0.5% w/v CHAPS, 0.15% w/v DTT, 0.5% v/v Biolyte 3-10 carrier ampholytes and a trace of bromophenol blue). Strips were placed in a Multiphor Ⅱ horizontal electrophoresis system (Amersham Pharmacia Biotech, Uppsala, Sweden) and 200 μL samples (about 1000 μg) of soluble and membrane protein preparations were cup loaded at the anode. Focussing was run at 20℃, 1 mA, 5 W at the following voltage gradients: 1 min 150 V, 20 min 150 V, 20 min 200 V, 2 h 300 V, 2 h on a linear gradient to 3500 V and 20 h at 3500 V. After isoelectric focussing, the strips were treated with equilibration solution I (40% v/v glycerol, 0.05 mol/L Tris-HCl pH 6.8, 6 mol/L urea, 2% w/v SDS and 2% w/v DTT) for 10 min and 10 min in equilibration solution Ⅱ (40% v/v glycerol, 0.05 mol/L Tris-HCl pH 6.8, 6 mol/L urea, 2% w/v SDS and 2% w/v iodoacetamide and 0.005% bromophenol blue). Second dimension SDS-PAGE was performed on a horizontal Multiphor Ⅱ electrophoresis system using precast Excel Gels with 12%-14% acrylamide gradient (Amersham Pharmacia Biotech, Uppsala, Sweden). Twin gels were loaded with a soluble protein and a membrane protein 11 cm Immobiline strip. Low molecular range markers (Amersham Pharmacia Biotech, Uppsala, Sweden) were loaded between the strips. Electrophoresis was performed at 200 V for 1 h 45 min and 600 V for 4-6 h, until the bromophenol blue front reached the edge of the gel. One of the twin gels was stained with CBB G250[24]. Approximately 150 spots were visualized for the soluble protein preparation and 25 for the membrane preparation.

### Immunoblotting

The remaining gel was used for immunoblotting, where the proteins were transferred to PVDF membrane using the horizontal semi-dry electrophoretic Pharmacia LKB NovaBlot system (Amersham Pharmacia Biotech, Uppsala, Sweden) at a constant current of 0.8 $mA/cm^2$. A reference map of proteins was produced by amido black staining of the membrane. The image was scanned before the membrane was destained[16].

The membrane was blocked with 5% skim milk powder/PBS/0.1% Tween-20 overnight at 4℃, washed three times with PBS/0.05% Tween-20 for 10 min each

and incubated overnight at 4℃ with 1:100 dilution of pooled sera from five *S. flexneri* patients (International Centre for Diarrhoeal Disease, Bangladesh) diluted in 1% skim milk powder/PBS/0.1% Tween-20. The serum samples were obtained by the International Centre for Diarrhoeal Disease, Bangladesh, from *S. flexneri* shigellosis patients during the acute stage of shigellosis, 3-6 d after the onset of diarrhoea. Sera were pooled due to the limited volume of patients' sera available. The membrane was washed three times with PBS/0.05% Tween-20 for 10 min and incubated with 1:100 000 dilution of sheep anti-human Ig-HRP (Chemicon International, Temecula, CA, USA) in 1% skim milk powder/PBS/0.1% Tween-20 for 1.5 h, at 4℃. The membrane was washed with PBS/0.05% Tween three times and twice with PBS, before being incubated for 5 min with SuperSignal West Pico Chemiluminescent Substrate (Pierce Biotechnology Inc, Rockford, IL, USA) and developed by autoradiography. Membranes were stripped as per Jungblut and Bumann[25] and reprobed as above using sera from five healthy individuals obtained from the Australian Red Cross Blood Bank.

### Peptide mass fingerprinting

Developed films, scanned pictures of the amido black stained membrane and the Coomassie stained twin gel were superimposed and compared using Adobe Photoshop® and transparencies prepared from the images. Protein spots from the Coomassie gel, which aligned to spots on the film, were excised from the gel. Some samples were sent for matrix-assisted laser desorption ionization-time of flight (MALDI-TOF) analysis at the Australian Proteome Analysis Facility (APAF) at Macquarie University. Alternatively protein spots were digested with trypsin for 16 h at 37℃ and the peptide mixture was mixed (1:1) with a saturated α-cyano-4-hydroxycinnamic acid solution in 30% acetonitrile-0.07% trifluoroacetic acid. One μL of mixture was spotted onto a sample template plate and mass spectra were obtained at the Research School of Biological Sciences (RSBS) Molecular Biology Facility (Australian National University) with an Omniflex mass spectrometer (Bruker Daltonics, Billerica, USA). Autolysing trypsin peptide 2211.1 Da was used as an internal calibration. Post-analysis data processing was done using XMASS™ software (Bruker Daltonics, Billerica, USA). Searches were performed against the MSDB database with the MASCOT peptide mass fingerprint search engine (Matrix Science)[26]. In all significant matches, the top match was a *S. flexneri* protein.

## RESULTS

### Soluble protein profile

Figure 1A shows the CBB G250 stained 2D-E gel of *S. flexneri* membrane and soluble protein preparations. This gel is a representative example of the three independent repeats of protein extraction and 2D electrophoresis performed for this study. Approximately 150 soluble protein spots were visualized from about 1 mg of soluble protein preparation applied to the CBB G250 stained gel. A twin gel was used for electroblotting onto PVDF membrane and membranes were transiently stained with amido black to aid in subsequent spot matching to the CBB gel. The membrane was probed with sera from *S. flexneri* patients and a map of immunoreactive proteins was visualized by chemiluminescence. The pattern of immunogenic proteins is shown on the film in panel B of Figure 1. This film is a representative of the three films from the immunoblot repeats. A total of 6 immunogenic proteins could be matched in each of the three repeats to a corresponding protein spot on the CBB G250 gel. These proteins were identified using peptide mass fingerprinting. The membranes from all three repeats were stripped and reprobed with sera from healthy volunteers. The resulting films had very little signal and displayed only 2 or 3 reactive spots (data not shown), none of which could be aligned to a visible *S. flexneri* protein spot on the CBB G250 gel and were not analysed by peptide mass fingerprinting.

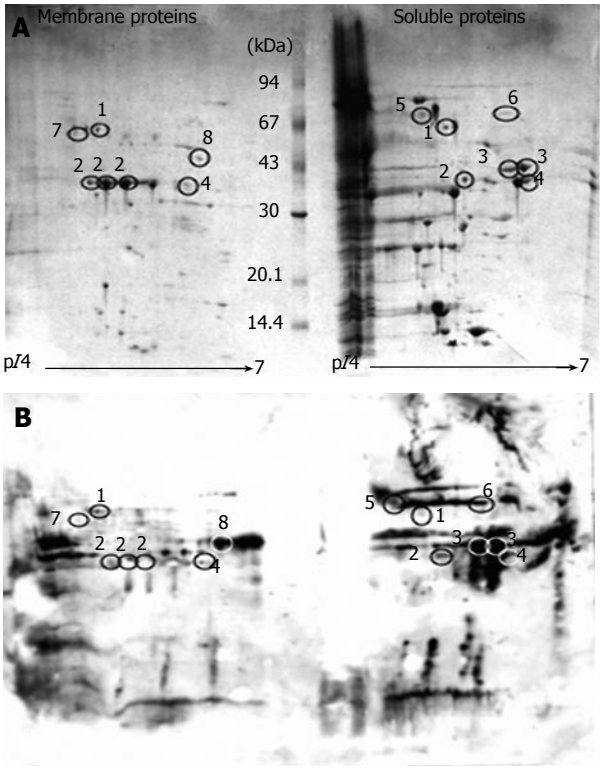

**Figure 1** **A**: Coomassie blue stained 2D gel of *S. flexneri* membrane and soluble protein preparations; **B**: Immunoblot of *S. flexneri* membrane and soluble protein preparations. Circles indicate immunoreactive spots successfully matched and identified from the Coomassie gel (**A**). Numbers correspond to Table 1.

### Outer membrane protein profile

The outer membrane protein extractions, stained by CBB G250, are shown on the representative gel in Figure 1A. Approximately 25 proteins were visualized for each of the three protein preparations. The film displaying the immunoreactive membrane proteins to *S. flexneri* patients' sera is shown in panel B of Figure 1. It was possible to match five immunogenic spots on the film to the corresponding protein spots on the twin CBB G250 gel. Membranes, from each of the three repeats, were stripped and reprobed with control sera from healthy individuals. However, no immunoreactive spots were detected against the membrane protein preparations.

[1]The observed pI and molecular weight of protein calculated from the protein spots position on the CBB G250 2D gel; [2]The predicted pI and molecular weight of the protein calculated from MSDB database.

### *Identified immunoreactive proteins*

Protein spots, which corresponded to an immunogenic spot from the immunoblot film were excised and submitted to in-gel tryptic digestion and MALDI-TOF. Of these protein spots, eight proteins were successfully identified by peptide mass matching. All eight proteins were shown as both the protein spot on the 2-DE gel and as the corresponding immunogenic spot on the matching film (Figure 1). Table 1 lists the identified proteins from the soluble and membrane preparations. Five of the eight proteins were detected in the membrane protein extraction: OmpA, AnsB, TolC, Ggt, TolB. However, OmpA, TolC and AnsB were also detected as immunogenic spots in the soluble protein extraction. Three proteins were identified exclusively as immunogenic soluble proteins: GroEL, Spa33 and IpaD. OmpA, TolC, IpaD and Spa33 were detected as immunogenic spots numerous times in the same gel, suggesting they are occurring as protein series, with each variation retaining its antigenic characteristics.

## DISCUSSION

A total of eight proteins were successfully identified in three separate 2D-E gel immunoblots with a pool of *S. flexneri* patients' sera. Of the eight immunogenic proteins, only two are known to be immunoreactive for *S. flexneri*: IpaD and OmpA. IpaD is a secreted protein essential for entry into epithelial cells and has been reported to be antigenic in a number of *S. flexneri* studies[8,10,27-29]. However, it remains unclear whether anti-IpaD antibodies contribute to protective immunity in humans[2]. All four Ipa proteins have previously been reported to be immunogenic in natural infection, yet IpaA, IpaB and IpaC were not detected as antigens in this immunoproteome study[8]. A two-dimensional proteome map of *S. flexneri* 2457T generated by Liao *et al*[30] was also unsuccessful in detecting any of the Ipa proteins besides IpaD. Likewise, all three previous immunoproteomic studies for *S. flexneri* were unsuccessful in detecting any of the Ipa protein series as immunogenic[20-22]. It is possible that IpaA, IpaB and IpaC were not present in the 2-DE gels at sufficient protein concentrations for detection by the CBB G250 staining. The numbers of *S. flexneri* protein spots visualized on the CBB G250 gels were quite low, possibly due to insolubility problems during the protein extractions or low resolution of the pI 4-7 IEF strips used. A number of immunogenic spots detected on the immunoblot X-ray film could not be matched to a corresponding Coomassie stained spot, suggesting that some proteins were simply present at concentrations not detectable by CBB G250. It would be possible to improve the resolution of the 2D-E gels by using silver staining which increases the sensitivity of protein detection by an order of magnitude over CBB. Alternatively, fluorescent stains that are readily compatible with MALDI-TOF could increase the sensitivity of protein detection.

OmpA is a 35 kDa outer membrane protein and was identified a number of times during the immunoproteome analysis. OmpA is most probably a constituent of the major outer membrane proteins described as immunoreactive in *Shigella* patients and thus is known to be immunogenic[8].

The other six proteins have not previously been shown to be reactive to antibodies found in patients with a natural *S. flexneri* infection. However, the *E. coli* L-asparaginase Ⅱ (AnsB) protein which shares 99.1% identity with *S. flexneri* AnsB, and the highly conserved chaperonin GroEL, in a number of bacterial species, have been reported as antigenic[31,32]. The remaining four proteins are potential candidates for *Shigella*-specific antigenic and immunization studies and could ultimately be useful in the development of new *Shigella* vaccines. However, being immunogenic does not necessarily mean that an antigen is capable of producing a protective immune response, with as little as 2.5% of antigens displaying protective properties[33]. Alternatively, because these antigenic proteins are clearly expressed during invasion of the host, as they are recognized by the host immune response, they may be important for pathogenesis. Any such proteins may be potential virulence factors and could be used in bacterial attenuation of live vaccine strains.

Membrane and surface associated proteins are often immunogenic due to their likelihood of being exposed to the host's immune response. A number of the immunogenic proteins identified in this study are membrane or surface displayed proteins. Three outer membrane proteins were identified as immunogenic, OmpA, TolC and TolB. TolC plays a role in outer

membrane permeability and has been used as an epitope carrier in *Salmonella*, while TolB is involved in the import of colicins[34,35]. Spa33 is a surface displayed protein involved in the regulation of the IpaB and IpaC secretion from the cell, an important virulence step during *S. flexneri* invasion[36]. Although Spa33 was identified as a significant match by MASCOT with peptide mass fingerprints produced from the corresponding protein spot, the observed molecular weight was inconsistent with the predicted mass. Spa33 was observed as a 68 kDa protein in Figure 1 but the predicted size was 33.4 kDa. This size discrepancy may be due to Spa33 interacting with itself as a dimer or possibly forming a complex with a protein which was not detected in the consequent peptide mass fingerprinting. There is no evidence in the literature for Spa33 forming homodimers although it is possible that Spa33 interacts with Spa32, which is predicted to be a protein of 35.6 kDa[36].

Often periplasmic proteins are immunogenic, particularly when they are found extracellularly where they are exposed to the host's immune response. In this study, two metabolic periplasmic enzymes, Ggt and AnsB were identified; gamma glutamyltranspeptidase (Ggt) is a periplasmic enzyme, which is essential for the utilization of gamma-glutamyl peptide as an amino acid source and L-asparaginase Ⅱ (AnsB) is a high affinity periplasmic enzyme, induced by anaerobiosis[37,38]. Both AnsB and Ggt were identified from the membrane extraction of *S. flexneri* proteins. It is possible that the membrane preparation contains some contaminating soluble proteins. The protein sequence of Ggt contains a signal peptide and has 99.7% aa identity to *E. coli* K12 Ggt which also contains a signal peptide and localizes to the periplasm[39]. However, the mammalian form of Ggt is linked to the plasma membrane and *Neisseria meningitidis* Ggt associates with the inner membrane, suggesting that the presence of *S. flexneri* Ggt in the membrane fraction may not simply be inefficient separation of membrane proteins from soluble proteins but perhaps due to a membrane association of the protein.

Control immunoblots were performed with each of the three membranes, using sera from five healthy individuals. It can be assumed that these five individuals have previously been exposed to commensal gut microflora, including *E. coli* of which *Shigella* is a clone[40]. Consequently, the control sera should contain antibodies reactive to *E. coli* and other commensal bacterial proteins, which may potentially recognize homologous *Shigella* proteins[41]. Thus, the control immunoblots could be used as a baseline, where any *Shigella* proteins recognized by the control sera were most likely reacting with antibodies raised against the commensal gut microflora. Consequently, immunogenic proteins, which were only detected in the *Shigella* immunoblots and not in control blots could be considered as part of a *Shigella*-specific immune response. The control immunoblots did not generate any spots that aligned to the eight *S. flexneri* protein spots from the *S. flexneri* patients, suggesting that the eight antigenic proteins identified reacted to anti-*Shigella* specific antibodies in the *Shigella* patients' sera.

This is the first *S. flexneri* proteomic study of the immunoreactive proteins expressed during natural *Shigella* infection of humans. A similar study has been performed using immunized mouse sera in 2-DE gel immunoblots of *S. flexneri* outer membrane protein and soluble protein preparations. That study identified 13 seroreactive proteins, none of which correspond with our identified proteins[20]. Another group has visualized immunoproteomes for *S. flexneri* protein probed with sera from immunized rabbits[20-22]. Only two proteins, OmpA and TolC identified as immunoreactive in the present study were also detected in that work. As *S. flexneri* does not naturally infect or cause shigellosis-like symptoms in mice or rabbits and the experimental animals were not immunized mucosally, it remains unclear how relevant these seroreactive proteins are to the natural human anti-*S. flexneri* immune response.

In this study, eight proteins with reactivity to sera from patients with *S. flexneri* infection were identified using immunoproteomics. Six of these identified proteins have not previously been reported as immunogenic in *S. flexneri* natural infection. These immunoreactive proteins could be novel candidates for vaccine development. Additionally, such proteins have great potential for roles in virulence, as it seems likely they are expressed by the bacteria during the infection of the host, making them prospective attenuation targets for live vaccine construction.

## ACKNOWLEDGMENTS

We would like to thank Dr. Ulrike Mathesius for her assistance with the 2D electrophoresis work, the Australian Red Cross Blood Bank for providing the control sera samples and Julie Christie of RSBS-MBF for technical advice and assistance with the MALDI-TOF.

## Abstract

**AIM:** To evaluate the usefulness of denaturing high performance liquid chromatography (DHPLC) for analyzing microsatellite instability (MSI) status in stool DNA of patients with colorectal cancer.

**METHODS:** A total of 80 cancer tissues from patients with primary sporadic colorectal tumor (proximal cancer: 27, distal cancer: 53) and matched stool (which were employed for comparison with the tissues) were analyzed for MSI status in BAT 26. DNA samples extracted from stool were evaluated by nested polymerase chain reaction (PCR) and DHPLC for MSI analysis.

**RESULTS:** Six cases (7.5%) of MSI were identified in BAT 26 from 80 cancer tissues. All the stool DNA samples from patients whose cancer tissue showed MSI also displayed MSI in BAT 26.

**CONCLUSION:** As MSI is one of the established fecal DNA markers to screen colorectal cancer, we propose to use DHPLC for the MSI analysis in fecal DNA.

**Key words:** Colorectal cancer; Denaturing high performance liquid chromatography; Fecal DNA; Microsatellite instability; Stool

## INTRODUCTION

Colorectal cancer, one of major causes of tumor-induced death in the Western population, becomes prevalent in Korea. The mortality rate from colorectal cancer has increased rapidly from 3.9 per 100 000 individuals in 1983 to 11.4 in 2003 in Korea[1]. Due to its orderly natural history, location within readily accessible organs, and high lifetime incidence, colorectal cancer is suitable for mass screening. It has been estimated that more than 50% of mortality due to colorectal cancer has been prevented through screening tests[2]. Fecal occult blood tests are non-invasive and useful, particularly as an adjunct to sigmoidoscopy[3]. However, the relatively high false positive rates and other problems have necessitated a search for more specific non-invasive tests. In this regard, assays for mutations in fecal DNA are particularly promising[4]. Following the initial identification of mutant K-*ras* in stools[5], many investigators have conducted molecular genetic analyses of stools. In view of the heterogeneity of mutations in colorectal cancer, multiple genetic targets have been screened. Dong *et al*[6] found that analysis of a combination of *p53*, BAT 26 and K-*ras* mutations in stools identified 71% cases of colorectal cancer. Ahlquist and colleagues[7] improved the detection sensitivity to 91% by using a panel consisting of *p53*, BAT 26, APC, and K-*ras*.

MSI is caused by a failure of the mismatch repair system to correct errors that occur during DNA replication. This phenomenon is characterized by the presence of novel alleles in DNA of cancer tissues that are absent in matched repetitive sequences in normal tissues designated 'microsatellites'[8,9]. The MSI status has notable biological significance. For instance, colorectal cancer patients with MSI show better prognosis[9-11]. Cancer detection via microsatellite analyses has been reported for several malignancies, including renal cell carcinoma[12], uterine cervical carcinoma[13] and head and neck squamous

cell carcinoma[14]. Koshiji *et al*[15] reported the results of MSI analysis of fecal DNA for colorectal cancer detection, while Traverso *et al*[16] demonstrated the practical application of the fecal BAT 26 assay with sigmoidoscopy.

In view of the importance of MSI analysis, these techniques required substantial improvement[17]. One particular concern was that the database would be limited if optimal high-throughput assays for running and interpreting microsatellite assays were not developed[18]. Thus, simple and automatic methods are required that make MSI analysis more systematic and convenient, and the many clinical approaches to cancer therapy feasible.

DHPLC has emerged as one of the most versatile technologies for the evaluation of genetic variations. The most patent advantage of this technique is the feasibility of automatic high-throughput analysis using computer-controlled systems. We have developed and reported a novel protocol for MSI analysis in cancer tissues that utilizes DHPLC [19]. In this study, we extended the protocol for MSI analysis using DHPLC to stool samples of patients with colorectal cancer.

## MATERIALS AND METHODS

### Patients

Eighty cancer tissues, taken from 27 patients with cancer of the proximal colon (i.e., between the cecum and splenic flexure) and from 53 patients with distal cancer were analyzed. Matched stool samples from the 80 patients were also analyzed. None of the patients investigated had familial adenomatous polyposis or hereditary nonpolyposis colorectal cancer. All cancer tissues and stool were collected from the Center for Colorectal Cancer, National Cancer Center, Korea. The tumor stage was determined using the American Joint Committee on Cancer TNM system[20]. All patients gave informed consent prior to entry into the study.

### DNA preparation

Genomic DNA was extracted from surgical specimens, using TRIzol reagent (Invitrogen, Carlsbad, CA, USA), according to the manufacturer's specifications. Stool samples were obtained before commencing laxative treatment to prepare for surgery or colonoscopy. Solid stools were weighed into 10 g lots, and stored at -70℃. After defrosting, we employed a QIAamp Stool Mini Kit (QIAGEN, Hilden, Germany) for DNA preparation. DNA was extracted according to the manufacturer's instructions. Briefly, 180-220 mg of stool was prepared in a 2 mL microcentrifuge tube, and 1.6 mL Buffer ASL was added for homogenization of samples. Following centrifugation at full speed for 1 min, supernatants were transferred a new 2 mL tubes, and one InhibitEX tablet was added. The tablet was thoroughly dissolved in the stool solution, followed by a second round of centrifugation for 3 min. The supernatant was transferred to a new 1.5 mL tube with 25 μL of proteinase K. AL buffer (600 μL) was added to the prepared solution, and incubated at 70℃ for 10 min. After the addition of 600 μL of ethanol, solutions (600 μL) were applied to the QIAamp spin column, and centrifuged three times. The column was washed with 500 μL of AW1 and AW2 and stool DNA samples eluted using 200 μL of AE buffer.

Primer sequences for amplifying microsatellite marker, BAT 26 were obtained from the GDB Human Genome Database (www.gdb.org). Stool DNA was initially amplified with the outer primers, forward, 5'-TTTAGGTTGCAGT TTCATCA-3', and reverse, 5'-ACCATTCAACATTTTT AACCC-3'. The outer PCR product (1 μL) was employed for a second inner round of amplification. Inner PCR primers for BAT 26 were follows as: forward primer, 5' -ACTGTCTGCGGTAATCAAGT-3'; and reverse primer, 5'-CCATTCAACATTTTTAACCC-3'. Amplification for DHPLC analysis was performed with 1 μL of the first PCR product, 1X PCR buffer supplemented with 1.5 m mol/L $MgCl_2$, 10 pmol/μL of primers, 50 μmol/L dNTPs (each), and 0.25 U of *Taq* polymerase (QIAGEN, Hilden, Germany) in a total volume of 25 μL. For heteroduplex formation, crude PCR products were denatured at 95℃ for 5 min, followed by gradual cooling from 95℃ to 25℃ over a period of 1 h.

### MSI analysis using DHPLC

DHPLC was performed with a fully automated system (WAVE, Transgenomic Inc., Omaha, NE, USA) as previously reported[19]. Amplified products were automatically injected into a DNA Seq® cartridge (Transgenomic Inc., Omaha, NE, USA), and eluted at a flow rate of 0.9 mL/min through a linear gradient of acetonitrile with 0.1 mol/L triethylammonium acetate (TEAA). Buffers A (0.1 mol/L triethylammonium acetate (TEAA) solution) and B (0.1 mol/L TEAA containing 25% acetonitrile) were automatically adjusted to obtain the best running conditions. The portion of Buffer A was 53% and Buffer B was 47%. The sample injection volume per analysis was 5 μL of PCR product. Regardless of the markers and samples, the running temperature was set to 50℃ for double-stranded DNA analysis in WAVEMAKER™ software (Transgenomic Inc., Omaha, NE, USA). The analysis of individual samples took an average of 9 min from sample injection to the finished result. UV detection was performed at 260 nm. DHPLC buffer conditions for the marker were automatically calculated. MSI analysis by DHPLC took 9 min per amplified DNA sample. Since no matched normal tissue DNA was required for quasimonomorphic markers of BAT 26, the MSI status was determined within 9 min. Results were analyzed using WAVEMAKER software (Transgenomic, Omaha, NE, USA.) in real time. No additional adducts (i.e., radioisotope or fluorescent-labeled primers) were employed other than the conventional PCR reaction, and no extra software was required.

### Statistical analysis

Statistical analysis was performed using the Pearson's Chi-square test, Fisher's exact test, or Student's *t* test, depending on the nature of the data. Two-tailed $P < 0.05$ was considered statistically significant.

## RESULTS

We evaluated the status of the microsatellite from surgical

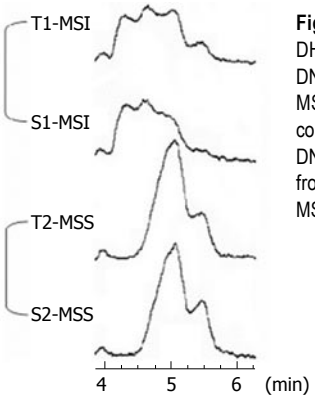

**Figure 1** MSI analysis in BAT 26 using DHPLC. Chromatograms of four different DNA samples are shown. T2-S2 displayed MSS, while T1-S1 exhibited MSI in both colorectal cancer tissue and stool DNA. T, DNA from colorectal cancer tissue: S, DNA from stool: MSI, microsatellite instability; MSS, microsatellite stability.

specimens of all 80 cancers by DHPLC. DNA of adequate quality was recovered from all the lesions. We identified six cases (7.5%) of MSI in BAT 26 from 80 cancer tissues, 4 of 27 proximal colon cancers and 2 of 53 distal colorectal cancers.

To determine the degree of concordance between BAT 26 alterations in cancer tissue and those in matched fecal DNA, we evaluated the status of the microsatellite from matched stool DNA samples of all 80 patients by nested PCR and DHPLC analysis. Seven cases of MSI in BAT 26 were identified from 80 stool DNA samples. Among 7 stool DNA samples with MSI, 6 stool samples corresponded to tissue MSI and the size of the BAT 26 alteration in the tumor and fecal DNA was identical in each patient (Figure 1). Cancer tissue from one proximal colon cancer did not display MSI, but displayed MSI repeatedly in the matched stool DNA.

## DISCUSSION

MSI induced as a result of failure of the mismatch repair system has significant clinical importance in the diagnosis and prognosis of colorectal cancer. Radioactive gel-based electrophoresis and fluorescent-labeled sequencing analysis have been used for MSI analysis. However, these methods have critical limitations for use in high-throughput analysis in a clinical setting. Thus, there is a need for improved MSI analysis techniques. We have developed a novel protocol for MSI analysis in cancer tissues that utilizes DHPLC[19]. In the proposed method, standardized experimental conditions facilitate robust, high-throughput MSI analysis, and consistent results are obtained with high specificity, regardless of sample type or individual researchers' skills. DHPLC can separate PCR products that differ by as little as a few base pairs[21]. This allows the size-dependent separation of double-stranded DNA fragments. In cases where there is a deletion in a microsatellite leading to a shorter allele, the resulting chromatogram is shifted to the left compared with that of the original allele. All the MSI samples in this investigation displayed left-shifted bands, indicating deletion alterations. The main advantage of DHPLC is that automatic high-throughput analysis is feasible using its computer-controlled systems[21].

The BAT 26 marker is employed as an indicator of microsatellite instability, since its mononucleotide tract is altered in nearly all mismatch-deficient tumors[22]. We initially attempted to amplify stool DNA using original BAT 26 markers, but failed to detect mutated DNA in DHPLC. Consequently, we devised a nested PCR analysis method by adding an outer amplification step. A comparison of the outer and inner PCR experiments disclosed that outer PCR followed by BAT 26 amplification led to the best results. Regarding the correlation between MSI status of stools and clinical data, MSI (+) status has been associated with proximal location[23]. Consistent with this, MSI (+) stools were significantly associated with proximal location in our data ($P = 0.040$).

Our data confirm the reliability of stool DNA for MSI analysis of colorectal cancers. Significantly, all 6 cases with BAT 26 mutations in their tissues displayed a positive stool DNA test. In one case with only MSI in stool DNA, it was possible that tumor heterogeneity influenced the result of tissue MSI. We used a part of tissue instead of whole tumor. Baisse *et al*[24] suggested that a molecular heterogeneity in tumors could modify MSI detection.

Main limitation of stool MSI was a low sensitivity. Colorectal cancers with MSI are less frequent even in the proximal colon compared with those without MSI. Using only MSI analysis is not suitable as a screening method. An analysis of a combination of several DNA alterations including MSI status using BAT 26 in stools improved the sensitivity over 90%[7].

In this work, we have extended the DHPLC method for MSI analysis to stool DNA and verified the reliability of stool DNA in the MSI analysis for one of the multiple markers of the genetic screening of colorectal cancers. As MSI is one of the established fecal DNA markers to screen colorectal cancer, we propose to use DHPLC for the MSI analysis in stool DNA.

## Abstract

**AIM:** To determine the changes of quantitative hepatitis B e antigen (HBeAg) that predicts early detection of non-response or breakthrough to long-term lamivudine (LAM) therapy.

**METHODS:** Among HBeAg positive chronic hepatitis B patients who failed to achieve HBeAg seroconversion within 12 mo, we retrospectively analyzed 220 patients who had received LAM more than 24 mo.

**RESULTS:** The mean duration of LAM therapy was 36 (range, 24-72) mo. HBeAg seroconversion after the first 12 mo of LAM therapy was achieved in 53 (24.1%) patients. Viral breakthrough was observed in 105 (47.7%) patients. To find out whether the changing patterns of HBeAg levels can predict the outcome of LAM therapy, we analyzed the reduction rates of HBeAg levels during LAM therapy. Using the decrease more than 90% of pretreatment HBeAg levels, the sensitivity and specificity of response were 96.2% and 70.1%, respectively. Patients were divided into 3 groups according to the reduction patterns of the decrease of quantitative HBeAg: decrescendo, decrescendo-crescendo, no change or fluctuating groups. The optimal time to predict non-response or breakthrough was the first 9 mo of therapy. At 9 mo of therapy, 49 (92.5%) of 53 patients who had achieved HBeAg seroconversion were included in the decrescendo group. On the contrary, in the no change or fluctuating group, only four (7.5%) had achieved HBeAg seroconversion. Among patients who did not show the continuous decrease of HBeAg levels at 9 mo, 95.2% (negative predictive value) failed to achieve HBeAg seroconversion.

**CONCLUSION:** Almost all patients who failed to show a continuous decrease of HBeAg levels at 9 mo of LAM therapy were non-response or breakthrough. Therefore, monitoring changes of HBeAg levels during LAM therapy in HBeAg positive chronic hepatitis B may be valuable for identifying patients who are at high risk of non-response or breakthrough.

## INTRODUCTION

Hepatitis B virus (HBV) infection is a serious public health problem worldwide and a major cause of chronic hepatitis, cirrhosis, and hepatocellular carcinoma[1]. Of the approximately 2 billion people who have been infected worldwide, more than 400 million are chronic carriers of HBV[2]. The goals of therapy in patients with HBV are to limit or reverse progression of disease through sustained suppression of HBV replication[3]. This is usually achieved through treatment-induced suppression of HBV DNA and through hepatitis B e antigen (HBeAg) seroconversion in HBeAg-positive chronic hepatitis B (CHB) patients[4,5]. Clinical trials for LAM have shown it to be effective in HBV DNA suppression, alanine aminotransferase (ALT) normalization, HBeAg seroconversion and for reducing liver inflammation and the progression of hepatic fibrosis and cirrhosis[4,6-9]. Recently, lamivudine (LAM) treatment has shown to prevent the emergence of hepatocellular carcinoma in patients with HBV[10]. However, the optimal duration of LAM therapy is not well established. In view of the long half-life of covalently closed circular DNA (cccDNA) and the variable turnover of infected hepatocytes[11], long-term treatment beyond 1 year is required to achieve complete HBV elimination[12].

Moreover, the HBeAg seroconversion rates gradually continue to increase with extended LAM therapy[5,8,9,13-15]. Unfortunately, long-term LAM therapy is associated with progressively increasing rates of viral resistance due to mutations within YMDD motif of the HBV DNA polymerase[9,13,14,16]. The incidence of viral resistance to LAM therapy is approximately 20% per year reaching approximately 70% of patients after 5 years of therapy[17]. The initial benefits of treatment with LAM seem to be lost among patients who develop YMDD mutations[4,14]. Nevertheless, acute exacerbation of hepatitis may occur after the emergence of YMDD mutant[18,19]. Fatal hepatic failure after emergence of YMDD mutant has also been reported[20,21]. Currently, the appearance of YMDD mutants during LAM therapy is considered an indication for switching or adding the other approved oral agents, adefovir dipivoxil (ADV) or entecavir.

Earlier identification of non-virologic response or viral breakthrough facilitates the change to other drugs or the addition of a second agent, and could help reduce considerably viral breakthrough and treatment cost in patients who can not get HBeAg seroconversion as well. Moreover, this goal would prevent premature discontinuation of treatment in those who would ultimately have achieved HBeAg seroconversion. However, few investigations have been made about the factors that identify earlier the non-response or breakthrough to LAM treatment in HBeAg positive chronic hepatitis B patients.

Compared with qualitative measurements, quantitative HBeAg levels are sensitive, with a high reproducibility and a wide dynamic range and easy to perform[22,23]. Quantification of HBeAg levels have already been found useful in several studies in monitoring and predicting the outcome of interferon treatment[22-26]. More recently, in our previous study, the changing patterns of quantitative HBeAg levels by serial monitoring during LAM therapy may allow not only the prediction of treatment responses, but also an early recognition of a viral breakthrough[27]. Moreover, viral breakthrough by the turning time in the decrescendo-crescendo group was an earlier detection than that in HBV DNA monitoring by a hybridization assay[27].

The aim of this study was to determine the patient-dependent or laboratory variables that predict earlier identification of virologic non-response or breakthrough in patients who had not achieved seroconversion by 12 mo of therapy. Especially, the change of quantitative HBeAg over time during LAM treatment may be valuable for earlier identifying patients who are at high risk of non-response or breakthrough.

## MATERIALS AND METHODS

### Patients

Among HBeAg positive naïve CHB patients who had not achieved HBeAg seroconversion by 12 mo of LAM therapy, we retrospectively analyzed 220 patients (176 men and 44 women; mean age, 38.6 ± 10.2 years) who had received LAM for more than 24 mo. All patients had high upper limit of normal (ULN) serum ALT levels, as well as hepatitis B surface antigen (HBsAg), and HbeAg. The HBV DNA in serum was documented for at least 6 mo before the start of LAM therapy. No patient had a history of previous interferon or nucleoside analogues therapy. None of the patients had clinical cirrhosis, and all were excluded from having hepatitis C, D, HIV infection and autoimmune hepatitis. The diagnosis of CHB was based on histological examination for 84 patients. The remaining 136 patients were diagnosed clinically. The clinical criteria for CHB were elevated serum ALT levels over 6 mo, the absence of clinical evidence of portal hypertension and imaging features suggestive of cirrhosis. Written informed consent was obtained from all patients participating in this study, and the study was approved by the Institutional Review Boards at the Ulsan University Hospital.

### Methods

Serum HBeAg, anti-HBe, HBV DNA and ALT were measured every 1 or 3 mo until HBeAg seroconversion. HBV DNA levels were measured with a hybridization capture assay with the lower limit of detection at 0.5 ng/L (Digene Hybrid Capture Ⅱ, Gaithersburg, MD, USA). Serum quantitative HBeAg and anti-HBe levels were measured by microparticle enzyme immunoassay (AxSYM, Abbott, Chicago, IL, USA). The AxSYM assay calculated a result based on the ratio of the sample rate (S) to the cutoff (CO) for each sample and control. Samples with S/CO value less than or equal to 1.0 were considered negative for HBeAg. In this study, HBeAg seroconversion was defined as the loss of HBeAg accompanied with detection of anti-HBe. Response to therapy was defined as a simultaneous HBeAg seroconversion and HBV DNA negativity on two occasions at least one month apart. A non-response to therapy was defined as persistent presence of HBV DNA during treatment. A viral breakthrough was considered as the reappearance of HBV DNA in serum on two or more occasions after its initial disappearance.

### Statistical analysis

All data was analyzed using the statistical package SPSS (version 12.0: SPSS Inc., Chicago, IL, USA). To identify favorable factors of response among pretreatment variables, we compared variables for response and non-response or breakthrough using $\chi^2$ test or using univariate logistic regression. Cut-off levels of reduction rate of quantitative HBeAg values were determined by univariate receiver operating characteristics (ROC) analysis. The cumulative rates of HBeAg seroconversion and viral breakthrough were calculated by the Kaplan-Meier method. In all cases, a 2-tailed *P* value less than 0.05 was considered statistically significant.

## RESULTS

### Treatment outcome

Baseline demographic and clinical features of the 220 patients who had not achieved HBeAg seroconversion by 12 mo of therapy are shown in Table 1. The mean duration of LAM therapy was 36.4 ± 10.5 (range, 24-72) mo. HBeAg seroconversion after 12 mo of LAM therapy was achieved in 53 (24.1%) patients. The cumulative rates of HBeAg seroconversion at 18, 24, 36, 48, and 60 mo were 9%, 15%, 24%, 31%, and 37%, respectively. Viral

**Table 1 Patient characteristics at baseline and response to LAM therapy ($n$ = 220)**

| Patient characteristics | |
|---|---|
| Age (yr) | 38.6 ± 10.2 (16-68) |
| Sex (M/F) | 176:44 |
| ALT (IU/L) | 232 ± 108 (41-1269) |
| < 2 × ULN | 24 (10.9%) |
| ⩾ 2- < 5 × ULN | 112 (50.9%) |

[1]Positive predictive value. The proportion of patients achieving HBeAg seroconversion among those with decrescendo pattern of HBeAg levels at each time after initiation of therapy; [2]Negative predictive value. The proportion of patients without HBeAg seroconversion among those with the decrescendo-crescendo and no change or fluctuating patterns during treatment; [3]Decrescendo pattern. Continuously decreasing HBeAg levels by more than 90% of pretreatment values; [4]No change or fluctuating pattern. No change or fluctuation of HBeAg levels during treatment; [5]Decrescendo-crescendo pattern. A continuous decrease of HBeAg levels by more than 90% of pretreatment values, and then progressively increasing.

breakthrough was observed in 105 (47.7%) patients at a mean of 19.8 ± 9.5 (range, 7-60) mo after the start of LAM therapy. The cumulative breakthrough rates at 24, 36 and 48 mo were 39%, 49% and 54%, respectively.

### *Changing patterns of quantitative HBeAg levels during therapy as predictive factors for non-response or breakthrough*

To find out whether the changing patterns of HBeAg levels at different times (6, 9, and 12 mo) of therapy can predict non-response or breakthrough, we analyzed the reduction rates of HBeAg levels by serial monitoring during LAM therapy. The cut-off values of reduction rate of HBeAg levels based on ROC curves provided the maximal test efficacy, as defined by the sum of sensitivity and specificity. Therefore, the decrease more than 90% of pretreatment HBeAg levels was chosen to significantly improve the specificity, without reducing the sensitivity, and was adopted as the cut-off level for subsequent subgroup analysis. Using the decrease more than 90% of pretreatment HBeAg levels, the sensitivity and specificity of non-responders were 96.2% and 70.1%, respectively. All the responders, except one, showed the decrease more than 90% of the pretreatment HBeAg values for the maximal reduction rate during LAM therapy. Patients were divided into 3 groups according to reduction patterns, as compared to the pretreatment HBeAg levels, at different times (6, 9, and 12 mo) of LAM therapy: (1) a continuous decrease of HBeAg levels to more than 90% of pretreatment values (decrescendo group), (2) a continuous decrease of HBeAg levels to more than 90% of pretreatment values, and then progressively increasing (decrescendo-crescendo group), (3) no change or fluctuation of HBeAg levels (no change or fluctuating group). The calculation of predictive values of response to therapy was performed using reduction patterns of quantitative HBeAg levels during LAM therapy. A positive predictive value (PPV) at different times of LAM treatment was defined as the proportion of patients achieving HBeAg seroconversion among those with the decrescendo pattern of HBeAg levels each time after the initiation of therapy. A negative predictive value (NPV) was defined as the proportion of patients without HBeAg seroconversion among patients with the decrescendo-crescendo and no change or fluctuating patterns during LAM treatment. Detailed analysis of reduction patterns of quantitative HBeAg at different times had revealed that sensitivity was excellent from 83.0% to 92.5%, while specificity was poor from 46.7% to 49.7% (Table 2). The early prediction of non-responder that optimized capture of potential responders (highest sensitivity) while excluding the largest proportion of non-response or breakthrough (highest negative predictive value) was the changing patterns of HBeAg levels at 9 and 12 mo of treatment (Table 2). Although the changing patterns of HBeAg levels at 9 and 12 mo had similar results, because of increasing rate of LAM mutants and treatment cost, it is desirable to define diagnostic markers that can allow identification of viral non-response or breakthrough as early as possible. Thus, the optimal time to predict non-response or viral breakthrough is month 9 of LAM treatment. According to the changing patterns of HBeAg levels at 9 mo of LAM therapy, the numbers of decrescendo, no change or fluctuating, and decrescendo-crescendo groups were 136, 71, and 13, respectively. Forty-nine (92.5%) of 53 patients who had achieved HBeAg seroconversion were included in the decrescendo group. On the contrary, from the no change or fluctuating group, only 4 (7.5%) had achieved HBeAg seroconversion, and remained patients were non-response or breakthrough. All patients in the decrescendo-crescendo group were non-response or breakthrough. Ultimately, not all patients who had the decrescendo pattern of HBeAg levels achieved HBeAg

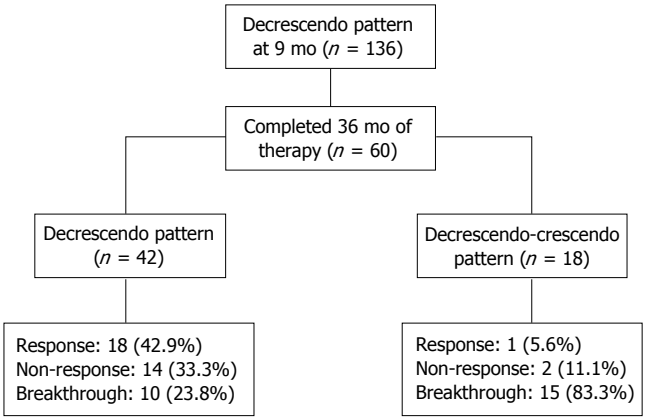

**Figure 1** Clinical courses of HBeAg positive chronic hepatitis B patients who were treated more than 36 mo among 136 patients in decrescendo group at 9 mo of lamivudine treatment. Decrescendo pattern, continuously decreasing HBeAg levels by more than 90% of pretreatment values over time; Decrescendo-crescendo pattern: continuous decrease by more than 90% of pretreatment values, and then progressively increasing.

seroconversion. The PPV at 9 mo was only 36.0%. Among the 136 patients with the decrescendo pattern of HBeAg levels at 9 mo, 106 patients failed to achieve HBeAg seroconversion within 24 mo of treatment. Of these 106 subjects, 60 received repeated quantitative HBeAg level testing at month 36 (Figure 1). According to the changing patterns of HBeAg levels at 36 mo after the start of LAM therapy, there were 42 (70.0%) and 18 (30.0%) patients in the decrescendo and decrescendo-crescendo groups, respectively. HBeAg seroconversion after 24 mo of LAM therapy was achieved in 19 (31.7%). Eighteen (94.7%) of these 19 patients were included in the decrescendo group. Only one of 18 patients in the decrescendo-crescendo group had achieved HBeAg seroconversion.

## DISCUSSION

Most HBeAg positive patients do not have a virologic response after 1 year of LAM treatment, and prolonged treatment beyond 1 year is often necessary. Treatment may be continued in patients who fail to achieve HBeAg seroconversion and have no evidence of viral breakthrough as HBeAg seroconversion may occur with continued treatment. However, treatment beyond 1 year has not been adequately investigated and the benefits of continued treatment must be balanced against the risks of resistant mutants. The current practice for CHB patients with YMDD mutants is options of continuing or stopping LAM or converting to other antiviral drug when LAM resistance develops, depending on the patient's clinical state, ALT and HBV DNA levels[3,12,28]. However, recently, resistance against ADV has been observed as well[29]. Moreover, the emergence of ADV mutation appeared to present earlier and more frequent in LAM-resistant patients than in nucleoside/-tide treatment naïve patients and was associated with reduced antiviral efficacy to ADV therapy[30,31]. In addition, LAM resistance leads to selection pressure for HBV with additional mutations in the DNA polymerase gene that reduces the susceptibility to entecavir[32]. Therefore, earlier prediction of non-response or breakthrough in the course of treatment would not only help reduce the incidence of HBV mutants and treatment cost, but would also allow alternative treatment options to be pursued sooner in the course of treatment. Such goal helps maximize the proportion of patients achieving response, which minimizes emergence of mutant virus in patients who might be ultimately non-response during continuation of LAM therapy.

Serum HBeAg, anti-HBe, and HBV DNA are currently the most important markers for assessing the response to antiviral therapy in patients with HBeAg positive CHB. HBeAg is used typically as a qualitative serological marker for diagnosing the virologic response in HBeAg positive CHB. Therefore, serum quantitative HBeAg levels may reflect levels of the cccDNA in hepatocytes because the mRNAs of HBeAg are transcribed from the cccDNA[33-36]. It is conceivable that patients with decreasing HBeAg levels are on the way to HBV clearance, and reflect the process towards HBeAg seroconversion. The absence of decline for quantitative HBeAg levels may indicate the persistence of ongoing viral replication, despite the antiviral treatment. Furthermore, a resurgence of quantitative HBeAg levels during antiviral therapy may be explained by the reappearance of wild type strains or emergence of mutant strain[27]. To date, available information on the association between the changing patterns of HBeAg levels and early prediction of viral non-response or breakthrough to LAV therapy in patients with HBeAg positive CHB is limited. In the present study, we have retrospectively investigated the utility of monitoring of HBeAg level changes to predict treatment outcomes in naive HBeAg positive CHB patients who had not achieved HBeAg seroconversion by 12 mo of therapy. Based upon the predictive values of a positive test for virologic non-response or breakthrough (NPV), the optimal time to earlier predict non-response or breakthrough is recommended to be month 9 of treatment. Forty-nine (92.5%) of 53 patients who had achieved HBeAg seroconversion after 12 mo of LAM therapy were included in the decrescendo group. On the contrary, from the no change or fluctuating group, only four (7.5%) had achieved HBeAg seroconversion and the remained patients were non-response or breakthrough. All patients in the decrescendo-crescendo group were non-response or breakthrough. That is, almost all patients who did not show a continuous decrease of HBeAg levels at 9 mo during LAM therapy were non-response or breakthrough. That is, among patients who did not have the decrescendo pattern of HBeAg levels at 9 mo during LAM therapy, 95.2% (NPV) failed to achieve HBeAg seroconversion. These patients have very little chance of attaining virologic response even if an additional therapy is administered, and thus it is recommended that other nucleoside analogues or the combination with another antiviral agents be used. However, not all patients who had the decrescendo pattern of HBeAg levels at 9 mo of therapy ultimately achieved HBeAg seroconversion. Positive prediction of virologic response during therapy remains disappointing on the basis of the data available. Indeed, the positive predictive value at 9 mo was only 36.0%. In addition, from 60 patients who were treated more than 36 mo among 136 patients of the decrescendo group at 9 mo of treatment, 19 (31.7%)

had achieved response. Eighteen patients (94.7%) were included in the decrescendo pattern of HBeAg levels at 36 mo of treatment. Only one of responders was included in the decrescendo-crescendo group at 36 mo of treatment. That is, if patient had the decrescendo pattern of HBeAg levels at 9 mo, further treatment should be continued, and serial monitoring of HBeAg levels during treatment would be necessary.

It is therefore imperative that HBeAg levels and HBV DNA are measured during LAM therapy to monitor the response to therapy and facilitate the early detection of drug-resistant strains. HBV DNA testing by PCR and mutant genotyping are very sensitive methods in detecting viral breakthrough during LAM therapy. Unfortunately, our study did not perform the quantitative PCR and assay for YMDD mutants. Also, HBV DNA monitoring by a hybridization assay has a rather low sensitivity, and it was expected to lag behind in the detection of viral breakthrough, as compared to quantitative PCR. Therefore, further studies are needed to compare the quantitative decrease in HBeAg with the HBV DNA level measurement by the sensitive PCR assay. However, these tests do not predict outcomes of treatment before the emergence of HBV mutants. Nevertheless, this is a very important practical point to clinicians because a quantitative HBeAg level test is easy to measure, less expensive, with a wider dynamic range than other molecular tests. Most importantly, it can identify the changing patterns of HBeAg levels during treatment that have the potential to serve as predictors of long-term drug response to LAM therapy. For patients with the decrescendo pattern of HBeAg levels during LAM therapy, continuous LAM therapy without rescue treatment could be expected for achievement of HBeAg seroconversion. On the contrary, for patients who had the decrescendo-crescendo and the no changing or fluctuating patterns of HBeAg levels at 9 mo of LAM therapy, most patients were viral non-response or breakthrough, and HBeAg seroconversion was rarely developed. Therefore, these patients should be monitored more strictly. In the near future, to prevent the development of breakthrough hepatitis, other antiviral agents should be applied when the decrescendo-crescendo pattern and the no changing or fluctuating of HBeAg levels at 9 mo is observed during LAM therapy.

In conclusion, almost all patients who failed to show the continuous decrease of HBeAg levels at 9 mo of LAM therapy were non-response or breakthrough. On-treatment prediction of no-response or breakthrough to long-term LAM therapy in HBeAg positive CHB can be predicted early at mo 9 of treatment based on the changing patterns of HBeAg levels. That is, monitoring of serum quantitative HBeAg levels, in addition to measurement of HBV DNA by PCR, is helpful for evaluating the response to LAM treatment and for the early detection of non-response or LAM-resistant strains as well.

## Abstract

**AIM:** To report the experience of the CHU Sart Tilman, University of Liège, Belgium, in the management of appendiceal carcinoid tumor.

**METHODS:** A retrospective review of 1237 appendectomies performed in one single centre from January 2000 to May 2004, was undertaken. Analysis of demographic data, clinical presentation, histopathology, operative reports and outcome was presented.

**RESULTS:** Among the 1237 appendectomies, 5 appendiceal carcinoid tumors were identified (0.4%) in 4 male and 1 female patients, with a mean age of 29.2 years (range: 6-82 years). Acute appendicitis was the clinical presentation for all patients. Four patients underwent open appendectomy and one a laparoscopic procedure. One patient was reoperated to complete the excision of mesoappendix. All tumors were located at the tip of the appendix with a mean diameter of 0.6 cm (range: 0.3-1.0 cm). No adjuvant therapy was performed. All patients were alive and disease-free during a mean follow-up of 33 mo.

**CONCLUSION:** Appendiceal carcinoid tumor most often presents as appendicitis. In most cases, it is found incidentally during appendectomies and its diagnosis is rarely suspected before histological examination. Appendiceal carcinoid tumor can be managed by simple appendectomy and resection of the mesoappendix, if its size is $\leqslant$ 1 cm.

**Key words:** Surgery; Digestive cancer; Laparoscopy;

## INTRODUCTION

The appendix is one of the most common single site for carcinoid tumor[1]. Histopathologically, appendiceal carcinoid tumor is mostly enterochromaffin (EC) cell type and derives from a subepithelial cell population, which is different from neuroendocrine tumor in other sites[2]. Although rare and usually detected incidentally in appendectomy, it is considered the most common type of appendiceal primary malignant lesion, and is found in 0.3%-0.9% of patients undergoing appendicectomy[3]. This tumor rarely presents with metastases[4,5]. Despite the fact that it is among the most frequently occurring carcinoids, in surgical practice most surgeons may encounter only one or two such lesions during their career[6]. Therefore, it is important to define a correct management of such a rare tumor. The authors report here a series of 5 appendiceal carcinoid tumors found during appendectomy in a single centre and compared this experience with the recent literature on this subject.

## MATERIALS AND METHODS

A retrospective review of all appendectomies was performed from January 2000 to May 2004 in a single department of abdominal surgery in a tertiary referral center (CHU Sart Tilman, University of Liège, Belgium). The data of the patients who were histologically reported to have carcinoid tumor of the appendix were further reviewed for demographic characteristics, clinical presentation, histopathology, operative reports and follow-up.

## RESULTS

A total of 1237 patients underwent appendectomy during the study period (991 for acute appendicitis or appendicular syndrome and 246 during other abdominal procedures). Out of these 1237 patients, 5 (0.4%) were found to have

histological evidence of carcinoid tumor of the appendix. There were 4 male and 1 female patients with a mean age of 29.2 years (range: 6-82 years). Acute appendicitis was the clinical presentation for all patients. Open appendectomy was performed in 4 patients and laparoscopic appendectomy in one. Histologically, all tumors were located at the tip of the appendix with a mean diameter of 0.6 cm (range: 0.3-1.0 cm). One patient was reoperated two months later to complete the excision of mesoappendix after histological analysis. All patients were alive and disease-free during a mean follow-up of 33 mo (range: 21-49 mo). Our results are summarized in Table 1.

**Table 1 Characteristics of 5 patients with appendiceal carcinoid tumor**

| | |
|---|---|
| Incidence (compared to appendectomy) | 0.4% |
| Sex ratio (M/F) | 4/1 |
| Mean age (range) (yr) | 29.2 (6-82) |
| Location | Tip of the appendix (100%) |
| Mean diameter (range) (cm) | 0.6 (0.3-1.0) |
| Clinical feature | Appendicitis |
| First procedure | Appendectomy |
| Second procedure | Resection of mesoappendix (1/5) |
| Mean follow-up (range) (mo) | 33 (21-49) |

## DISCUSSION

Appendiceal carcinoid tumor is a unique carcinoid tumor and differs from those encountered elsewhere in the gastro-intestinal system characterized by a relatively common frequency, small size of the appendix, usually indolent behavior, occurrence in younger patients and a trend towards female predominance[6,7]. It accounts for 32%-57% of all appendiceal tumors[6,8] in patients with a reported mean age of 42 years[9]. Surprisingly, there is a male predominance in our series (male/female: 4/1). Appendiceal carcinoid tumor lacks specific clinical features and its clinical presentation may not differ from that of acute appendicitis. It is usually diagnosed incidentally during surgery for acute appendicitis and occasionally during other abdominal procedures (colectomy, cholecystectomy, salpingectomy)[5,10]. In our series, the diagnosis of all patients with symptoms of acute appendicitis was made only after histological analysis of the surgical specimen. Appendiceal carcinoid tumor exhibits little metastatic potential and therefore rarely presents with metastases[4,5]. Characteristics of the tumor predicting aggressive behavior include size, histological subtype and mesoappendiceal involvement[3]. The predictive value of tumour size is supported by many studies[4,11,12]. The calculated risk of metastasis from tumors $\leqslant$ 1 cm is zero, while a definite increase of risk occurs with tumor size $\geqslant$ 2 cm, the rate of metastasis ranges from 20%[13] to almost 85%[14]. In the present study, all the tumours were less than 1cm (mean diameter of 0.6 cm) and localized at the tip of the appendix with no evidence of regional or distant metastases. Appendiceal carcinoid tumor usually metastasizes to the regional lymph nodes rather than to the liver[15,16]. Carcinoid syndrome occurs in less than 10% of patients with carcinoid tumor[17]. Clinically, this syndrome develops when vasoactive substances produced by carcinoid tumor escape hepatic degradation and gain access into the systemic circulation. Its clinical features include cutaneous flushing, bronchoconstriction, diarrhea, and right-sided cardiac valvular fibrosis. This syndrome can be seen in appendiceal carcinoid tumor patients with liver metastases (< 2% of all appendiceal carcinoid tumors)[10].

The vast majority of appendiceal carcinoid tumor patients do not require any further procedure or investigation following appendectomy. Those who may benefit from additional screening are patients with high-grade malignant tumor though smaller than 1 cm, patients with tumor of between 1 cm and 2 cm or larger than 2 cm, and patients with incomplete resections and metastatic disease[3]. Plasma chromogranin A is the currently available most accurate blood marker, with its level raised in 80%-100% of neuroendocrine tumor patients[18,19]. Other investigations include 24-h urinary levels of 5-hydroxyindoleacetic acid, computed tomography and $^{111}$In-labelled octreotide scintigraphy.

Appendix tumor less than 1 cm in diameter is unlikely to be metastatic and may be managed with simple appendectomy. Our five appendiceal carcinoid tumor patients underwent appendectomy. Reoperation was performed in 1 patient two months later to complete the resection of mesoappendix, since histological analysis of the surgical specimen showed an incomplete mesoappendix. Therefore, consideration should be given to perform a complete mesoappendix resection during appendectomy. Appendiceal carcinoid tumor greater than 2 cm in size demonstrates an increased incidence of regional and distant spread and should be managed with a formal right hemicolectomy[17]. Controversy exists over the management following appendectomy, especially with regard to the role of right hemicolectomy in patients with tumor 1 to 2 cm in size[3]. Acceptable indications for right hemicolectomy in controversial cases have been recently suggested by Goede *et al*[3], including histological evidence of mesoappendiceal extension, tumor at the base of the appendix with positive margins or involvement of the caecum, high-grade malignant carcinoid tumor with a raised tumor prognostic index as measured by mitotic index and Ki67 levels.

The management of metastatic tumors and carcinoid syndrome has focused on cytoreductive chemotherapy and pharmacologic control of the bioactive substances produced by these tumors[17]. Response rates less than 40% have been reported for combined chemotherapy with streptozotocin and 5-fluorouracil or doxorubicin but the response time is short and chemotherapy regimen has significant side effects[20]. Thus, chemotherapy is not the first choice of treatment for patients with carcinoid tumor. Its use has to be discussed in a multidisciplinary approach related to other available treatments. The limited efficacy of systemic chemotherapy underlines the need to restrict its use in progressive cases or in patients with uncontrolled hormone-mediated symptoms despite biological or local treatment[20,21]. Octreotide, a somatostatin analog, is the most effective pharmacologic agent available to improve symptoms associated with carcinoid syndrome with a clinical and biochemical response rate of up to 60%. Available

data on growth control indicate that stabilisation of tumor growth seems to be the most beneficial anti-proliferative effect occurring in up to 50% of patients with slowly growing tumor. Partial tumor regression is marginal and occurs in only 3%-5% of cases. The long-acting somatostatin analogs are actually preferred[22].

Several studies on the antiproliferative effect of interferon-$\alpha$ in metastatic neuroendocrine tumor patients have reported that index hormone is reduced more than 50% in 40%-60% of patients with concomitant improvement of flushing and diarrhea. Stabilisation of tumor growth is observed in 20%-40% and a reduction in tumour size in 12%-15% of patients[23,24]. However, this therapeutic gain must be outweighed by the frequency and severity of toxic reactions[25]. Other treatment modalities such as local therapy and tumor-targeted radiotherapy are available for metastatic carcinoid tumor. Hepatic arterial chemoembolization (HACE) for non-resectable diffuse liver metastases could represent a good therapeutic option if the disease is not under control with other available treatment modalities[26,27]. HACE can be sued as a first line treatment. By targeting somatostatin receptor-positive tumor, it is possible to deliver a tumoricidal dose of radiation with $^{111}$In or $^{90}$Y coupled to somatostatin analogs. Preliminary studies in end-stage neuroendocrine tumor patients have shown promising results[28,29]. This treatment might be effective in patients refractory to conventional strategies and merits further development.

The prognosis of appendiceal carcinoid tumor is much better than midgut carcinoid tumor[17]. The 5-year survival rate of patients with local disease is reported to be 92% and 81% of those with regional metastases, and 31% of those with distant metastases, respectively[1]. All the patients in our series were alive and disease-free during a mean follow-up of 33 mo.

In summary, appendiceal carcinoid tumor occurs most often as acute appendicitis. In most cases, it is found incidentally during appendectomies and its diagnosis is rarely suspected before histological examination. Although appendiceal carcinoid tumor has an excellent overall prognosis, consideration should be given to screening this group of patients, since the frequency of associated synchronous and metachronous colorectal cancer is high (13%-33%)[1,4,6,8].

## Abstract

**AIM:** To study the Hepatitis B virus (HBV) genotypes and their effect on the progression and outcome in patients with chronic liver diseases from New Delhi, India.

**METHODS:** Sera from 100 HBV-related chronic liver disease (CLDB) cases were tested for HBV genotype using Polymerase Chain Reaction-Restriction Fragment Length Polymorphism (PCR-RFLP) and Type-specific primers-based PCR (TSP-PCR) targeting to the surface (S) gene encoding hepatitis B surface antigen.

**RESULTS:** Only genotypes A and D were present and genotype D was dominant. Genotype D was present in all CLDB patient categories. The genotype distribution for the 100 patients with CLDB was as follows: genotype A, 16/100 (16%) (7/40- 17% chronic hepatitis B (CHB); 8/47, 17%, HBV-related cirrhosis (CRB); 1/13, 7.6%, HBV-related hepatocellular carcinoma (HCCB); genotype D- 84/100 (84%) (32/40- 80% CHB; 38/47- 81%, CRB; 11/13, 85%, HCCB); genotype A + D, 3/100 (3%) (1/40- 3% CHB; 1/47- 2%, CRB; 1/13, 7.6%, HCCB); C, 0; B, 0; E, 0; F, 0; G 0, H 0; ($P < 0.01$, genotype D *vs* A).

**CONCLUSION:** Only HBV genotypes A and D were present in patients with CLDB from New Delhi, India. Compared with genotype D, genotype A patients had no significant clinical or biochemical differences ($P > 0.05$). Mixed infection with genotype A and D were seen in 3% of the cases. Genotype D was the dominant genotype prevalent in all patient categories.

**Key words:** HBV-related chronic liver disease; Hepatitis B virus genotypes; PCR-RFLP; Type-specific primer-based PCR

## INTRODUCTION

Approximately, two billion people in the world have been infected by Hepatitis B virus (HBV), 350 million of whom are chronic carriers of the virus[1,2]. Worldwide HBV isolates have been classified into eight genotypes: A, B, C, D, E, F, G and H[1,3]. The eight genotypes have a characteristic geographical distribution[1]. Several studies have revealed the association of HBV genotypes with the severity of chronic liver disease, but the results are not consistent[1, 4-6]. In Europe, most patients with genotype D are reported to have acute hepatitis B, while most patients with genotype A have chronic hepatitis B[5]. In northern Taiwan, 52% of asymptomatic carriers have genotype B, while 60% of patients with cirrhosis harbor genotype C; genotype B is more common in patients less than 50 years of age with HCC[7]. In Japan, HCC patients with genotype B younger than 60 years of age are rare[8]. Thus, the influences of HBV genotypes on clinical outcomes need to be clarified. Recent studies have shown that virological characteristics and clinical manifestations may differ even among HBV isolates of the same genotype[1]. Two subgroups of genotype B can be differentiated: a Japanese subgroup Bj with no indication for recombination events and an Asian subgroup called Ba which shows a recombination of the precore and core region from HBV genotype C. Response to antiviral therapies and the prevalence of hepatitis B e antigen (HBeAg) differ among patients with chronic liver diseases who are infected with HBV/Ba and HBV/Bj. Also, among isolates of HBV genotype A (HBV/A), two subtypes have been reported, one of which is distributed widely in European countries and the USA (Subtype A), while the other prevails in sub-Saharan Africa (Subtype A'). Subtype A' seems to be virologically distinct from the original genotype A and is associated with reduced serum levels of HBV DNA and a low capacity to encode HBeAg. In addition, subtype A' tends to induce hepatocellular carcinoma[1]. HBV genotype C isolates from Australian Aboriginees shows several features of a separate subgroup called genotype $C_{australia}$. The South American genotype F segregates into two clades F1 and F2[1].

Scanty information exists regarding the prevalence of HBV genotypes, their clinical relevance and therapeutic impact within CLDB category from India[9-12]. We have used recently developed two genotyping methods based on restriction fragment length polymorphism (RFLP)[13] and polymerase chain reaction (PCR) with type-specific primers[14] both targeting to the S-gene encoding the hepatitis B surface antigen.

## MATERIALS AND METHODS

### Patients

The study subjects included HBV DNA positive patients belonging to different clinical categories: (1) The diagnosis of HBV-related cirrhosis (CRB) was made when the patients presented with features of HBV-related chronic liver disease associated with portal hypertension, had biochemical evidence of hepatocellular failure and barium swallow or endoscopy showed evidence of esophageal varices (When possible confirmation was done by histology). Other causes of portal hypertension were excluded on the basis of clinical features, liver function tests, and liver biopsy. The severity of the cirrhosis was quantified using the Childs-Pugh Classification strategy[15]. Forty-seven CRB cases were selected on the basis of the above-mentioned criteria. (2) Patients with infection of HBV showing symptomatic, biochemical (alanine aminotransferase more than upper limit of normal) or serological (hepatitis B surface Antigen (HBsAg), Hepatitis B e Antigen (HBeAg), IgG antibodies to hepatitis B core antigen (IgG- Anti- HBc) positivity), evidence of continued liver disease of more than 3 to 6 mo without steady improvement were diagnosed as suffering from Chronic Hepatitis B (CHB)[9-12,15]. Forty CHB cases were selected based on the above-mentioned criteria. (3) HBV related hepatocellular carcinoma (HCCB) was diagnosed in those HBV related cases when a percutaneous liver biopsy showed histological features of a primary malignancy of hepatocytes and/or alfa-fetoprotein levels of more than 30 nanogram/mL[1,12,15]. Thirteen HCCB cases were selected on the basis of the above-mentioned criteria.

### Sample size estimation

With the assumption of prevalence of HBV, based on Indian Council of Medical Research (ICMR), Government of India, multicenter data[10-12], to be 70 % in chronic hepatitis (CH), 80% in liver cirrhosis (CRR), 60% in hepatocellular carcinoma (HCC), the minimum sample size required at 80% power level and 5% level of significance would be 30 cases each of HBV-related liver cirrhosis (CRB) and chronic hepatitis B (CHB) and 11 HBV-related hepatocellular carcinoma (HCCB). This sample size was achieved and some more cases were included by consecutive screening of 900 cases of various chronic liver disease patients over a period of 42 mo (June 2002 to December 2005). The study was approved by the institutional ethical committee of Maulana Azad Medical College, New Delhi. Study protocol was explained to all eligible participants and informed consent was obtained before subject enrollment.

### Serological tests

Serological status was investigated by the third generation enzyme immuno-assay (EIA) method using the following commercially available EIA kits: hepatitis B surface antigen (HBsAg), hepatitis B e antigen (HBeAg), IgG antibodies to hepatitis B core antigen (IgG- Anti- HBc), IgG antibodies to hepatitis D (IgG anti-HDV) (Abbott Laboratories, Chicago, IL, USA) and anti-HCV by Innotest HCV AB Ⅲ (Innogenetics NV, Ghent, Belgium).

### Biochemical investigations

Serum aspartate aminotransferase (AST), serum alanine aminotransferase (ALT), alkaline phosphatase (ALP), total bilirubin (T. Bil.), Prothrombin time (PT) tests were done weekly when the patients were admitted to the wards, while routine biochemical tests were done at monthly follow-up after the patients were discharged from the hospital.

### Lamivudine therapies for CHB patients

In all CHB cases, Lamivudine monotherapy was provided. The drug was given at a dose of 100 mg per day for 18 mo. End of therapy response (ETR) in HBeAg positive patients was defined as loss of HBeAg (with or without the appearance of anti-HBe), reduction of viral DNA to undetectable level and normalization of ALT. However, in HBeAg negative/anti-HBe positive patients it was defined as loss of viral DNA accompanied with the normalization of ALT[16]. Sustained virological response (SVR) was considered when the status of ETR persisted for six months after the therapy was stopped[16].

### DNA extraction and amplification of S-gene of HBV by PCR

Total nucleic acid from 100 μL serum was isolated using standard Proteinase-k/ phenol/ chloroform method[7]. Part of the S-gene was amplified by nested PCR as described earlier[13].

### Determination of HBV genotypes by RFLP analysis of S-gene

The second round PCR Product with a length of 485 bp was subjected to digestion with five kinds of restriction enzymes i.e. *Ear* Ⅰ, *Alw* Ⅰ, *Nci* Ⅰ, *Hph* Ⅰ, *Nla* Ⅳ[13].

### Determination of HBV genotypes by PCR using type-specific primers

Genotyping was done on the basis of PCR based type-specific DNA bands as performed earlier by Naito H *et al* 2001[14].

### Sensitivity of TSP-PCR

The amount of DNA corresponding to 100 μL of serum was dissolved in 25 μL of sterile deionised water and 10 μL was subjected to PCR. A $10^{-1}$ to $10^{-6}$ dilution of this sample was used to determine the sensitivity of the PCR protocol. Products were obtained up to $10^{-5}$ dilution. The detection limit of the PCR was calculated to be 200 HBV genomes/mL serum.

### HBV Genotype analysis based on nucleotide sequencing

Representative PCR amplified products of S-gene (485

M: *Hae* Ⅲ digested *Phi* X 174 DNA ladder, Lanes 1- 4: Restriction Digestion of 485 bp into 265 bp and 186 bp fragments showing the presence of Genotype D; lanes 5,6: Restriction Digestion of 485 bp into 265 bp, 220 bp and 186 bp fragments showing the presence of mixed Genotypes A and D; lanes 7: Restriction digestion of 485 bp into 265 bp and 220 bp fragments showing the presence of genotype A.

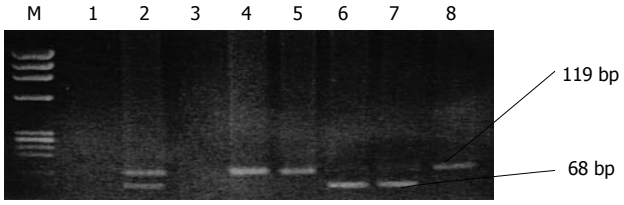

**Figure 2** Agarose gel electrophoresis of HBV genotypes A and D, (Using Mix-A, Mix-B, PCR with type-specific primers based genotyping strategy). PCR Product of 119 base pairs (type D) and 68 base pairs (type A). Lane M- (*Phi* X 174*Hae* Ⅲ) Molecular weight marker, lane 1, 3- Negative Control, lane2-Positive Controls, lanes 4-8: Samples; Lanes 4, 5, 8: Type D; Lanes 6, 7: Type A.

bases) were sequenced using the dideoxy chain termination method in an automated DNA sequencer (ABI 377-18 sequencing system, Perkin Elmer). Nucleotide sequences were aligned with CLUSTALW software. DNA sequences of Genotypes A-H were downloaded from the Gene bank according to the accession numbers for the respective genotype and phylogenetic analysis was carried out with the CLUSTALW algorithm.

### *Statistical analysis*

Quantitative data was expressed as mean ± SD (Standard Deviation). Statistical significance was determined by Chi-square test with Yates' correction (wherever needed) or by 2-sided Fisher exact test and Student's *t* test using SPSS-10 software. The p values of less than 0.05 were considered significant throughout.

## RESULTS

### *Demographic and clinical profile of the patients*

The S-gene of HBV isolates from 100 various CLDB patients were analyzed for HBV genotypes. The demographic and baseline clinical characteristics of the patients belonging to the three different groups (CHB, CRB, HCCB) is shown in Table 1. In all the three groups, the frequency of male patients was more than the female patients (Table 1). None of the patients was anti-HCV or anti-HDV positive as revealed by EIA tests.

### *HBV genotyping by PCR-RFLP*

The PCR products of 100 HBV DNA positive subjects were digested with restriction enzymes specific for genotypes B, C, E and F and no characteristic fragment for each genotype was observed. Finally, by digestion with *Nla* IV, characteristic fragments of genotype A were observed in 16 subjects, characteristic fragments of genotype D were found in 81 subjects (Figure 1). Genotypes A+D mixed infections were found in three cases (Table 1).

### *HBV genotyping by PCR with type specific primers*

As explained in the methodology two sets of the 2nd PCR was carried out for detection of genotypes A to F. Sixteen (16%) of the 100 subjects had a PCR product of 68 bp that was characteristic of genotype A (Figure 2). The other 81/100 (81%) had PCR product a length of 119 bp and were classified into genotype D. Genotype A + D mixed infections were found in three cases (Table 1).

### *Verification of RFLP and TSP-PCR genotyping methods by sequencing*

Twenty representative sequences were selected randomly from both genotype A ($n$ = 5) and D ($n$ = 15) samples. The 20 sequences were recorded in Gen Bank (Accession numbers: DQ875877 and DQ885267-DQ885285). A phylogenetic tree was constructed based on 410 bp of the S-gene of the HBV genome using CLUSTALW software. Out of the 20 isolates, 15 isolates were clustered with

genotype D, and five were clustered with genotype A, validating both the genotyping strategies. The genotype A and D sequences were further classified into subtype A1 and $D_1$ by blast analysis. None of the sequences was clustered with the sequences of the genotypes B, C, E, F, G or H.

### *Virological response in CHB patients*

Sustained virological response on treatment with lamivudine was seen in 28.5% of patients of genotype A while it was seen in 37.5% of patients of genotype D (*P* value is not significant) (Table 1). The clinical data of CHB patients on therapy harboring either genotype A or genotype D did not differ significantly.

### *Comparison of clinical profiles between genotypes A and D in northern India*

The majority of the cases turned out to be genotype D; 81/100 (81%), followed by genotype A; 16/100 (16%) using both the genotyping methods. Genotypes A + D mixed infections were found in three cases (Table 1). The ALT and AST levels, mean age, and HBeAg, IgG anti-HBc positivity were compared between genotypes A and D within each of the study groups and no significant differences were observed (Table 1). However, ALT, AST, HBeAg and IgG-anti-HBc positivity were significantly different between HCCB and CHB/ CRB cases ($P < 0.05$ CHB, CRB *vs* HCCB, Table 1).

## DISCUSSION

There have been no studies from northern India comparing the clinical outcome of CLDB patients infected with different HBV genotypes using the TSP-PCR method. We have attempted to validate two most commonly used methods originally described by Naito *et al* and Mizokami *et al*[13,14]. Genotypes determined by both the methods were concordant in all the subjects.

The present study demonstrates that HBV genotype D is highly prevalent. This result, however, differs from that of two earlier studies on chronic liver diseases where genotype A and D were found to be prevalent in equal proportions[9,17]. The major reason of the different results might be due to the differential demographic distribution of the HBV-genotypes. The previous study was carried out in Lucknow; a city situated 600 km away from New Delhi, India. Also, the majority of the cases in Lucknow come from semi-urban and rural areas. The patients in New Delhi are more or less from urban or semi-urban areas[17]. Another reason could be selection bias, as earlier studies were conducted on small series of non-consecutive chronic cases [9,17].

In this study, mixed infection of genotypes A and D of HBV were found in 2% CRB cases, 3% CHB and 7.6% HCCB cases. This is in accordance with what has been reported earlier[17]. Interestingly, all the cases (3/3) with mixed infections with genotype A and D had histories of blood transfusions. In our study, genotype A was found only in the minority of the patient categories (Table 1). The impact of HBV genotypes on response to lamivudine therapy has been studied in various countries[18]. A study in Germany suggested that the rate of resistance to lamivudine was higher in patients with HBV genotype A infection than in patients with genotype D infection. No difference in the risk of lamivudine resistance is found between patients with genotype B and patients with genotype C. In patients with genotype C infection, however, virological response is worse during lamivudine therapy, and is also less durable after the discontinuation of therapy than in patients with genotype B infection[18]. The response to lamivudine is poorer in patients infected with subtype Ba, which contains a recombination with genotype C, than in those with subtype Bj without such a recombination[19]. Influence of genotypes on therapeutic response needs to be examined in patients infected with the other genotypes, particularly in those with genotype A or D infection[19]. In the present study, a significantly higher percentage of patients with CLDB were infected with genotype D and they did not influence the therapeutic response. Sustained virological response on treatment with lamivudine was seen in 28.5% of patients of genotype A while it was seen in 37.5% of patients of genotype D (*P* value is not significant). Determining the genotype could be helpful for predicting the outcome of antiviral therapy in patients with chronic hepatitis B. Transfusion was associated as the most important risk factor of HBV transmission in all the patient categories (Table 1).

Twenty representative samples from the study population were sequenced for the S-gene which led to confirmation of the RFLP and TSP-PCR results. Based on the nucleotide sequence of the S-region, genotype D emerged as the predominant genotype (15/20, 75%). Indian strains belonging to genotype A and D differed from each other by about 5.2% in the S-gene (410 bases).

In conclusion, genotype D appears to be the dominant genotype circulating in north Indian population with CLDB. Genotype A appears to be the minor genotype.

## Abstract

**AIM:** To investigate the prevalence of celiac disease serologic markers (antigliadin IgA, IgG, and anti-endomysial IgA) in patients with reflux esophagitis and to detect the relationship between reflux esophagitis and celiac disease (CD).

**METHODS:** This study was performed prospectively between January 2003 and January 2004. Sixty-eight adult reflux esophagitis patients and 40 people as control group for symptoms related with gastrointestinal system were enrolled in this study. The diagnostic work-up included an accurate medical history with gastrointestinal symptoms, routine laboratory measurements, the detection of antibodies against gliadin (IgA and IgG) and endomysium (IgA), and an upper endoscopy with postbulbar biopsy.

**RESULTS:** IgA-AGA and IgG-AGA were positive at 8.8% and 10.3% in patients with reflux esophagitis. In control group, it was found that 10% people had positive IgA-AGA, and 7.5% people had positive IgG-AGA. There was no significant relationship between patients and control group regarding positive IgA-AGA and IgG-AGA. The patients and persons in control group had no positive IgA-EMA. On postbulbar biopsies, no finding was detected concerning celiac disease. There were no symptoms and signs for gluten enteropathy in patients and control group.

**CONCLUSION:** This review supports that an association does not exist between celiac disease and reflux esophagitis. We think these diseases exist independently from each other.

**Key words:** Celiac disease; Reflux; Esophagitis

Bagcı S, Ercin CN, Yesilova Z, Ozcan A, Degertekin B, Dagalp K. Levels of serologic markers of celiac disease in patients with reflux esophagitis. *World J Gastroenterol* 2006; 12(41): 6707-6710

## INTRODUCTION

Celiac disease (CD) is a chronic inflammatory disorder characterized by damage of the mucosa of the small intestine[1,2]. CD is induced in sensitive individuals by the ingestion of gluten and may range from overt malabsorption to few or no symptoms when only malabsorption of selective nutrients present[3,4]. Clinical manifestations of CD vary markedly with the age of the patient, the duration and extent of disease[1,5]. Clinical and histological improvement occurs with withdrawal of gluten from the diet[6]. The diagnostic criteria of CD are based on the finding of small intestinal mucosal villous atrophy with crypt hyperplasia. Small intestinal histology is the current gold-standard diagnostic test for celiac disease[7].

Subtle and atypical symptoms often make the diagnosis difficult, and, therefore serological screening tests have proved essential in the diagnostic approach[8]. Serological studies currently in clinical use include IgA endomysial antibody (IgA-EMA), IgA tissue transglutaminase antibody (IgA-tTG) and antigliadin antibodies IgA and IgG (AGA). Serology has a limited value in diagnostic procedures and a negative result does not rule out the diagnosis of CD[9].

CD patients have been demonstrated to be associated with a number of motor abnormalities of upper gastrointestinal tract[10-14]. The patients with untreated CD show a significant decrease in low esophageal sphincter (LOS) pressure[13]. However, whether adult celiac patients are more susceptible to reflux esophagitis is still unknown. A few reports support that patients with CD are more susceptible to reflux esophagitis, whereas others do not support this connection[16,17].

So far, no data are available on the relationship between reflux esophagitis and CD. Therefore, we aimed in this study to investigate the prevalence of celiac disease serologic markers (antigliadin IgA, IgG, and antiendomisyum IgA) in patients with reflux esophagitis and to detect the relationship between these two gastrointestinal pathologies.

## MATERIALS AND METHODS

This study was performed prospectively in Gastroenterology Department of Gulhane Military Medical Academy between January 2003 and January 2004. Sixty-eight adult reflux esophagitis patients (20 women and 48 men, median age 41 years, range 20-77) were enrolled in this study (Table 1). The diagnostic work-up included an accurate medical history with gastrointestinal symptoms (heart burn, abdominal pain, regurgitation, dysphagia, odynophagia, pulmonary symptoms, diarrhea, meteorism), routine laboratory measurements, the detection of antibodies against gliadin (IgA and IgG) and endomysium, and an upper endoscopy with postbulbar biopsy (Table 2). Upper gastrointestinal endoscopy was performed in the standard way, after a 6-h fast. The severity of esophagitis was assessed according to the Los Angeles Criteria[18].

Forty people (12 women and 28 men, median age 38 years, range 20-68) formed the control group for symptoms related with gastrointestinal system. The control groups comprised patients suffering from dyspepsia and no evidence of gastro-oesophageal reflux disease. The other exclusion criteria were age < 20 or > 80 years and use of any drugs. CD was eliminated by small-intestinal biopsy in all controls. There was no statistical difference of the gender between the two groups.

Small intestinal biopsy specimens were taken from each patient, and the diagnosis of celiac disease was made based on the findings of total or subtotal small intestinal mucosal villous atrophy, crypt hyperplasia, and lymphoplasmacellular infiltration[7]. Enzyme-linked immunosorbent assay (ELISA) technique was used for the detection of serum level of antigliadin IgA and IgG. Serum IgA endomysial antibodies were fixed by indirect immunofluorescence.

The aim of this study was explained to all patients and control subjects and informed consent form was obtained from all. The study was applied according to the principles of the Declaration of Helsinki and was approved by the Ethical Committee of Gulhane Military Medical Academy.

### *Statistical analysis*

All of the statistical analyses were performed using statistical software package SPSS 11.5 (SPSS Inc., Chicago, IL, USA). The results were shown as the median (min-max). Odds ratios and their 95% confidence intervals were calculated, also. Relationships between the controls and patients were investigated with Chi-square test. *P* values less than or equal to 0.05 were considered as statistically significant.

**Table 1 Demographic data of patients and controls**

| Demographic data | Patients | Controls |
|---|---|---|
| Gender (M/F) | 20/48 | 12/28 |
| Median age (min-max) | 41 (20-77) | 38 (20-68) |
| Esophagitis | | |
| Grade A | 80.90% | - |
| Grade B | 14.70% | - |
| Grade C | 4.40% | - |
| Grade D | - | - |

**Table 2 Esophageal symptoms in patients with reflux disease (*n* = 68)**

| Symptoms | *n* (%) |
|---|---|
| Heartburn | 48 (70.6) |
| Chest pain | 40 (58.8) |
| Regurgitation | 48 (70.6) |
| Bleeding | 5 (7.4) |
| Dysphagia | 3 (4.4) |
| Odynophagia | 2 (3.0) |
| Pulmonary symptoms | 10 (14.7) |
| Others (diarrhea…) | 11 (16.2) |

**Table 3 Prevalence of positive serologic markers for coeliac disease according to the esophagitis grade (*n* = 68)**

| Grades | Antigliadin IgA | | Antigliadin IgG | | Antiendomysium IgA | |
|---|---|---|---|---|---|---|
| | *n* | % | *n* | % | *n* | % |
| Grade A (*n* = 55) | 4 | 7.2 | 3 | 5.4 | - | - |
| Grade B (*n* = 10) | 1 | 10 | 2 | 20 | - | - |
| Grade C (*n* = 3) | 1 | 33.3 | 2 | 66.6 | - | - |

**Table 4 Prevalence of positive serologic markers for coeliac disease in control subjects (*n* = 40)**

| Serologic markers | Control subjects (*n* = 40) | |
|---|---|---|
| | *n* | % |
| Antigliadin IgA | 4 | 10 |
| Antigliadin IgG | 3 | 7.5 |
| Antiendomysium IgA | - | - |

## RESULTS

Antigliadin IgA (IgA-AGA) was found positive in 6/68 (8.8%) patients with reflux esophagitis. Four of 6 patients were grade A (4/55, 7.2%), one was grade B (1/10, 10%) and one was grade C (1/3, 33.3%). Seven (7/68, 10.3%) patients had positive antigliadin IgG (IgG-AGA); 3/55 (5.4%) were grade A, 2/10 (20%) grade B, and 2/3 (66.6%) grade C (Table 3). No patient had positive antiendomysium IgA (IgA-EMA) and in addition, there were no patients with both positive IgA-AGA and positive IgG-AGA.

On endoscopy in control cases, the macroscopic appearance of the esophageal mucosa was normal. In control group, it was found that 4 (10%) people had positive IgA-AGA, and 3 (7.5%) people had positive IgG-AGA (Table 4), while none in control group had positive IgA-EMA.

On postbulbar biopsies, no finding was detected

concerning celiac disease. In 3 of 6 patients with positive IgA-AGA, histologically slightly chronic non-specific duodenitis was seen and the others had normal duodenal mucosa. The number of moderate chronic nonspecific duodenitis, slightly chronic nonspecific duodenitis, and normal duodenal mucosa were 2, 2, and 3, respectively, in 7 patients with positive IgG-AGA. All other patients had normal duodenal mucosa on histology.

There was no statistically significant relationship between controls and patients for IgA-AGA ($\chi^2 = 0.041$; $P = 0.839$; OR = 0.871, 0.230-3.294). The similar result was obtained for IgG-AGA ($\chi^2 = 0.234$; $P = 0.629$; OR = 1.415, 0.345-5.813).

## DISCUSSION

Gastroesophageal reflux disease (GERD) is a motor disorder involving lower esophageal sphincter (LES) and esophageal peristalsis. The mean basal pressure of the LES and peristaltic waves are significantly lower in patients with GERD. These abnormalities are responsible for an ineffective removal of refluxed contents, longer contact of acid with the esophageal mucosa, and possibly esophagitis[19].

The increased frequency of reflux esophagitis in CD was reported in some studies[13,15]. In our study, CD was not seen in patients suffering from reflux esophagitis and in control group suffering from unspecific upper gastrointestinal symptoms. Epidemiological studies using serological tests with biopsy verification have revealed higher prevalence of 1:300 to 1:500 for CD in most countries[20]. In primary care practice it is not recommended that cases with reflux esophagitis must be searched for CD. Moreover, the diagnosis depending GERD is difficult and invasive procedures are needed, including endoscopy, biopsy and pathology. Investigations available include flexible oesophagoscopy (with biopsy), ambulatory or static pH manometry, and radiological assessment. A perfect method for diagnosing reflux disease does not yet exist. For this reason, finding a specific marker for reflux esophagitis is necessary.

The results of our study are apparently in contrast with those of Iovino *et al* who suggested that celiac patients with steatorrhea present a higher prevalence of esophageal symptoms and a lowered esophageal sphincter pressure compared with celiac patients without steatorrhea and control subjects[13]. Cuomo *et al* found a twofold increase in the prevalence of endoscopic esophagitis in adult patients who had been diagnosed with CD compared with control non-celiac subjects[15]. All patients in our study were investigated in primary-care setting and all of them were reflux esophagitis patients. None of our patients had severe esophagitis. The most important finding was that none of the patients had CD. The apparent discrepancy with our study might be due to the fact that subjects enrolled in those studies had CD.

Recently, Collin *et al* evaluated the occurrence of esophagitis in CD. In this study, 0.9% of patients with esophagitis and 0.6% of those with esophageal reflux symptoms had CD[17]. They interpreted that the association between these two conditions was weak. This supports our findings and makes weak the claims that CD may play a role in the pathogenesis of GERD.

The abnormalities in LES and esophageal peristalsis associated with GERD are the important factors in the presence of reflux esophagitis. Some gastrointestinal hormones appear contributing to these dysfunctions. One of these, plasma enteroglucagon, which decreases LES pressure and delays gastric emptying was significantly higher in CD patients than controls[21,22]. Despite of this finding supporting the association between reflux esophagitis and CD, we believe that it needs further clarification.

It is known that reflux esophagitis can be seen in celiac patients, but reflux esophagitis is not accepted as a basic finding in CD. This review suggests that an association does not exist between CD and reflux esophagitis. We think these two diseases exist independently from each other. The negative results are possibly due to the small sample size. Since the correlation between celiac disease and reflux esophagitis may be very weak, much bigger sample size is needed to support the null hypothesis.

## Abstract

**AIM:** To unravel the differences between systematic inflammatory response syndrome (SIRS) of acute pancreatitis compared to the same syndrome in sepsis.

**METHODS:** Twenty-five patients were enrolled, 12 with sepsis and 13 acute pancreatitis. After diagnosis 20 mL blood was sampled. Half were assayed for isolation of monocytes and 10 mL was centrifuged for serum test of tumor necrosis factor alpha (TNFα) and interleukin-6 (IL-6). Half of monocytes were incubated in the presence of patients' serum and supernatants were collected. The other half was treated for estimation of optical photometry under caspase-3 inhibition. TNFα and IL-6 were estimated by an enzyme immunoassay.

**RESULTS:** median ± SE of serum IL-6 in septic patients and acute pancreatitis patients was 192.30 ± 35.40 ng/L and 21.00 ± 16.05 ng/L, respectively ($P < 0.01$). Respective values of caspase-3 were 0.94 ± 0.17 pmol/min $10^4$ cells and 0.34 ± 0.09 pmol/min $10^4$ cells ($P < 0.05$). IL-6 of monocyte supernatants of patients with sepsis was significantly increased after addition of patients' serum, while that of patients with acute pancreatitis did not show significant difference.

**CONCLUSION:** The data have shown that monocyte activity is different between acute pancreatitis and sepsis. This phenomenon might be explained as a different pathway to the pro-inflammatory cytokines release or could be a novel anti-inflammatory response in acute pancreatitis.

## INTRODUCTION

Although the knowledge about the underlying pathogenic mechanisms in acute pancreatitis and sepsis has been considerably enriched, comparative studies are lacking. There is evidence that pro-inflammatory cytokine cascade plays a crucial role in both acute pancreatitis and sepsis[1]. Acute pancreatitis is an inflammation often complicated with systematic inflammatory response syndrome (SIRS). During the evolution to sepsis microbial components trigger serum monocytes, which release pro-inflammatory cytokines; and the latter leads to SIRS[2].

Septic cascade is thought to be initiated from pro-inflammatory cytokines released from blood monocytes[3]. Acute pancreatitis is one major cause of systemic inflammation attributed to the secretion of pro-inflammatory mediators but the contribution of monocytes to the biosynthesis of these mediators is not yet defined at least with data of the current literature. The aim of the present study was to unravel the differences of the *ex vivo* activity of monocytes upon occurrence of SIRS between patients with acute pancreatitis and sepsis.

## MATERIALS AND METHODS

Twenty-five patients were enrolled in a prospective study from January 2003 to June 2003; 13 patients were diagnosed with acute pancreatitis and 12 with sepsis. All were hospitalized in the 4th Department of Internal Medicine of the Medical School of Athens during that period. The study was conducted in accordance to the Helsinki Declaration.

Exclusion criteria for the study were the presence of (1) neutropenia (< 500 neutrophils/μL), (2) HIV infection, (3) corticosteroids administration for more than one month, defined as more than 1 mg/kg daily of equivalent

prednisone, and (4) protein C administration at least five days before admission.

SIRS was defined by the presence of at least two of the followings[4]: (1) pulse rate > 90/min, (2) breath rate > 20/min or $P_{CO2}$ < 32 mmHg, and (3) leukocytosis [white blood cells (WBCs) > 12000/μL] or leucopenia (WBCs < 4000/μL) or more than 10% bands.

Inclusion criteria were the following for acute pancreatitis[5]: (1) SIRS, (2) initiation of a typical epigastric pain radiating to the back over the last 12 h before admission; (3) serum amylase at least three times above normal values, (4) urine amylase at least three times above normal values, (5) findings of acute edematous pancreatitis on ultrasound or on computed tomography, and (6) the absence of any primary liver disease.

Inclusion criteria for sepsis were the following in accordance to ASCP/SCCM 1997 classification[4]: (1) clinically proven infection with fever as its first manifestation over the last 12 h before admission, and (2) SIRS. Primary infections for sepsis were acute pyelonephritis, lower respiratory tract infection (LRTI) and acute cholangitis.

The diagnosis of acute pyelonephritis was made on the basis of the following criteria[6,7]: (1) a case history compatible with acute pyelonephritis comprising at least two spikes of fever above 38℃ and presence of lumbar tenderness on examination, (2) pyuria defined as presence of more than 10 polymorphs per high power field under a light microscope, and (3) positive urinary culture with the colony count exceeding $10^4$ cfu/mL for a single Gram-negative bacterial species. Diagnosis of LRTI was established in any patient presenting with the following signs: (1) core temperature > 38℃, and (2) new or persistent consolidation on lung X-ray[8]. Diagnosis of acute cholangitis was based on the following criteria: (1) core temperature > 38℃, (2) acute pain of upper right quadrant of abdomen elicited on palpation, and (3) ultrasound findings compatible with cholangitis[9].

Upon admission, a total of 20 mL of blood were collected after puncture of one forearm vein. Ten milliliters of blood were collected in a sterile heparinized syringe and the remaining in a sterile tube. Blood was centrifuged and the supernatant was kept at -70℃ until assayed.

For the isolation of blood monocytes[10], the collected heparinized venous blood was layered over Ficoll Hypaque (Biochrom, Berlin, Germany) and centrifuged. Isolated mononuclear cells were washed three times with PBS (pH 7.2) (Merck, Darmsadt, Germany) and incubated with RPMI 1640 enriched with 10% FBS and 2 mmol/L of glutamine in the presence of 100 U/mL of penicillin G and 0.1 g/L of streptomycin (Sigma Co, St. Louis, USA) in flasks of 25 $cm^3$. After one hour of incubation at 37℃ in 5% $CO_2$, non-adherent cells were removed; adherent monocytes were thoroughly washed with Hanks' solution (Biochrom). Monocytes were then harvested with the application of a 0.25% trypsin/0.02% EDTA solution (Biochrom) and counted in a Neubauer plate. Their purity was more than 95% as determined after staining with the anti-CD14 monoclonal antibody at the fluorocolor FITC (emission 520 nm, Immunotech, Marseille, France) and reading through the EPICS XL/MSL flow cytometer (Beckman Coulter Co, Miami, Florida).

Half of the isolated monocytes were treated with an ice-cold cell lysis buffer (50 mmol/L HEPES, 0.1% CHAPS, 5 mmol/L DTT, 0.1 mmol/L EDTA, pH 7.4). After centrifugation for 10 min at 10000 × *g*, and 4℃, activity of caspase-3 was estimated in the cytosolic extract by an enzymatic chromogenic assay (BIOMOL Research Laboratories, Plymouth, PA). It was based on the rate of hydrolysis at 37℃ of a substrate releasing p-nitroaniline over-time, as assessed by sequential photometry at 405 nm. The assay was also performed in the presence of a caspase-3 inhibitor. The activity of caspase-3 in cell lysates was expressed as pmol/min $10^4$ cells.

The remaining half of monocytes were distributed in two wells of a 12-well plate; they were incubated with RPMI 1640 supplemented with 10% FBS and 2 mmol/L of glutamine for 18 h at 37℃ in 5% $CO_2$ in the absence/presence of 0.1 mL of serum of the patient. The total volume of the added growth medium was 2.4 mL where patients' sera represented 4.1%. After incubation, cell supernatants were collected and kept refrigerated at -70℃ until assayed.

Concentrations of TNFα and IL-6 in sera and monocyte supernatants were estimated by an enzyme immunoabsorbent assay (Diaclone, Paris, France). Lowest limits of detection were 0.5 pg/mL for TNFα and 6.25 ng/L for IL-6. Their concentrations in supernatants were expressed as pg/$10^4$ monocytes. TNFα and IL-6 and activity of caspase-3 were selected as parameters since the former two represented the considerable burden of pro-inflammatory cytokines secreted from monocytes in an early course of events leading to inflammation and the latter an index of apoptosis.

### Statistical analysis

Concentrations of TNFα, IL-6 in sera and monocyte supernatants and caspase-3 intracellular activity were expressed as their median ± 95% confidence intervals of the mean (CI) or standard error of the mean (SE). Comparison between groups was made by Mann-Whitney *U* test. Correlations between concentrations of TNFα and IL-6 in serum, intracellular activity of caspase-3 and concentrations of TNFα and IL-6 of monocyte supernatants were performed according to Spearman's rank of order. According to the estimated intracellular monocytic activity of caspase-3, patients were divided into those with activity lower and higher than 100 pmol/min $10^4$ cells. Comparisons between sepsis and acute pancreatitis were performed by Pearson's chi-square test. Any *P* value less than 0.05 was considered as significant.

## RESULTS

mean ± SD age of enrolled patients with acute pancreatitis was 59.6 ± 18.5 years and of patients with sepsis 61.5 ± 17.6 years. Predisposing factors of pancreatitis were gallstones in eleven patients and hypertriglyceridemia in two patients. Primary infection for sepsis was acute pyelonephritis in six patients, LRTI in four patients and

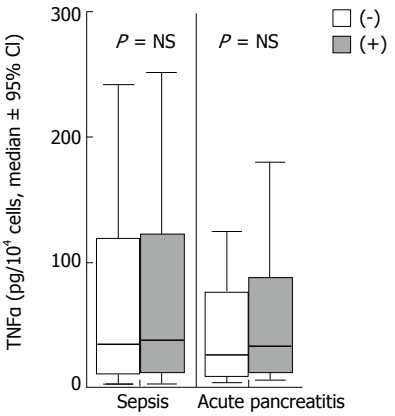

**Figure 1 Comparisons of the concentrations of tumor necrosis factor-alpha (TNFα) in the supernatants of monocytes isolated from patients with sepsis and acute pancreatitis.** (-): incubation in the absence of patients' serum; (+): incubation in the presence of patients' serum.

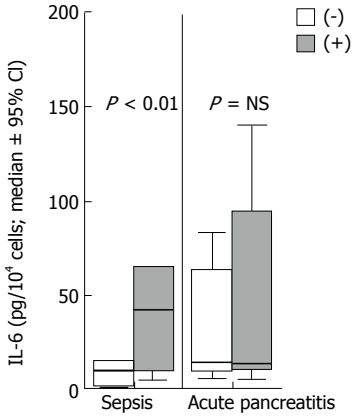

**Figure 2 Comparisons of the concentrations of inteleukin-6 (IL-6) in the supernatants of monocytes isolated from patients with sepsis and acute pancreatitis.** Circles denote outliers. (-): incubation in the absence of patients' serum, (+): incubation in the presence of patients' serum.

acute cholangitis in two patients.

mean ± SD APACHE Ⅱ scores in patients with acute pancreatitis and sepsis were 7.68 ± 1.22 and 8.23 ± 1.48 respectively ($P$ = NS). mean ± SD of Ranson Index score in patients with pancreatitis on admission and during the first 48 h after admission was 1.34 ± 0.32 and 1.69 ± 0.82 respectively.

median ± SE TNFα in serum was 11.61 ± 7.57 pg/mL and 17.01 ± 8.64 pg/mL, in patients with sepsis and acute pancreatitis, respectively ($P$ = NS). Respective values for IL-6 were 192.30 ± 35.40 pg/mL and 21.00 ± 16.05 pg/mL ($P < 0.01$) and for intracellular activity of caspase 3, 0.94 ± 0.17 pmol/min $10^4$ cells and 0.34 ± 0.09 pmol/min $10^4$ cells, respectively. Occurrence of high-level caspase-3 monocytic intracellular activity was greater in patients with sepsis than in patients with acute pancreatitis ($P < 0.05$).

Concentrations of TNFα of monocyte supernatants of patients with sepsis and acute pancreatitis incubated in the absence or presence of patients' sera are shown in Figure 1. No differences were found between yielded concentrations in the absence and presence of sera from either patients with sepsis or pancreatitis.

Concentrations of IL-6 of monocyte supernatants of patients with sepsis and acute pancreatitis incubated in the absence or presence of patients'sera are shown in Figure 2. The ratios of concentration of IL-6 in the presence of patients' sera to concentration in the absence of patients' sera were estimated. The ratio was significantly higher in sepsis than in acute pancreatitis ($P < 0.01$).

No correlation was found between intracellular activity of caspase-3 and TNFα and IL-6 of serum from either patients with acute pancreatitis or sepsis. Neither was correlation found between the intracellular activity of caspase-3 and either TNFα or IL-6 concentrations of monocyte supernatants in patients with either acute pancreatitis or sepsis.

## DISCUSSION

Acute pancreatitis and sepsis represent two significant causes of mortality; subsequent multiple organ failure is thought to be the most severe complication of both[2]. SIRS is considered to result from pro-inflammatory cytokines released by the inflamed tissues or cells of the innate immune system. Recent data evidence for probable alterations of the function of cells of the innate immunity in both acute pancreatitis and sepsis. These changes are expressed as decreased expression of HLA-DR on cell membranes of monocytes[11,12]. Based on the latter evidence, the present study was focused on the comparative *ex vivo* activity of monocytes between patients with sepsis and acute pancreatitis.

It has been observed that most of the patients with acute pancreatitis develop organ dysfunction 48-72 h after initiation of their first clinical symptoms[13]. To our knowledge, the present study is the first attempting to investigate the probable role of monocytes in acute pancreatitis compared to their respective role in sepsis at an early time course; blood was sampled within 12 h after the first clinical symptom in both study groups[14].

Our results revealed that serum concentrations of IL-6 in patients with sepsis were significantly increased compared with that in patients with acute pancreatitis; similar finding was not observed for TNFα. The lack of similarities between TNFα and IL-6 might be attributed to the earlier release of TNFα in the pro-inflammatory cascade than that of IL-6[15].

TNFα of monocyte supernatants did not differ between sepsis and acute pancreatitis; it remained unaffected by the addition of patients' serum (Figure 1). The lack of difference of TNFα release by monocytes between sepsis and pancreatitis might also be explained by its early production in the inflammatory cascade.

On the other hand, IL-6 secretion by monocytes was significantly increased in the presence of serum of patients with sepsis compared to that of patients with acute pancreatitis (Figure 2). Presence of serum in monocyte supernatants represented only 4% of the total culture volume; that percentage might be considered minimal to produce any confounding. A limitation of the study is the lack of evidence to explain the effect of serum and only hypotheses may be made. It might be presumed that

an anti-inflammatory mediator was present in serum in patients with acute pancreatitis inhibiting further release of IL-6 from monocytes. That response might be implicated in sepsis also, but probably was inadequate to inhibit secretion of IL-6. However, it is of great significance that monocytes preserve secretion activity in acute pancreatitis; a finding seen for the first time.

Caspase-3 is involved in the intracellular apoptotic process[16]. Its intracellular activity was significantly increased in patients with sepsis compared to those with acute pancreatitis. Increased apoptosis of monocytes in sepsis may constitute an attempt of the host to reduce inflammatory responses. In patients with acute pancreatitis, apoptosis of monocytes was minimal. However, it might designate a late activation of monocytes in the evolution of acute pancreatitis compared to sepsis, as described by others[17].

The presented data reveal a different *ex vivo* activity of monocytes between sepsis and acute pancreatitis. This phenomenon might be explained by the existence of either of different pathways for the release of pro-inflammatory cytokines or of a novel anti-inflammatory activity of serum of patients with acute pancreatitis.

## Abstract

**AIM:** To observe the efficiency and safety of thymosin-α1 treatment in patients with hepatitis B e antigen (HBeAg) and HBV DNA positive chronic hepatitis.

**METHODS:** Sixty-two patients were randomly divided into groups A and B. The patients in group A received subcutaneous injection of 1.6 mg thymosin-α1, twice a week (T-α1 group) for six months, and the patients in group B received 5 MU interferon alpha (IFN-α) each day for fifteen days, then three times weekly (IFN-α group) for six months. The results between two groups treated with and the group untreated with IFN-α which was followed up for 12 mo (historical control group consisting of 30 patients) were compared, and three groups were comparable between each other ($P > 0.05$) at baseline (age, sex, clinical history, biochemical, and serological parameters).

**RESULTS:** At the end of treatment, complete response, which was defined as alanine aminotransferase (ALT) normalization and HBV DNA and HBeAg loss, occurred in 9 of 29 (31.0%) patients in the T-α1 group and in 15 of 33 (45.5%) patients in the IFN-α group ($\chi^2 = 1.36$, $P > 0.05$). After a follow-up period of six months, a complete response was observed in 14 of 29 (48.3%) patients in the T-α1 group and in 9 of 33 (27.3%) patients in the IFN-α group ($\chi^2 = 2.93$, $P > 0.05$). Compared with the results observed in the historical control (HC) group untreated with IFN-α which was followed up for 12 mo, the rate of complete response was significantly higher in IFN-α group at the end of therapy (1 of 30 *vs* 15 of 33, $\chi^2 = 14.72$, $P < 0.001$) and in the T-α1 group at the end of follow-up (1 of 30 *vs* 14 of 29, $\chi^2 = 15.71$, $P < 0.001$). In T-α1 and IFN-α treatment groups, the area under (the plasma concentration time) curve (AUC) of negative HBV DNA and HBeAg was 34%, 17%, 31% and 19% smaller than that in the HC group. By the end of the follow-up period, the proportions of ALT normalization and negative HBV DNA in the T-α1 group were significantly higher than those in the IFN-α and HC groups. The odds of ALT normalization and negative HBV DNA at the end of the follow-up was three-fold higher in the T-α1 group than in the IFN-α group. Unlike IFN-α, T-α1 was well tolerated by all patients, and no side effects appeared in T-α1 group.

**CONCLUSION:** The results suggest that a 6-mo course of T-α1 therapy is effective and safe in patients with chronic hepatitis B. T-α1 is able to reduce HBV replication in patients with chronic hepatitis B. Furthermore, T-α1 is better tolerated than IFN-α and can gradually induce more sustained ALT normalization and HBV DNA and HBeAg loss. However, a response rate of 48.3% is still less ideal. A more effective therapeutic approach warrants further study.

## INTRODUCTION

Chronic hepatitis B virus (HBV) infection is a serious problem worldwide and may result in adverse sequelae, such as cirrhosis and hepatocellular carcinoma (HCC)[1-2], which is becoming more prevalent worldwide, especially in HBV-endemic areas[3-4]. According to the World Health Organization estimation, more than 350 million people are infected with HBV worldwide, of them up to 20% will become chronic HBV carriers, and 50% would develop chronic liver disease with a significant risk of developing liver cirrhosis and HCC[4]. Despite the introduction of universal vaccination against hepatitis B in over 100 countries, persistent HBV infection is still a serious problem worldwide, causing one million deaths each year[4-6]. It may take several decades to reduce its transmission and morbidity by vaccination. Meanwhile, patients with persistent HBV infection require better antiviral therapeutic modalities than the currently available ones[4]. The ultimate goal of therapy for chronic hepatitis B is to prevent its progression to cirrhosis and development of HCC. Recent prospective studies from Taiwan indicate that higher plasma HBV DNA levels in persons infected with HBV are associated with increased risk of developing HCC, reinforcing the importance of controlling viral replication among patients with chronic hepatitis B[7-10].

Over the past 20 years, many antiviral or immunomodulatory agents have been used in the treatment of chronic HBV infection[11-20]. Among them, interferon alpha (IFN-α), has been shown to be effective against chronic HBV infection, and induces an apparent initial response in approximately 30%-40% of treated patients[21-23]. However, the response rate is far from satisfactory, particularly in Asian patients. The relapse rate after treatment withdrawal is high[24].

Lamivudine suppresses viral replication, resulting in HBeAg seroconversion in 16%-17% of patients and histologic improvement in 52%-56% patients after one year of therapy[25,26]. However, within four years, the rate of emergence of lamivudine-resistant HBV mutants approaches 70%[27-30], which is usually associated with a rebound in viral load and exacerbation of hepatitis[31-34]. Pegylated-interferon alfa-2a (IFNα- 2a) appears to have a better efficacy than lamivudine HBeAg seroconversion rate was 32%, 27% and 19%, respectively in pegylated-IFNα-2a monotherapy, plus Lamivudine and lamivudine monotherapy; alanine aminotransferase (ALT) normalization was 41%, 39% and 28%, respectively in HBeAg-positive patients 6 mo after 48-wk treatment. However, the rate of adverse events associated with pegylated IFNα-2a is higher than that of lamivudine[35]. Patients with HBeAg-negative chronic hepatitis B treated with pegylated IFNα-2a have a significantly higher rate of response which could sustain for 24 wk after the therapy (monotherapy or in combination with lamivudine) than those treated with lamivudine monotherapy. After 24 wk of follow-up, the percentages of patients with ALT normalization or HBV DNA level below 20 000 copies/mm$^3$ are 59%, 43%, 60% and 44% *vs* 44% ($P$ = 0.004 and $P$ = 0.003) and 29% ($P$ = 0.007 and $P$ = 0.003)[36].

Thymosin-α1 (T-α1) is an immune modifier that can trigger maturational events in lymphocytes, augment T-cell function, and promote reconstitution of immune defects[37]. T-α1 has been shown to promote disease remission and cessation of HBV replication in patients with HBeAg-positive chronic hepatitis B without significant side effects[38,39]. Clinical trials using T-α1 in the treatment of patients with immunodeficiency or cancer indicate that this agent is nontoxic, enhances immune responsiveness and augments specific lymphocyte functions, including lymphoproliferative responses to mitogens, maturation of T-cells, antibody production, and T-cell-mediated cytotoxicity[40-42]. On the basis of these observations, we conducted a randomized, controlled trial to compare the efficacy and safety of T-α1 *vs* INF-α therapy in patients with chronic hepatitis B.

## MATERIALS AND METHODS

### Patients

Sixty-two Chinese patients were enrolled in the study. All met the following criteria for entry: age 18-60 years, presence of hepatitis B surface antigen (HBsAg) and hepatitis B e antigen (HBeAg) in serum for at least 12 mo, positive serum tests for HBV DNA documented on at least two occasions and at least 3 mo apart 12-mo before entry, aminotransferase levels higher than 1.5 times the upper normal limit for at least 12 mo, and liver biopsy taken within 3 mo before enrollment showing chronic hepatitis. Eligible patients with evidence of cirrhosis were also included. Patients treated with immunosuppressive or antiviral therapy within 1 year before entry, and those with concurrent hepatitis C virus, hepatitis delta virus, and human immunodeficiency virus infections, causes of liver disease other than HBV, intravenous drug abuse, pregnancy, malignancy, chronic renal failure, or other serious medical illness that might interfere with this trial were excluded.

Another 30 patients with the same virological and clinical characteristics, never treated with IFN-α and followed up for at least 12 mo were used as a historical control (HC) group to evaluate the efficacy of the therapies.

### Methods

The 62 patients were randomly divided into two groups to receive either subcutaneous injection of T-α1 twice a week for 6 mo or of 5 MU IFN-α once a day for 15 d, then 3 times weekly for 6 mo. The patients in HC group were followed up without specific treatment. All patients were assigned to receive general liver-protecting medication in the first month.

Efficacy and safety analysis was performed for all randomized patients who received both thymosin-α1 and interferon-α medication dose in the study. Two predetermined primary measures of efficacy assessed after 24 wk of treatment-free follow-up were HBeAg seroconversion (defined by the loss of HBeAg and the presence of anti-HBe antibody) and suppression of HBV DNA to levels below 1000 copies per milliliter. Secondary efficacy mea-

**Table 1 Characteristics of the patients at entry to the study[1]**

| Characteristics | HBeAg-positive CHB | | |
|---|---|---|---|
| | T-α1 group | IFN-α group | HC group |
| Number | 29 | 33 | 30 |
| Male: Female | 26:3 | 27:6 | 21:9 |
| Age (yr)[2] | 45 ± 8 | 42 ± 11 | 44 ± 10 |
| Duration of infection (yr)[2] | 10.8 ± 5.6 | 9.3 ± 4.7 | 9.6 ± 5.5 |
| Cirrhosis at entry | 2 | 3 | 2 |
| Previous 1FN therapy | 2 | 0 | 0 |
| Serum ALT (U/L)[2] | 177.79 ± 58.82 | 189.94 ± 63.08 | 183.5 ± 68.32 |
| Serum AST (U/L) | 167.72 ± 34.19 | 154.27 ± 73.34 | 141.8 ± 49.85 |
| Albumin (g/L)[2] | 44 ± 9 | 47 ± 8 | 45 ± 8 |
| Total bilirubin (μmol/L) | 18.57 ± 9.65 | 17.92 ± 9.22 | 16.68 ± 8.72 |
| Serum HBV DNA (copies/mL)[3] | | | |
| $< 5.0 \times 10^5$ copies/mL | 10 (34%) | 15 (45%) | 13 (43%) |
| $\geqslant 5.0 \times 10^5$ copies/mL | 19 (66%) | 18 (55%) | 17 (57%) |

[1]No significant differences were observed among groups. [2]Data are expressed as mean ± SD. [3]Data are expressed as *n* (%). Normal values: ALT < 40 IU/L; AST < 40 IU/L; albumin = 35-55 g/L; total bilirubin < 17 μmol/L. ALT: Alanine aminotransferase; AST: aspartate aminotransferase; HBV: hepatitis B virus; T-α1: thymosin - α1; IFN-α: interferon -α; HC: historical control.

sures assessed after 24 wk of treatment-free follow-up included the combined response (HBeAg seroconversion, normalization of ALT levels, and suppression of HBV DNA levels to below 1000 copies per milliliter). Measures of safety included adverse events, vital signs, hematologic measurements, clinical and chemical measurements, and routine urinalysis. The severity of adverse events was graded on a three-point scale (mild, moderate, and severe), and causality was determined by the investigator. These safety parameters were assessed at wk 0, 1, 2, 4, 6, 8, and every four weeks thereafter throughout the treatment and during the follow-up.

All patients were assessed biweekly for the first 2 mo, and then monthly for 12 mo. Clinical and laboratory assessments consisted of a detailed history, including post injection symptoms and physical examination, routine serum biochemical tests [serum ALT, aspartate transaminase (AST), r-glutamine transpeptidase (r-GT), alkaline phosphatase (AKP), albumin, globulin, bilirubin, *etc*], complete cell count, markers of HBV replication and urine analysis. All biochemical and hematological tests were performed with routine automated techniques. HBV-markers (HBsAg, HBsAb, HBeAg, HBeAb, HBcAb, and Igm HBcAb) were measured at virological laboratory by using enzyme linked immunosorbent assay (ELISA). Serum HBV DNA was detected by polymerase chain reaction (PCR).

Responses were evaluated both at the end of therapy and at the end of follow-up. A complete virological response was defined as a sustained loss of serum HBeAg in association with the disappearance of serum HBV DNA during the 12-mo study period. A biochemical response was defined as sustained normalization of serum ALT. At the end of treatment and follow-up, a complete response was defined as HBV DNA and HBeAg clearance from the serum and normalization of ALT activity. Relapse was assessed on the basis of ALT flare and/or HBV DNA/HBeAg reappearance during the follow-up period.

**Table 2 Response to treatment at the end of therapy *n* (%)**

| | T-α1 (*n* = 29) | IFN-α (*n* = 33) | HC (after 6 mo of follow-up) (*n* = 30) |
|---|---|---|---|
| ALT normalization | 11 (37.9) | 16 (48.5)[b] | 5 (16.7) |
| Negative HBV DNA | 16 (55.2)[c] | 22 (66.7)[c] | 2 (6.7) |

[a]$P < 0.05$ *vs* HC; [c]$P < 0.05$ *vs* IFN; [b]$P<0.01$ *vs* HC; [d]$P < 0.01$ *vs* IFN; [f]$P < 0.001$ *vs* HC.

### *Statistical analysis*

Initial calculation was performed with a sample size of 20 patients per treatment group, which provided a statistical power of 80% at the 0.025 level of significance to detect the difference in negative HBV DNA (suppression below 1000 copies per milliliter) rates of 45% *vs* 6.7% or HBeAg seroconversion rates of 40% *vs* 3.3%. The sample size increased in 25 patients to allow for withdrawals.

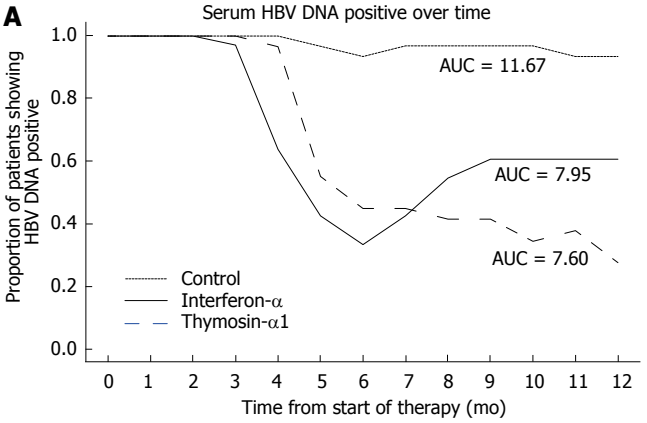
Differences in the final virological and biochemical response rates of two treatment groups and the non-treatment group were compared using the chi square test or Fisher's exact test when the expected number in the cells was below 5. Odds ratio and corresponding 95% confidence intervals were also computed. $P \leqslant 0.05$ was considered statistically significant.

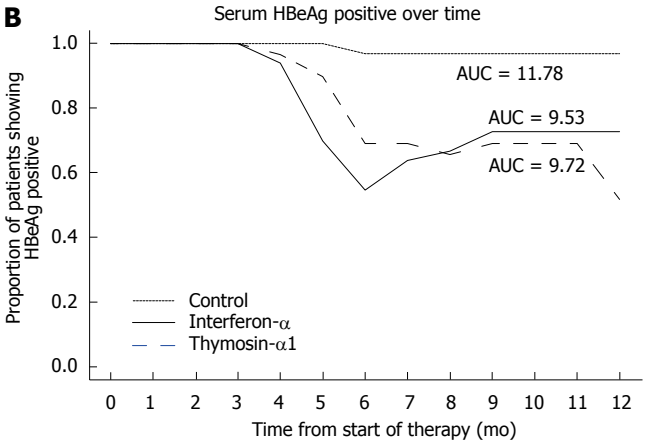
## RESULTS

Of the 92 patients enrolled in the study, 30 were never treated with IFN-α for HBV infection, 2 were non-responders to earlier IFN-α therapy who received T-α1 in the study, 29 patients were randomized to receive T-α1 and 33 to receive IFN-α. All patients completed the 6-mo follow-up period. No significant difference in age, sex, clinical history, biochemical, histological and serological parameters was found among the 3 groups (Table 1).

The biochemical and virological modifications at the end of treatment and follow-up period in the two treated groups and the biochemical and virological events in the HC group are listed in Tables 2 and 3 and Figure 1.

At the end of treatment, IFN treatment group had the highest ALT normalization followed by the T-α1 and HC groups, with no statistical significance. The IFN treatment group also had the highest rate of negative HBV DNA and other combined favorable results, differing from those





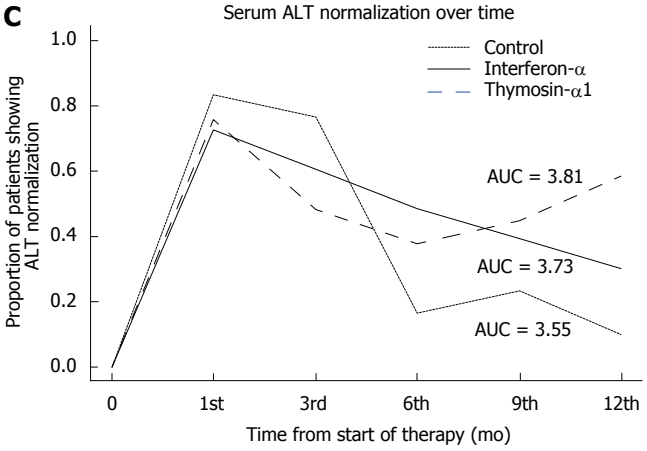


**Figure 1** Rates of virologic response (**A**, **B**) and biochemical response (**C**) during the 12-mo study period. A virologic response was defined as a serum HBV DNA loss (HBV DNA level of less than 1000 copies per milliliter) and a serum HBeAg loss. A biochemical response was defined as the normalization of alanine aminotransferase levels.

of the HC group but not from those of the T-α1 group. During the follow-up period, the results were however more favorable in the T-α1 group. This group had seven additional patients showing HBV DNA loss (at mo 2-4 in 4 patients and at mo 6 in 3 patients, respectively), whereas HBV DNA reappeared in two patients (at mo 3 and 5, respectively). In the group receiving IFN-α, HBV DNA reappeared in 9 patients (in 3 patients at mo 1, 4 at mo 2 and 2 at mo 3), while no one lost HBV DNA. In the HC group, HBV DNA became negative in 3 of 30 patients (at mo 5, 6, and 11, respectively), whereas HBV DNA reappeared in one patient (at mo 7).

**Table 4 Response to treatment between thymosin-α1 & IFN-α groups**

| | At the end of therapy OR (95% CI) | At the end of follow-up OR (95% CI) |
|---|---|---|
| ALT normalization | 0.65 (0.21, 2.01) | 3.19 (1.02, 10.61)[a] |
| HBVDNA-negation | 0.62 (0.19, 1.94) | 3.94 (1.23, 13.69)[b] |
| HBeAg-negation | 0.55 (0.17, 1.72) | 2.45 (0.77, 8.23) |
| ALT normal/ HBeAg & HBVDNA-negation | 0.55 (0.17, 1.72) | 2.45 (0.77, 8.23) |

[a]$P < 0.05$, [b]$P < 0.01$ *vs* IFN-α.

HBV DNA loss was significantly higher in the T-α1 and IFN-α groups than in the HC group at the end of therapy ($\chi^2 = 16.36$, $P < 0.001$ and $\chi^2 = 23.99$, $P < 0.001$, respectively) and follow-up period ($\chi^2 = 26.81$, $P < 0.001$ and $\chi^2 = 9.28$, $P < 0.01$, respectively). The rates of seroconversion of HBeAg antibody in the T-α1, IFN-α and HC groups were 31.0% (9/29), 45.5% (15/33) and 3.3% (1/30), respectively at the end of treatment, and 48.3% (14/29), 27.3% (9/33) and 3.3% (1/30), respectively at the end of follow-up. Serum ALT levels returned to the normal range in 11 of 29 patients given T-α1, in 16 of 33 patients in IFN-α group at the end of treatment and in 5 of 30 of the HC group after 6 mo of follow-up. During the follow-up period, 7 additional patients receiving T-α1 had normal ALT and one patient showed ALT flare, whereas 6 patients of the IFN-α group showed ALT flare, and no one had normal ALT. In the HC group, two patients had normal ALT during months 6 and 12 of follow-up and ALT flare was seen in 4 patients who had normal ALT during the first 6 mo of follow-up. At the end of the study period a complete response (ALT normalization and HBV DNA/HBeAg loss) was observed in 14 of 29 (48.3%) patients treated with T-α1, in 9 of 33 (27.3%) receiving IFN-α, and in 1 of 30 (3.3%) in HC group (T-α1 *vs* IFN-α and HC, $\chi^2 = 2.93$, $P > 0.05$ and $\chi^2 = 15.71$, $P < 0.001$).

As shown in the graphs (Figure 1), the AUC of HBV DNA and negative HBeAg was 31% and 19% smaller in IFN-α-treated subjects than in HC subjects. The AUC of ALT normalization was 1.5% greater in IFN-α-treated subjects than in HC subjects. The AUC of HBV DNA and negative HBeAg was 34% and 17% smaller in T-α1 treated subjects than in HC subjects, and was 2.2% greater in IFN-α-treated subjects than in HC subjects. The AUC of HBV DNA and negative HBeAg in T-α1 group was 2.9% and 1.6% smaller than in IFN-α-treated subjects.

By the end of the follow-up period, the proportions of ALT normalization and negative HBV DNA in the T-α1 group were significantly higher than those in the IFN-α and HC groups. The odds of ALT normalization and negative HBV DNA at the end of the follow-up was more than three-fold higher in the T-α1 group than in the IFN-α group (Table 4).

Typical side effects of IFN-α treatment, such as flu-

like syndrome, fatigue, irritability, and headache, were seen in most of the patients treated with IFN-α. However, no serious or long-term side effects were noted and no patients discontinued the treatment. Therapy with T-α1 was not associated with significant side effects. Three patients reported local discomfort at injection sites. No systemic or constitutional symptoms were observed after T-α1 administration.

## DISCUSSION

The results of the present randomized, controlled trial have shown that T-α1 therapy at a dose of 1.6 mg *via* subcutaneous injection, twice a week for 6 mo, is effective and safe in patients with chronic hepatitis B. Compared with IFN-α, T-α1 has a slower speed but more sustainable and better end results of virological clearance. Nearly 50% of the treated patients became seronegative for HBeAg and HBV DNA 6 mo after the therapy. This response rate was not only significantly higher than that of the spontaneous seroconversion rate (3.3% in this study), but also obviously higher than the response to IFN-α therapy alone (27.3%) assessed 6 mo after the therapy, suggesting that T-α1 has the same efficacy as IFN-α in inducing clinical and virological remission of chronic hepatitis. The rate of response in terms of ALT normalization and/or HBV DNA and/or HBeAg loss was not significantly different in the T-α1 group compared with the IFN-α group at the end of the treatment ($P > 0.05$). However, there was a significant difference in the rate of response between the two groups at the end of the follow-up period ($P < 0.05$). The normalization of serum ALT and loss of HBV DNA and HBeAg was observed more frequently in the IFN-α group at the end of therapy and in the T-α1 group at the end of the follow-up period. Furthermore, the response to the treatment was observed also in the T-α1 group during the follow-up period, but not in the IFN-α group. On the basis of these results and considering that ALT normalization and negative HBV DNA and HBeAg may spontaneously occur in untreated patients, we retrospectively compared the two treated groups with a untreated group which was followed up for at least 12 mo. The results showed that a significant higher rate of complete response occurred in the IFN-α group at the end of therapy and in the T-α1 group at the end of follow-up period than that in the HC group.

The benefit of T-α1 was not immediately significant at the end of therapy and complete virological response had a tendency to increase or accumulate gradually after the therapy in our study. In contrast, the effect of IFN-α was relatively more quick but less sustainable. The beneficial effect of T-α1 has been reported in a multicenter American trial in which 5 of the 12 responders to T-α1 therapy showed a delayed response[43]. This is in contrast to therapy with IFN-α, in which responses usually occur during the first 4 mo of treatment. These contrasting patterns of response have been demonstrated in a recent Italian study involving HBeAg-negative, HBV DNA-positive, interferon-naive patients with a higher ALT level (181 ± 159 U/L), in which the complete response (ALT normalization and HBV DNA loss) rate increased gradually from 29.4% at the end of therapy to 41.2% 6 mo after the T-α1 therapy, the response to IFN therapy decreased from 43.8% at the end of therapy to 25% 6 mo after the therapy[44]. This delayed effect of T-α1 has also been reported by Chien *et al*[45,46] in patients with chronic hepatitis B recently.

The reasons for the delayed effect of T-α1 are not clear. The delayed response is not likely a result of direct antiviral effects similar to those of interferon. T-α1 may exert an immunoregulatory function that promotes the endogenous antiviral immune response, improves the effectiveness and coordination of the host cellular immune mechanisms in clearing HBV-infected hepatocytes. It was reported that patients treated with T-α1 have a higher peripheral blood helper T cell count (CD4) and IFN- r production by peripheral blood mononuclear cells during and after the T-α1 therapy[39]. In view of the immune mechanisms involved in the pathogenesis of liver injuries in chronic HBV infection, it is possible that T-α1 may activate viral-specific helper T cells, result in the amplification of humoral immune response to viral proteins, induce viral antigen-specific cytotoxic T lymphocytes through secreting endogenous IFN-α, IFN-r, interleukin-2, and tumor necrosis factor, and increase lymphocyte interleukin-2 receptor expression[47-58]. Moreover, T-α1 is able to stimulate natural killer activity by acting synergistically with endogenous IFN-α and IFN-β[41]. Although T-α1 is not known to possess antiviral properties, it was reported that this agent is able to inhibit woodchuck hepatitis virus replication[59,60], suggesting that the delayed effect after T-α1 therapy in the present study is possibly caused by the immunomodulating effect of T-α1 that induces persistently higher helper T-cell function. Because noncytolytic inhibition of HBV RNA, nucleocapsid particles, and replicative DNA intermediates by cytotoxic T lymphocytes has been described in the transgenic mouse model[61,62], it is also possible that viral clearance after T-α1 therapy, particularly preceding ALT flare, is mediated by noncytolytic antiviral effects of cytotoxic T lymphocytes. Further studies are needed to elucidate the possible mechanisms.

In addition to having better HBV clearance, T-α1 is also more tolerable than IFN-α and has no side effects. These together with a small number of weekly injections could favor better patient compliance.

In conclusion, the results of this trial indicate that a 6-mo T-α1 therapy is safe and effective in arresting HBV replication and reducing lobular activity in patients with chronic hepatitis B. Furthermore, T-α1 is better tolerated than IFN-α, and may gradually induce more sustained ALT normalization and HBV DNA/HBeAg loss. A more effective therapeutic approach warrants further study.

## ACKNOWLEDGMENTS

The authors acknowledge the cooperation of the staff of the Department of Hepatopathy of Third Kunming Municipal People's Hospital, the Department of Internal Medicine of Third People's Hospital of Yunnan Province and Yunnan General Hospital of The Chinese People's Armed Police Forces for participating in the research

project. The authors are indebted to the staff of the Epidemiology Unit, Faculty of Medicine, Prince of Songkla University, Thailand, for their critical analysis of the study data, and especially thank Professor Virasakdi Chongsuvivatwong for providing excellent advice and review and technical assistance.

## Abstract

**AIM:** To clarify the incidence and nature of postoperative hyperbilirubinemia in patients after modern extracorporeal circulation, to analyze possible perioperative risk factors, and to elucidate the clinical significance of postoperative hyperbilirubinemia associated mortality and morbidity.

**METHODS:** Between March 2005 and May 2006, three hundred and eighty six consecutive patients undergoing extracorporeal circulation surgery due to a variety of cardiac lesions were investigated prospectively. The incidence of postoperative hyperbilirubinemia was defined as a serum total bilirubin concentration of more than 51 μmol/L. Several perioperative parameters were compared by logistic regression between hyperbilirubinemia and non-hyperbilirubinemia patients to determine possible risk factors contributing to postoperative hyperbilirubinemia and mortality.

**RESULTS:** Overall incidence of postoperative hyperbilirubinemia was 25.3% (98/386). In patients with postoperative hyperbilirubinemia, 56.2% reached peak total bilirubin concentration on the first postoperative day, 33.5% on the second day, and 10.3% on the seventh day. Eighty percent of the increase of total bilirubin resulted from an increase of both conjugated and unconjugated bilirubin. Development of postoperative hyperbilirubinemia was associated with a higher mortality ($P < 0.01$), longer duration of mechanical ventilation ($P < 0.05$) and longer ICU stay time ($P < 0.05$). Preoperative total bilirubin concentration, preoperative right atrium pressure, numbers of valves replaced and of blood transfusion requirement were identified as important predictors for postoperative hyperbilirubinemia.

**CONCLUSION:** Early postoperative hyperbilirubinemia after modern extracorporeal circulation is mainly caused by an increase in both conjugated and unconjugated bilirubin, and is associated with a high mortality. Important contributing factors are the preoperative total bilirubin concentration, preoperative severity of right atrial pressure, numbers of valve replacement procedures, and the amount of blood transfusion requirement during and shortly after surgery. We suggest that postoperative hyperbilirubinemia is a multifactorial process, which is caused by both the impaired liver function of bilirubin transport and the increased production of bilirubin from haemolysis.

**Key words:** Extracorporeal circulation; Open-heart surgery; Hyperbilirubinemia; Liver function

## INTRODUCTION

It has long been recognized that early hyperbilirubinemia or transient jaundice could occur after extracorporeal circulation surgery. According to earlier studies, overall incidence of postoperative hyperbilirubinemia ranges from about 8.6% to even as high as 40%[1-3]. Despite improvements in perioperative management, as well as in surgical and anaesthetic techniques, early hyperbilirubinemia after modern extracorporeal circulation surgery is still seen quite often. The high frequency of hyperbilirubinemia after cardiac surgery in our department prompted us to start a prospective study recently. It is aimed to clarify the incidence and nature of postoperative hyperbilirubinemia in patients following modern extracorporeal circulation, to analyze possible perioperative risk factors, and to elucidate the clinical significance of postoperative hyperbilirubinemia associated mortality and morbidity.

## MATERIALS AND METHODS

### *Patients' backgrounds*

Three hundred and eighty six patients older than 17 years undergoing extracorporeal circulation surgery from March 2005 to May 2006 in our department were consecutively

**Table 1 Comparison of perioperative changes of liver function in two groups (mean ± SD)**

| Variable | HB group | | | | NHB group | | | |
|---|---|---|---|---|---|---|---|---|
| | Preop | d1 | d2 | d7 | Preop | d1 | d2 | d7 |
| TB (mmol/L) | 26.8 ± 2.6[d] | 72.7 ± 9.1[b,d] | 82.8 ± 10.4[b,d] | 63.8 ± 7.5[b,d] | 14.5 ± 1.4 | 33.8 ± 5.5[b] | 20.8 ± 4.5 | 17.1 ± 3.7 |
| UCB (mmol/L) | 9.9 ± 1.9 | 47.6 ± 6.5[b] | 40.9 ± 6.7[b,d] | 32.6 ± 5.6[b,d] | 6.5 ± 1.7 | 18.6 ± 3.9[b] | 11.9 ± 3.2 | 9.7 ± 1.9 |
| CB (mmol/L) | 16.7 ± 1.5[d] | 24.7 ± 5.1[b,d] | 39.6 ± 6.1[b,d] | 31.2 ± 5.4[b,d] | 8.4 ± 1.3 | 15.5 ± 3.1[b] | 9.4 ± 2.1 | 7.6 ± 1.6 |
| ALT (IU/L) | 40.6 ± 3.9[d] | 112.6 ± 11.6[b,d] | 176 ± 15.6[b,d] | 56.6 ± 5.5[d] | 28.5 ± 2.6 | 84.6 ± 11.6[d] | 60.6 ± 5.7 | 50.2 ± 5.1 |
| AST (IU/L) | 40.5 ± 3.6 | 102.6 ± 10.7[d] | 184 ± 17.1[b,d] | 53.2 ± 5.2[d] | 42.6 ± 3.3 | 80.5 ± 10.5[d] | 55.1 ± 5.5 | 48.3 ± 4.9 |

Preop: Preoperative; d1, d2, d7: first, second, and seventh postoperative days, respectively. [b]$P < 0.01$ versus Preop: [d]$P < 0.01$ HB group versus NHB group at the same time point.

enrolled into the study. One hundred and eighty were male and 206 were female. Their ages ranged from 17 to 78 years (mean, 47 years). The disease categories comprised valve disease (Valve, 220 cases), congenital heart disease (CHD, 140 cases), coronary atherosclerotic heart disease (CAHD, 16 cases) and valve combined with coronary disease (Valve + CAHD, 10 cases). The protocol was approved by the Committee of Human Study of our institution. Patients were not selected with any other major diseases, such as viral hepatitis, HIV, and syphilis. Patients with preoperative hyperbilirubinemia were defined as a total bilirubin concentration of more than 2 mg/dL (34 μmol/L). Postoperative hyperbilirubinemia was defined as a total bilirubin level over 3 mg/dL (51 μmol/L) within the first postoperative week, and accordingly, patients were divided into two groups: postoperative hyperbilirubinemia group (HB group) and non-postoperative hyperbilirubinemia group (NHB group).

### Surgery and parameters tested

Anesthesia was induced with fentanyl (40 to 100 μg/kg), etomidate (0.3 to 0.4 mg/kg) or vecuronium (0.1 to 0.15 mg/kg). All patients had cardiopulmonary bypass (CPB), with isovolemic haemodilution, moderate hypothermia (28℃ ± 5℃), roller pump and bubble or membrane oxygenators. The perfusion flow was kept over 2.2 L/m$^2$ during northemia and over 1.8 L/m$^2$ during hypothermia in every patient. The mean arterial pressure (MAP) was kept between 50 to 80 mmHg with dopamine, nitroglycerin, and nitroprusside. Arterial blood gas was monitored routinely every half an hour or on any occasion when considered necessary. The priming solution contained 1.5 to 2.0 L of lactated Ringer's solution, heparin (2000 U/L) and 1/2 to 1 unit of packed red cells if blood cardioplegic solution was indicated or predicted hematocrit level during CPB was blow 20%. Systemic heparin was given through the right atrium at a dose of 300 U/kg just before cannulation. For valvular replacements operations, either a Carbomedics (Carbomedics, Inc) or a St, Jude Medical (St, Jude Medical, Inc) Mechanical prosthesis was used.

### Parameters tested

**Preoperative**: Blood samples were collected within 2 d before operation by vein puncture. Serum was stored at -70℃ for future biochemical and virological studies. Preoperative right atrial pressure was monitored through the preoperative cardiac catheterization recorder. Full blood-count, urea and electrolytes, alanine amino transferase (ALT), aspartate amino transferase (AST), total bilirubin (TB), unconjugated bilirubin(UCB), and conjugated bilirubin (CB) were tested. In all patients, serological viral studies were performed to rule out infection with hepatitis A (HAV IgG + IgM), hepatitis B (HBsAg and HBcAb), hepatitis C (HCV - IgM) and HIV virus.

**Perioperative**: In every operation, the routine clinical monitors including lead electrocardiogram, the radial arterial line, the pulse oximeter, end-tidal carbon dioxide, nasopharyngeal and rectal temperatures, urine output via Foley catheter, the central venous pressure line, pulmonary artery catheters, the operating time, CPB time, aortic cross-clamp time, types of oxygenator, quantity of packed red cells primed during CPB, and the types and numbers of mechanical valves replaced were recorded.

**Postoperative**: We recorded right atrial pressure, minimum MAP, and minimum arterial oxygen tension ($mPO_2$) daily. Blood samples were obtained through the central venous line or venopuncture on the first, second and seventh postoperative days and analyzed for concentrations of albumin, globulin, haemoglobin, ALT, AST, TB, UCB, CB, and reticulocyte count by an automated biochemical analyzer (Beckman Array 3000, USA). Serum bile acids (cholyglycine) were tested using stored serum (RIA). Reticulocyte count, plasma haemoglobin, haptoglobin levels, urinary haemosiderin, and urobilinogen were examined to detect haemolysis. The blood transfusions shortly after surgery, the days of hospitalization in the intensive care unit (ICU), mechanical ventilation days, and the numbers of patients who died during hospitalization were registered.

### Statistical analysis

Statistical analysis was carried out using SPSS version 10.0 software (SPSS, inc, USA). Data were presented as mean ± SE of the mean. The chi-squared test and Student's *t* test were used to compare categorical variables. Stepwise logistic regression was employed for multivariate analysis. Values of *P* less than 0.05 were considered significant.

## RESULTS

The perioperative changes of liver function are shown in Table 1. The incidence of the postoperative hyperbilirubinemia in these patients is shown in Figure 1.

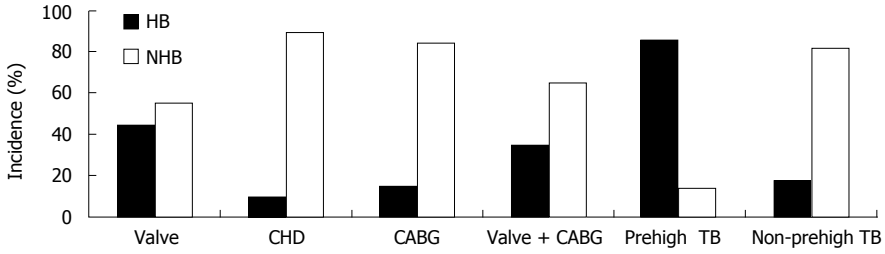

**Figure 1** Incidence of postoperative hyperbilirubinemia among different disease categories, and in patients with and without preoperative hyperbilirubinemia; CHD: Congenital heart disease, CABG: Coronary artery bypass grafting.

**Table 2 Comparison of mortality, ventilation time and ICU stay time in two groups (mean ± SD)**

| Variable | HB group | NHB group | *P* value |
|---|---|---|---|
| Mortality | 4.10% | 0.3%[b] | $P < 0.01$ |
| Ventilation time (h) | 25.5 ± 13.3 | 16.5 ± 9.2[a] | $P < 0.05$ |
| ICU stay time (d) | 11.5 ± 6.5 | 4.1 ± 3.9[a] | $P < 0.05$ |

[b]$P < 0.01$ *vs* HB group; [a]$P < 0.05$ *vs* HB group.

Among the 386 patients enrolled in this study, 36 had preoperative hyperbilirubinemia. The overall incidence of the postoperative hyperbilirubinemia was 25.3%. For patients with preoperative hyperbilirubinemia, the incidence of postoperative hyperbilirubinemia was 86.1%.

In patients with postoperative hyperbilirubinemia, 56.2% reached a peak total bilirubin concentration on the first postoperative day, 33.5% on the second day, and 10.3% on the seventh day. Among the patients with preoperative hyperbilirubinemia, 69% had severe postoperative hyperbilirubinemia with highest TB concentration greater than 171 μmol/L; whereas, in other patients, only 18% had a highest TB concentration greater than 171 μmol/L ($P < 0.01$). The highest TB concentration was significantly greater in patients with preoperative hyperbilirubinemia than in patients without (210.8 ± 28.4 μmol/L *vs* 62.8 ± 9.6 μmol/L, $P < 0.01$). On the first postoperative day, the TB, UCB, and CB concentrations increased in both the patients in HB and NHB groups compared with preoperative levels ($P < 0.01$, Table 1). For the patients with postoperative hyperbilirubinemia, 80.2% of the increased TB was from an increase of the mixture of CB and UCB.

With regard to the effects of the disease and operation category, postoperative hyperbilirubinemia occurred more frequently in patients receiving valvular replacements than in patients undergoing coronary artery bypass grafting (CABG) or operation for CHD($P < 0.01$, Figure 1). The incidence of postoperative hyperbilirubinemia was significantly higher in patients with valvular replacements with mechanical prostheses than in the patients without valvular replacements ($P < 0.01$, Figure 1). The result was similar when patients with preoperative hyperbilirubinemia were excluded.

The comparison of mortality, ventilation time and ICU stay time are shown in Table 2. Only one patient undergoing CABG died in NHB group. He died on 12th d after the operation of respiratory failure. Among four operative mortality cases in the HB group, three had a progressive increase in TB after operation. The highest TB concentration level (over 400 μmol/L) was reached on the seventh postoperative day. One had an increase in TB immediately on the first postoperative day. Two of the four died from hepatic failure, and another two died from multiple organic function failure. Development of postoperative hyperbilirubinemia was associated with a higher mortality ($P < 0.01$), longer duration of mechanical ventilation ($P < 0.05$), and longer ICU stay time ($P < 0.05$).

Analysis of possible risk factors for the postoperative hyperbilirubinemia is shown in Table 3. The results of stepwise logistic regression are shown in Table 4. Preoperative total bilirubin concentration, preoperative

**Table 3 Analysis of possible risk factors for the postoperative hyperbilirubinemia (mean ± SD)**

| Possible risk factors | HB group | NHB group | *P* |

right atrial pressure, numbers of valves replaced and blood transfusion requirement were identified as important predictors for the postoperative hyperbilirubinemia. Combination of these four perioperative risk factors could predict development of postoperative hyperbilirubinemia in 81.2% of the patients.

## DISCUSSION

It has been well known that early jaundice and transient liver damage could occur after extracorporeal circulation surgery[1,2]. The mortality can reach 85%-90% once the postoperative jaundice progresses to hepatic failure[4-7]. On the other hand, for patients with preoperative cirrhosis of liver, mortality of CPB surgery can reach 31%[8]. Thus recently, more attention has been paid to the studies of jaundice and liver injuries following CPB.

This prospective study showed that the overall incidence of the postoperative hyperbilirubinemia was 25.3%, similar to the literature report[3]. Despite advances in techniques of perioperative management in cardiac operations, CPB, and cardiac anaesthesia, early hyperbilirubinemia after modern extracorporeal circulation surgery still occurs frequently. With regard to the effects of the disease and operation category, controversies exist about whether incidence differs among different disease category[2,3]. The current results showed that postoperative hyperbilirubinemia occurred more frequently in patients receiving valvular replacements than in patients undergoing CABG or operation for CHD ($P < 0.01$). The incidence of postoperative hyperbilirubinemia was significantly higher in patients with valvular replacements with mechanical prostheses than in the patients without receiving valvular replacements ($P < 0.01$). For patients with preoperative hyperbilirubinemia, the incidence of the postoperative hyperbilirubinemia was 86.1%. The decreased hepatic capacities for bilirubin disposal and bile transport, in addition to the haemolysis from CPB, cardiotomy suction, and mechanical prosthesis result in the postoperative hyperbilirubinemia. Both Weber[1] and Lockey[2] proposed that haemolysis contributed to postoperative jaundice; in contrast, Collins[3] and Chu[4] reported that serum TB concentration mainly resulted from increased CB, i.e., hepatic cellular jaundice. However, for the patients with postoperative hyperbilirubinemia in our study, 80.2% of the increased TB was due to an increase of both CB and UCB; 56.2% reached peak TB concentration on the first postoperative day, 33.5% on the second day and 10.3% on the seventh day. Among the patients with preoperative hyperbilirubinemia, 69% had severe postoperative hyperbilirubinemia with highest TB concentration greater than 171 μmol/L, while in other patients only 18% had a highest TB concentration greater than 171 μmol/L ($P < 0.01$). Development of postoperative hyperbilirubinemia was associated with a higher mortality ($P < 0.01$), longer duration of artificial ventilation ($P < 0.05$), and longer ICU stay time ($P < 0.05$). Furthermore, the mortality of the patients with postoperative hyperbilirubinemia was higher in patients whose TB concentration reached the peak level on the seventh postoperative day than in patients whose TB concentration increased to peak level on the first two days after operation. The occurrence of postoperative hyperbilirubinemia should alert the doctor to the possibility of higher morbidity and mortality, though it might not be considered as a high risk indicator.

Results of the logistic regression showed that preoperative total bilirubin concentration, preoperative right atrium pressure, numbers of valves replaced, and blood transfusion requirement were identified as the important predictors for the postoperative hyperbilirubinemia. Combination of these four perioperative risk factors could predict development of postoperative hyperbilirubinemia in 81.2% of all patients. Patients with severe preoperative cardiac failure may have higher right atrial pressure and preoperative hyperbilirubinemia, both reflecting the degree of liver congestion. The capacity of both bilirubin disposal and bile transport may be impaired[6], which also can lead to a higher preoperative TB level. Collins *et al* had suggested that severe heart failure predisposes the patients to the development of clinical jaundice after CPB[3]. Multiple valve replacements with mechanical prostheses are associated with more haemolysis as a result of CPB, cardiotomy suction, and mechanical prosthesis itself. Haemolysis of transfused blood is a common cause for postoperative jaundice. Our patients who developed postoperative jaundice had received significantly more blood transfusions, which would certainly cause an increased bilirubin load to the liver[9]. The immediate occurrence of postoperative hyperbilirubinemia and rapid decline thereafter may reflect the transient damaging effects on the blood and hepatic function following CPB; whereas, steady progressive increase of TB level to reach its peak on the seventh day indicates liver injury and hepatic dysfunction. CPB can lead to a severe and complicated change of pathophysiology of the liver. Operation stress, reperfusion injury, endotoxemia, and inflammatory reaction may contribute to the liver injury[6,10,11], however, the complex functional and metabolic effects of hepatocyte in CPB require further investigation.

In summary, early postoperative hyperbilirubinemia often occurs after modern extracorporeal circulation. It is mainly caused by an increase in both conjugated and unconjugated bilirubin, and is associated with a higher mortality. Important contributing factors are the preoperative total bilirubin concentration, preoperative severity of right atrial pressure, numbers of valve replacement procedures, and the frequencies of blood transfusion requirement during and shortly after surgery. We suggest that postoperative hyperbilirubinemia is a multifactorial process, which is caused by both the impaired liver function of bilirubin transport and increased production of bilirubin because of haemolysis.

## Abstract

We describe a rare case of HCV-related recurrent multiple hepatocellular carcinoma (HCC) metastasizing to the skull base involving multiple cranial nerves in a 50-year-old woman. The patient presented with symptoms of ptosis, fixation of the right eyeball, and left abducens palsy, indicating disturbances of the right oculomotor and trochlear nerves and bilateral abducens nerves. Brain contrast-enhanced computed tomography (CT) revealed an ill-defined mass with abnormal enhancement around the sella turcica. Brain magnetic resonance imaging (MRI) disclosed that the mass involved the clivus, cavernous sinus, and petrous apex. On contrast-enhanced MRI with gadolinium-chelated contrast medium, the mass showed inhomogeneous intermediate enhancement. The diagnosis of metastatic HCC to the skull base was made on the basis of neurological findings and imaging studies including CT and MRI, without histological examinations. Further studies may provide insights into various methods for diagnosing HCC metastasizing to the craniospinal area.

**Key words:** Hepatocellular carcinoma; Distant metastasis; Skull base; Cranial nerve

## INTRODUCTION

Hepatocellular carcinoma (HCC), the most common primary tumor of the liver, is estimated to cause more than a quarter of a million deaths throughout the world each year. Metastasis is one of the most significant factors affecting prognosis. In HCC, intrahepatic metastasis is frequent, and extrahepatic metastasis to the lung, bone and adrenal glands is detected sometimes, while cranial nerves are not likely to be involved in metastatic HCC. We describe a case of a 50-year-old woman with symptoms of ptosis, fixation of the right eyeball, and left abducens palsy caused by HCC metastasizing to the skull base, diagnosed through neurological findings and imaging studies.

## CASE REPORT

A 50-year-old woman was admitted to Kobe Asahi Hospital in October 2002 with symptoms of ptosis, fixation of the right eyeball and left abducens palsy. Since 1989, multiple HCCs which had occurred repeatedly with the background of type C liver cirrhosis were treated more than ten times with percutaneous ethanol injection (PEI) and transcatheter embolization (TAE). Neurological findings were normal except for disturbances of the right oculomotor and trochlear nerves and bilateral abducens nerves. Laboratory studies on admission disclosed the following abnormal values: aspartate aminotransferase 84 kIU/L (normal 5-35 kIU/L), alanine aminotransferase 38 IU/L (normal 4-43 IU/L), hemoglobin 103 g/L (normal 113-152 g/L), platelets 14.7 $\times 10^{10}$/L (normal 13.0-36.9 $\times 10^{10}$/L), thymol turbidity 5.0 $\times 10^{6}$ IU/L (normal 0-4.0 $\times 10^{6}$ IU/L), zinc surface turbidity 15.1 $\times 10^{6}$ IU/L (normal 2.0-12.0 $\times 10^{6}$ IU/L), and γ-globulin 266 g/dL (normal 105-203 g/dL). The levels of tumor markers were 184 mg/L (normal 0-0.02 mg/L) for alfa-fetoprotein (AFP), 6.4% (normal 0%-10%) for lens culinaris agglutinin A-reactive fraction of AFP (AFP L3) and 22.3 kAU/L (normal

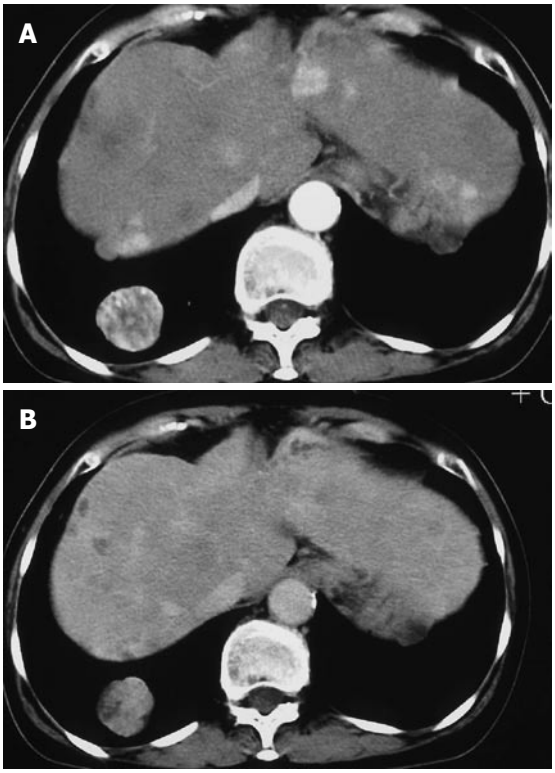

**Figure 1** Abdominal incremental computed tomography (CT) (**A**) showing multiple contrast-enhanced tumors (arterial phase) and abdominal incremental CT scan (**B**) showing low density tumors (portal phase).

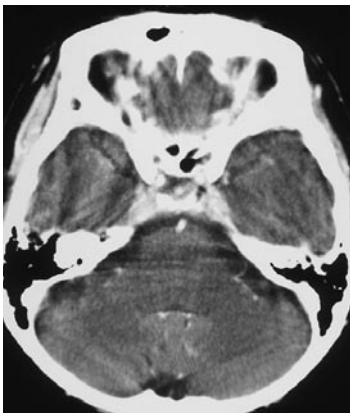

**Figure 2** Brain contrast-enhanced CT image. Abnormal enhancement around the sella turcica is observed.

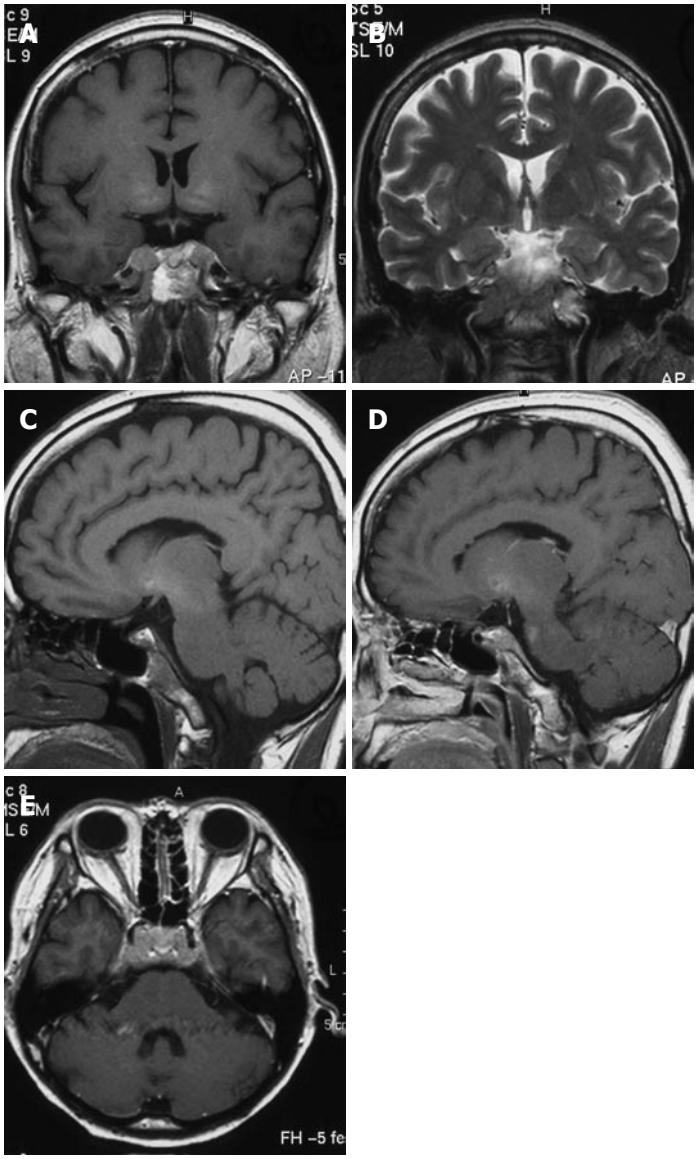

**Figure 3** Brain MRI image. **A**: Unenhanced coronal T1-weighted image reveals ill-defined mass around the sella turnica. The mass shows intermediate signal intensity; **B**: A mass reveals high signal intensity on coronal T2-weighted image; **C**: Unenhanced saggital T1-weighted image reveals ill defined mass involving the sella turcica. **D**, **E**: On contrast-enhanced saggital (**D**) and transverse (**E**) T1-weighted images, the mass shows inhomogeneous intermediate enhancement and involves the clivus, cavernous sinus and petrous apex. Meningeal thickening between the posterior sella turcica and the clivus and dilation of the superior carotid vein are observed.

0-0.04 kAU/L) for protein induced by vitamin K absence (PIVKA Ⅱ). Incremental dynamic computed tomography (CT) revealed multiple HCC nodules in both lobes (Figure 1). Chest X-ray showed extrahepatic metastases to both lungs; however, imaging studies did not show metastases to the bone or adrenal gland. Brain contrast-enhanced CT (Figure 2) revealed an ill-defined mass with abnormal enhancement around the sella turcica. On unenhanced brain magnetic resonance imaging (MRI) the mass was shown to involve the clivus, cavernous sinus, and petrous apex**.** Inhomogeneous intermediate enhancement of the mass was confirmed by contrast-enhanced MRI with gadolinium-chelated contrast medium. Meningeal thickening from the posterior of the sella turcica to the clivus and dilation of the superior carotid vein were observed (Figure 3).

## DISCUSSION

The third, fourth, and sixth cranial nerves may be involved in lesions affecting their nuclei or fibers of efferent in the pons or the mesencephalon, or in the course of nerves through the subarachnoid space, the cavernous sinus, and the superior orbital fissure. Different syndromes occur with lesions at each of these sites. From neurological findings such as ptosis, fixation of the right eyeball, and left abducens palsy, we suspected the involvement of the multiple cranial nerves. Brain CT and MRI with contrast medium revealed abnormal enhancement around the sella turcica, and brain MRI revealed that the mass involved the clivus, cavernous sinus, and petrous apex, therefore we made the definite diagnosis of HCC metastasizing to the

skull base.

Metastasis appears to be a late event in the natural history of HCC, and most patients die of liver failure attributed to liver replacement by the tumor. Extrahepatic metastases are commonly found at autopsy in over half of the cases[1-3], the lung, being the most frequent (approximately 50%) and the regional lymph nodes often being the sites of metastasis. In addition, bone metastases are common, and patients may show a bony metastasis as the initial presentation of occult HCC. Adrenal metastases are found in up to 15% of autopsies, and some cases of pedunculated HCC have been reported as actual metastasis to the right adrenal gland from a nearby tumor. Conversely, the brain is less common metastatic sites. Incidental extrahepatic lesion at such more uncommon site is less confidently viewed as potential metastases when metastatic disease is not detected at the more common sites (the lungs, lymph nodes, and bone). According to neurological findings and imaging studies of brain CT and MRI, our case was confirmed as metastatic HCC to the skull base involving multiple cranial nerves including the third, fourth, and sixth.

The central nervous system is an unusual site of metastatic HCC[4-12]. Seven cases of HCC presenting as cranial metastasis without obvious hepatic involvement have been described: metastatic spread of HCC to the cerebrum in one case, and to the cranium in six cases[8], all manifesting mildly abnormal liver function when first evaluated, leading to the conclusion that in cranial metastasis of unknown origin in a geographical area where HCC is a common disease, HCC should be considered in the differential diagnosis[8]. In Japan as in Taiwan, where HCC is a common disease, however, metastatic HCC to the skull base involving multiple cranial nerves has not been reported so far, except for a case of skull metastasis of HCC associated with acute epidural hematoma[9].

Before 1990, the diagnosis of metastatic HCC to the craniospinal area was confirmed by histological examinations of biopsy, surgical and autopsy specimens. Recently diagnosis is reached by neurological findings and imaging studies, such as CT and MRI because of improvements in these modalities. With the recent advances in the nonsurgical treatment of HCC, such as percutaneous ablation including percutaneous ethanol injection therapy (PEIT), radiofrequency ablation (RFA) and transcatheter embolization, longer-term survival has been attained, even in cases of advanced HCC compared with older autopsy populations. This may be due to current treatment regimens of chemotherapy or chemoembolization, or both, that result in the longer survival of patients diagnosed with HCC, as was in our case. Although HCC metastasizing to the skull base involving multiple cranial nerves is very rare, clinicians need to be vigilant and would do well to conduct imaging studies such as CT and MRI, when neurological findings reveal suspected cranial nerve involvement.

## Abstract

Foreign bodies and bezoars are commonly encountered in children. We describe a child aged 11 years who ingested large amounts of plastic material used for knitting chairs and charpoys. The conglomerate of plastic threads, entrapped food material and other debris, formed a huge mass occupying the whole stomach. Chronic irritation of the gastric antral mucosa led to ulceration and formation of hyperplastic polyps. We labeled this new entity as a "plastobezoar". The entire bezoar could be removed endoscopically.

**Key words:** Bezoar; Stomach; Gastric; Endoscopy; Foreign body; Gastric polyps; Plastic

## INTRODUCTION

Bezoar is adapted from Arabic "bazahr" or "badzehr" which means an antidote or counter-poison due to the fact that till the 19th century, bezoars obtained from sacrificed animals were widely used as antidote[1]. Foreign bodies and bezoars are commonly encountered in children. We describe a child aged 11 years who ingested large amounts of plastic material used for knitting chairs and charpoys. The conglomerate of plastic threads, entrapped food material and other debris, formed a huge mass occupying the whole stomach and even caused ulceration and polyp formation due to irritation of the stomach wall. It is debatable as to whether to call this a bezoar or a foreign body. The appearance, behavior and management of the gastric mass was more like a bezoar than that of a foreign body, and therefore we strongly feel that it should be called a "plastobezoar".

## CASE REPORT

An 11-year-old boy was admitted with complaints of vomiting and abdominal pain of six months duration and swelling over the face and feet for the last one month.

On clinical examination the child was pale with puffiness over the face. Pedal edema was present. Abdominal examination found a firm lump palpable in the epigastrium, which moved with respiration. No crepitus was felt over the lump. There was mild tenderness present over the mass.

The hemoglobin was 5.6 g/dL, total and differential leukocyte counts were normal. The serum urea was 36.4 mmol/L, creatinine 314 μmol/L, and serum albumin was 2 g/dL. Serum globulin, fasting and post-prandial blood glucose, serum amylase, bilirubin and transaminases were normal. Urine examination did not reveal any abnormality. Serum sodium was 135 mmol/L, potassium 2.8 mmol/L and calcium 1.8 mmol/L.

Just after admission, the patient developed typical grandmal epileptic attack, which was managed by intravenous diazepam injection. Intravenous and oral supplements of potassium and calcium were given and the child did not have any further episodes of epilepsy.

The patient was considered to have pre- renal failure due to severe vomiting and dehydration and was managed conservatively with intravenous fluid. Two packs of whole blood were transfused and 100 mL of 20% albumin was given intravenously. Gradually, the serum creatinine and urea became normal. Clinically the puffiness over the face and pedal edema disappeared and the patient started feeling better. Dialysis was not required.

A contrast enhanced CT scan revealed an irregular, large, non-attached mass of varying attenuation with pockets of air, occupying the stomach (Figure 1). A portion of the mass was also encroaching the duodenum. A few polypoidal masses were seen in the antrum of the stomach near the pylorus. There was no post-contrast enhancement of the mass lesion.

UGI endoscopy revealed a large bezoar occupying nearly the whole stomach (Figure 2). It was black and dark green in color and appeared to be composed of flat plastic thread/grass like material along with entrapped food

**Figure 1** Contrast-enhanced CT scan showing a large unattached mass (bezoar) in the stomach with air trapped in it. There was no post-contrast enhancement of the mass.

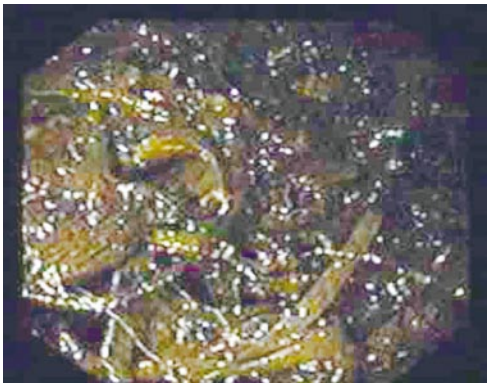

**Figure 2** Endoscopic appearance of the plastobezoar. The bezoar was made of hundreds of plastic strands.

**Figure 3** Hyperplastic gastric polyps in the pre-pyloric region of the stomach.

particles. A small "tail" of the bezoar was also entering the pylorus into the first and second parts of the duodenum. There were several polypoid, masses in the peri-pyloric area of the antrum. Some of the polypoid masses had superficial ulcerations (Figure 3). Ulcerations were also seen at the incisura of the stomach. A few strands of the material forming the bezoar were removed using a rat-toothed forceps. The material was found to be flat plastic threads used in knitting chairs and charpoys. At places, flat cables used for receiving television signals were also found. Attempts to entrap the bezoar in conventional polypectomy snare failed. It could be snared with a large-diameter improvised snare but it could not be delivered through the cardio-esophageal sphincter as one piece due to its size.

On inquiring from the parents of the child, the father said that he had occasionally seen the child peeling off plastic material from chairs and charpoys and eating it for the last three years. It happened when the child was confined to bed (made of plastic) after surgery for an abscess, three years ago, and during this period he started peeling off bits and pieces and strands off the charpoy and swallowing them. Gradually he developed a taste for the plastic material, and even when he recovered he continued to chew and swallow plastic from the charpoys.

The next day, under conscious sedation using injection pentazocine, diazepam and propofol, an overtube was passed into the esophagus over a tightly fitting Savary-Gilliard dilator. Thereafter, the whole bezoar was removed in pieces using rat-toothed forceps, snare and Dormia basket, in an endoscopy session lasting over three hours. Some of the strands from the bezoar measured more than 50 cm. Biopsies were obtained from the polyps in the antrum. The patient was kept nil p.o. overnight. Intravenous pantoprazole was given. A barium meal examination was performed the next day, which did not reveal any abnormality. No obvious delay in the transit time was observed either in the stomach or in the small and large intestines. Psychiatric evaluation did not reveal any abnormality. Histological examination of the biopsy obtained from the polyps in the pre-pyloric region of the stomach revealed the polyps to be hyperplastic in nature. The patient was started on oral pantoprazole and discharged. He is on a regular follow-up about recurrence of the bezoar and disappearance of the hyperplastic polyps.

## DISCUSSION

The word bezoar is a word derived from the Arabic "bazahr" or "badzehr" which means an antidote or counter-poison. Till the 19th century, bezoars obtained from sacrificed animals had been widely used as antidote.[1] The origin of most bezoars is thought to be due to delayed gastric emptying as a result of either vagotomy, antral resection, gastroparesis or gastric outlet obstruction[2,3]. However, in a Japanese study, no evidence of delayed gastric emptying was observed[4]. Phytobezoar formation has also been reported to form in an adolescent with achalasia cardia and hypertrophic pyloric stenosis[5] and in one patient each having intestinal pseudo-obstruction[6] and scleroderma[7]. However, our patient did not have any of the above mentioned conditions. Ingestion of large amounts of indigestible solids may also precipitate bezoar formation[2]. The case in discussion had swallowed a large amount of plastic material and since plastic cannot be digested, a bezoar formed in the stomach. Stomach phytobezoars are also known to occur in uremic patients[8] and although in the present case, serum creatinine rose at the time of hospitalization, it was due to protracted vomiting and hypovolemia leading to pre-renal failure and

not due to any renal disease per se. The renal functions became normal within a few days by conservative management.

Bezoars are conventionally defined as retained concretions of animal or vegetable material in the intestinal tract[1]. Therefore, in the truest sense, our patient did not have a bezoar but will be said to have a foreign body in the stomach. However, the appearance, behavior and management of the gastric mass was exactly like a bezoar and therefore it may aptly be called a "plastobezoar." Apart from common phytobezoars, trichobezoars and diospyrobezoars, cotton bezoars[9], paper bezoars[10], bezoars due to medication (pharmacobezoars)[11-12], synthetic glue[13] and even iron bezoars[14] have been reported. Considering the fact that even non-organic substances have been responsible for producing bezoars, the case in discussion is a fit case to be considered as a bezoar and not a foreign body.

Our patient had a unique bezoar due to eating disorder in which he was eating plastic material used for knitting chairs and charpoys. This abnormal eating disorder of plastikophagia has been reported earlier too[15]. However, the formation of a giant bezoar and its consequences were unique in this patient.

CT scan in our patient revealed a non-attached gastric mass lesion with air pockets. There was no post-contrast enhancement. This appearance was very similar to that described in a patient with trichobezoar[16,17] and therefore it appears that all bezoars may give a similar appearance on CT scan, irrespective of the contents. The fact that all the bezoars are retained substances of foreign origin gives the typical CT picture of a non-attached mass that does not enhance after intravenous contrast injection. Since the bezoar forms umpteen number of pockets in which air is trapped, this is also visualized on the CT scan.

Surgery is frequently resorted to for the removal of bezoars, especially the larger ones[2,3,18]. However, laparoscopic removal[19,20] and endoscopic extraction of bezoars have also been successful. Use of lithotriptor[21], laser ignited mini-explosives[22], mono- polar diathermy knife[21] and electrohydraulic lithotripsy[23] have been successful in removing the bezoars of varying etiologies. In our patient, surgery was considered to be an option but was abandoned in view of his poor general condition and the presence of renal failure. Since the bezoar was made up of hundreds of thread-like strands of plastic and food debris, we were unable to use the above-mentioned endoscopic techniques. The bezoar could be trapped as one piece in a large self-made snare, which has been used by us earlier for removal of large foreign bodies such as a mango kernel from the esophagus[24], but due to its large size it could not be negotiated across the cardio-esophageal sphincter. Therefore, it had to be removed the hard way in bits and pieces using an overtube, a rat-toothed forceps, a Dormia basket and a polypectomy snare. We did not have a large channel endoscope, which has been used to remove gastric phytobezoars of 500, 700 and 1000 ml successfully in one go by sucking them from the stomach[25].

The hyperplastic gastric polyps (Figure 3), in the prepyloric region of the stomach, probably occurred because of chronic irritation of the gastric mucosa by the bezoar. This was also the reason for the ulcerations seen in the stomach. It is logical to think that these polyps may have caused further stasis in the stomach by deforming the pyloric opening and impeding the flow of the gastric contents. It is interesting in this regard to find a couple of case reports where gastric polyposis[26] and hyperplastic gastric polyps[27] were noted to be associated with gastric bezoar formation[4].

## Abstract

Hepatic veno-occlusive disease (HVOD) is rarely encountered and easily misjudged as Budd-Chiari syndrome. It is often related to stem cell transplantation in recent years. We report a case of HVOD that is related to ingestion of some palatable local dishes. The diagnosis was confirmed by liver biopsy pathology with specific observation of inflammatory changes and fibrosis of venules intima, dilated sinusoids and central veins. Chronic diarrhea is unique for this case as a result of ingesting harmful stuffs. This case demonstrated that supervision and instruction of food recipe and traditional medicine are crucial, and prompt diagnosis, supportive care and specific treatment are essential to decreasing the morbidity and mortality of HVOD.

## INTRODUCTION

Hepatic veno-occlusive disease (HVOD) is a rarely encountered ailment in the literature[1,2]. The establishment of the diagnosis of this condition can be very difficult because there is no specificity in the clinical manifestations and some common findings are similar to Budd-Chiari syndrome (BCS), a peculiar condition with many pitfalls leading to misdiagnosis[3]. Until now, the mechanism of etiology has not been clearly identified and only considered by some authors[2,4] correlated to the non-thrombotic occlusion of the central veins of hepatic lobules, certain inflammatory factors, detoxification of the liver, *etc.* This is a case of HVOD that is related to ingestion of some palatable local dishes.

## CASE REPORT

A 17-year-old female was admitted with a complaint of escalating abdominal pain, increased abdominal circumference and recurrent diarrhea. The symptoms started 2 mo ago, mild at first, but now became more and more obvious and bothersome. Physical examination revealed mild jaundice in sclera, no skin petechia, no edema, no superficial varices, and no positive findings in the heart and lungs. The abdomen was distended, no tenderness or rebound pain. The liver and spleen were not palpable. The sign of ascites was positive. Laboratory results showed WBC 6.82 × $10^9$/L, Hb 122 g/L, BPC 81.30 × $10^9$/L, HbsAg (-), ALT 66 U/L, AST 81 U/L, serum total bilirubin 39.7 μmol/L, direct bilirubin 10.6 μmol/L, and ALB 32.8 g/L. Abdominal paracentesis aspirated clear ascites, with a total cell count of 6400, WBC 5/mL, and ALB 15.3 g/L. CT scan of the abdomen revealed moderate ascites, hepatomegaly, with areas of inhomogeneously reduced density, delayed enhancement of parenchyma, and obscure hepatic veins.

Considering the symptom of repeated diarrhea, the physicians inquired time and again that if she had eaten anything harmful, but nothing was determined. At last, the details of the patient's food consumption found that she had enjoyed a "cuisine recipe for longevity" for a dozen of times. The dish was delicious, the patient admitted, and all the local people thought that it is one of the valuable dainties. The content of the ingredients proved to consist of the seeds of a plant called "wild sesame" by the local people, whereas actually the entity of it is not barbate deadnettle but rattlebox[5], *Crotalaria sessiliflora.*

Venography by catheterization revealed patent inferior vena cava (IVC) and main hepatic veins (HV). Finally, a percutaneous puncture of liver biopsy was completed with the pathological findings of inflammatory changes and fibrosis of venules intima, dilated sinusoids and central veins, and no obvious degeneration of hepatocytes was found. Then the diagnosis of HVOD was established. The patient was given supportive and hepatoprotective treatment. Her symptoms were relieved and she was completely recovered within two weeks.

## DISCUSSION

In recent years, HVOD often occurs secondary to stem cell transplantation as the most common regimen-related toxicity[6]. However, herbs or plants are occasionally reported to cause HVOD, especially those used in traditional medicine[7].

The mechanism of liver damage caused by plants has not been elucidated, only a hypothesis of "conflict of plant versus animal or plant-animal interaction" seems more acceptable[8]. The defence system of many plants are used to produce compounds such as alkaloids and polypeptides against the animals that ingest them. Such animals are also self-protected by efflux transporters in the gut and detoxification of the liver, herbivore countermechanism to plant chemical defenses, and multidrug resistance-associated protein isoform, *etc.*

Senecio plants[7,9] as well as *Crotalaria* and *gynura segetum* are reported potentially hepatoxic if consumed over a period of weeks. Poisoning can occur through ingestion of especially the seeds, but also leaves and stems. After ingestion of the plants, the major toxic components pyrrolizidine alkaloids (PAs) are absorbed and converted to highly reactive alkylating pyrroles that cause hepatocellular necrosis, biliary hyperplasia, fibrosis, and hepatocytomegaly.

The clinical manifestations of HVOD fall into the categories of mild, moderate and severe according to its final outcome[4,6,10] or acute, subacute and chronic according to its onset and course. Typical findings include abdominal pain, ascites with elevated ALB, jaundice and hepatomegaly. Chronic diarrhea is unique for this case as a result of ingesting harmful stuffs. Imaging diagnoses including gray-scale US, Doppler US, CT and MRI have been reported as convenient and useful. Venography often reveals patent IVC and main outflow of HV.

Pathology of liver biopsy definitely establishes the diagnosis of HVOD, with the hallmark of fibrous obliteration of terminal hepatic venules and small lobular veins. Both percutaneous and laparoscopic liver biopsies[4] are helpful, and transvenous (transjugular) approach[11] as well. The latter has the advantages of possible hemorrhage to be drained intravascularly and the feasibility of measuring hepatic venous pressure gradients with the upper limit of 10 mmHg for the establishment of HVOD diagnosis, and the higher, the more severe. Unfortunately, this case failed to go through this procedure.

It is very important to differentiate the diagnosis of HVOD from that of BCS[2-4] as both of them present the common signs of abdominal distention, jaundice and ascites with elevated ALB. Several points to identify BCS for this differentiation should be kept in mind: (1) superficial varices of the trunk and lower extremities with edema and pigmentation; (2) stricture or obstruction of IVC and /or HV outflow by venography; (3) thromboses in hepatic venules by liver biopsy pathology.

Supportive care remains the therapy available to date. For some severe cases, ascites must be drained in order to allow sufficient pulmonary ventilation. The drug defibrotide[4,12] has been selected for the treatment of severe HVOD, and in a large, FDA-approved, pivotal, prospective, multi-institutional, global phase Ⅲ trial, seems to have few significant side effects and well-tolerated. Transjugular intrahepatic portosystemic shunting (TIPS) was evaluated[4] for chronic cases with serious obstruction of outlet of main HVs, but should be indicated with discretion. In some severe cases, charcoal hemofiltration[13] has been shown to be effective for adsorbing circulating bilirubin and other protein-bound toxins and for supporting patients in hepatic failure.

This case demonstrated that supervision and instruction of food recipe and traditional medicine are crucial[14], and that prompt diagnosis, supportive care and specific treatment are essential to decreasing the morbidity and mortality of HVOD.

# Meetings

## MAJOR MEETINGS COMING UP

First Biennial Congress of the Asian-Pacific Hepato-Pancreato-Biliary Association
March, 2007
Fukuoka, Japan
http://www.congre.co.jp/1st-aphpba

American College of Gastroenterology Annual Scientific
20-25 October 2006
Las Vegas, NV

14th United European Gastroenterology Week, UEGW
21-25 October 2006
Berlin, Germany

APDW 2006: Asian Pacific Digestive Week 2006
26-29 November 2006
Lahug Cebu City, Philippines

## EVENTS AND MEETINGS IN THE UPCOMING 6 MONTHS

Falk Symposium 151: Emerging Issues in Inflammatory Bowel Diseases
24-25 March 2006
Sydney - NSW
Falk Foundation e.V.
symposia@falkfoundation.de

10th International Congress of Obesity
3-8 September 2006
Sydney
Event Planners Australia
enquiries@ico2006.com
www.ico2006.com

Easl 2006 - the 41st annual
26-30 April 2006
Vienna, Austria
Kenes International

Prague hepatology 2006
14-16 September 2006
Prague
Foundation of the Czech Society of Hepatology
veronika.revicka@congressprague.cz
www.czech-hepatology.cz/phm2006

12th International Symposium on Viral Hepatitis and Liver Disease
1-5 July 2006
Paris
MCI France
isvhld2006@mci-group.com
www.isvhld2006.com

Falk Symposium 152: Intestinal Disease Part I, Endoscopy 2006 - Update and Live Demonstration
4-5 May 2006
Berlin
Falk Foundation e.V.
symposia@falkfoundation.de

Falk Symposium 153: Intestinal Disease Part II, Immunoregulation in Inflammatory Bowel Disease - Current Understanding and Innovation
6-7 May 2006

***World Journal of Gastroenterology*** ISSN 1007-9327

# Instructions to authors

## GENERAL INFORMATION

*World Journal of Gastroenterology* (*WJG, World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc.*, from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

### *Indexed and abstracted in*

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

### *Published by*

The WJG Press

## SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

### *Online submission*

Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

### *Postal submission*

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

### Editorial Office

***World Journal of Gastroenterology***
Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com
Telephone: +86-10-85381901
Fax: +86-10-85381893

## MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

### *Title page*

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

### *Abstract*

An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc.* should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

### *Key words*

Please list 5-10 key words that could reflect content of the study mainly from *Index Medicus*.

### *Text*

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

### *Illustrations*

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 85 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

### *Tables*

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

### *Notes in tables and illustrations*

Data that are not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ should be noted ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used. Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under

illustrations should be expressed as $^1F$, $^2F$, $^3F$; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.* in a certain sequence.

### *Acknowledgments*

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

## REFERENCES

### *Coding system*

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24 ], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

### *PMID requirement*

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (http://www.wjgnet.com/cgi-bin/index.pl), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

### *Style for journal references*

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (http://www.aushome.cn/cgi-bin/index.pl)

### *Style for book references*

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

### *Inappropriate references*

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

### *Statistical data*

Present as mean ± SD or mean ± SE.

### *Statistical expression*

Express $t$ test as $t$ (in italics), $F$ test as $F$ (in italics), chi square test as $\chi^2$ (in Greek), related coefficient as $r$ (in italics), degree of freedom as $\gamma$ (in Greek), sample number as $n$ (in italics), and probability as $P$ (in italics).

### *Units*

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, $p$(B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; $CO_2$ volume fraction, 50 mL/L $CO_2$ not 5% $CO_2$; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

***Abbreviations***

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

***Italics***

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H pylori, E coli, etc.*

## SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

***Language evaluation***

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

***Copyright assignment form***

Please downloaded CAF from http://www.wjgnet.com/wjg/help/9.doc.

We certify that the material contained in this manuscript:

**Ms:**

**Title:**

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to WJG all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

**Criteria for authorship:** The WJG requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1)direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3)supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The WJG does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to WJG if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

## Abstract

Our relationship with the colonic bacterial flora has long been viewed as benign, but recent studies suggest that this symbiosis has risks as well as benefits. This relationship requires that the host not only provide a supportive environment for the symbiotic bacteria, but also actively maintain intact mechanisms for properly managing the physiologic stresses that are closely associated with the symbiont's essential survival functions. Failure to do so breaches the host-symbiont contract, and can result in serious effects on the health of the host. Recent investigations that employ several knockout mouse models reveal the consequences of genetic deficiency in the host regarding these mechanisms, and the latent, pro-inflammatory, tumorigenic nature of normal bacterial flora. Further study of the interactions between normal bacterial flora and hosts could shed light on the etiologies and pathogenesis of inflammatory diseases and related cancers, with implications for human health.

**Key words**: Commensal bacteria; Chronic inflammation; Colon cancer; Germfree mice; Gene knockout

## INTRODUCTION

Our relationship with the colonic bacterial flora has long been viewed as a symbiotic one. We provide a nutrient-rich habitat, while the bacteria play important roles in the development of the mucosal immune system, the maintenance of a physiological environment, the provision of essential nutrients, and the prevention of colonization by pathogenic bacteria[1,2]. Recently, the concept that normal bacterial flora are essential for the development of inflammation-induced carcinoma has emerged from studies of well-known colonic bacterial floras. This hypothesis is reviewed here because the lessons learned from investigations of the colonic flora could serve as a general guide to studies of the etiology and pathogenesis of chronic inflammatory diseases and related cancers in the gastrointestinal tract. These include conditions such as reflux esophagitis and esophageal adenocarcinoma, and *Helicobacter* gastritis and gastric adenocarcinoma and lymphoma, as well as inflammatory bowel diseases (IBD) and colorectal cancer.

Human colorectal carcinomas can be classified by etiology as inherited (e.g., hereditary nonpolyposis colorectal cancer due to genetic instability and familial adenomatous polyposis coli due to a mutation in the adenomatous polyposis coli gene, APC), inflammatory (e.g., Crohn's disease and ulcerative colitis), or sporadic (accounting for greater than 80% of colorectal cancers, but poorly defined etiologically). The availability of genetically-engineered rodent models has greatly facilitated the etiologic study of colorectal cancers.

### *The normal bacterial flora is a prerequisite for the development of inflammation-related colorectal tumors*

The role of bacteria in the development of colorectal tumors is best exemplified by the experimental dysplasia and cancer developed in the TCRβ/p53 double knockout mouse colitis model that mimics the development of adenocarcinoma in ulcerative colitis[3]. In conventional mice at four months of age, adenocarcinomas of the ileocecum developed in 70% of animals. However, there was no development of colonic adenocarcinoma in mice raised under germ-free housing conditions. A similar observation was also made in IL-10 knockout[4] and Gpx1/Gpx2[5] double knockout mice (Table 1). There is a growing list of genetically-engineered mouse models for gastrointestinal cancers, for which the effect of the normal bacterial flora on tumorigenesis has not yet been evaluated (Table 1)[6].

These include knockouts of the G protein subunit alpha i2 (Gαi2)[7], Smad3[8], Muc2[9], and double knockouts of TGF-β1/Rag2[10,11] and IL-2/β2m[12].

Comparison of the results for conventional and germ-free mice indicates that hosting a beneficial bacterial flora is not cost-free. The symbiotic contract that has evolved between the bacterial flora and its host includes obligations-it requires that the host actively maintain intact mechanisms for properly managing the physiologic stresses that are closely associated with essential survival functions of the symbiotic bacteria. These stresses include the generation of oxygen free radicals in basic metabolic pathways and the production of proinflammatory bacterial structures, among others. The health of the host thus depends on preserving functional genes for handling peroxidative stress, bacterial antigens, and inflammation, as well as on the maintenance of an intact mucosal barrier.

The serious consequences of this contract between host and symbiont become evident in its breach. Heretofore considered quite benign, the normal bacterial flora has been shown in recent studies with knockout mouse models to harbor latent tumorigenic potential. An imbalance in the host-symbiont relationship can trigger this hidden potential, to the detriment of the host. It is reasonable to suppose that similar pathways operate in the human body.

### The normal bacterial flora is a prerequisite for the development of inflammation in the colon

Though most genetically-engineered mouse colon cancer models have not yet been tested under germ-free conditions, they present the common picture of a close association between inflammation and cancer development. There are several studies on the development of inflammation in these models under germ-free conditions (Table 2).

One of the best-characterized models in this respect is the IL-10-deficient mouse. Interleukin-10 (IL-10) affects the growth and differentiation of many hemopoietic cells *in vitro*; in particular, it is a potent suppressor of macrophage and T cell functions. IL-10-deficient mice showed increased morbidity and mortality when exposed to normal bacterial flora. All male IL-10-deficient mice housed under conventional conditions died by 4 mo, while 50% of females remained alive. In contrast, both male and female IL-10-KO mice were healthy when housed under germ-free conditions (up to 8 mo). Marked inflammation was observed in the conventional IL-10-deficient mice. Abnormal changes included: (1) thickening of the mucosa, (2) disorganization and hyperplasia of crypts, (3) epithelial erosion/ulceration, (4) accumulation of bacteria, (5) marked infiltration of leukocytes, and (6) crypt abscess formation. None of these inflammatory changes were found in the germ-free IL-10-deficient animals[13,14]. Neutrophil chemokine KC was produced by epithelial cells in response to the inflammatory mediators TNF-alpha and IFN-gamma that were expressed following exposure to normal flora in animals lacking IL-10[13]. Inducible nitric oxide synthase (iNOS) had no impact on the development or severity of spontaneous chronic inflammation in IL-10-deficient mice[15]. In contrast to other genetically-engineered rodents, germ-free IL-2-deficient mice were not free of inflammation. They developed mild inflammation, but remained clinically healthy during observation periods of up to 46 wk with no mortality[16]. In contrast, specific pathogen-free IL-2-deficient mice developed massive mononuclear infiltration with frequent crypt abscesses, and usually died between 28 and 32 wk of age. The enteric bacterial flora was also required for the development of inflammation in HLA-$B_{27}$/β2m transgenic rats and TCRα-deficient mice[17,18]. Mice deficient in the multiple drug resistance (mdr) gene (*mdr1a*) were susceptible to developing a severe, spontaneous intestinal inflammation when maintained under specific pathogen-free animal facility conditions. This model has not been tested under nonspecific germ-free conditions, but treating *mdr1a*-deficient mice with oral antibiotics both prevented the development of disease and resolved active inflammation, supporting the hypothesis that the enteric bacterial flora is required for colonic inflammation[19]. Similar to *mdr1*a-deficient mice, colitis in keratin 8-deficient mice was amenable to antibiotic therapy[20]. These studies indicate an essential role for the normal bacterial flora in the pathogenesis of inflammation.

Colonic inflammation could also be induced with Tgfβ1/Rag2, Smad3, Gαi2, or cytokeratin 8 gene knockouts[7,8,11,21], but the effect of the normal enteric bacterial flora on the development of inflammation has not been examined under germ-free conditions in these models (Table 2).

**Table 1 Effect of colonic bacterial flora on the development of gastrointestinal cancers in genetically-engineered mice**

| Gene | Function | Incidence of carcinoma (%) | |
|---|---|---|---|
| | | Conventional | Germ-free |
| TCRβ/p53[3] | Cellular immunity/ growth and division | 70 | 0 |
| IL-10[4] | Anti-inflammation | 7 | 0 |
| Gpx1/Gpx2[5] | Peroxidative stress | 25 | 0 |
| Gαi2[7] | Cellular signaling | 31 | ND |
| Smad3[8] | Tgfβ signaling | 100 | ND |
| Muc2[9] | Major component of the mucus | 69 | ND |
| Tgfβ1/Rag2[10,11] | Anti-inflammation/antigen receptor rearrangement | 100 | ND |
| IL-2/β2m[12] | Proinflammation | 32 | ND |

ND: Not determined.

### The bacterial flora as a whole is important in colonic inflammation and tumorigenesis

Abundant data have implicated intestinal bacteria in the initiation and amplification stages of inflammatory bowel diseases. However, the precise role of intestinal bacteria remains elusive. One theory is that both "protective" species and "harmful" species exist within the normal enteric bacterial flora. A healthy balance between these two populations in a normal host might be detrimental for an inflammation-prone host. Alternatively, a breakdown in the balance between the two populations, termed "dysbiosis", could by itself promote inflammation in a normal host.

**Table 2 Effect of colonic bacterial flora on the development of intestinal inflammation in genetically-engineered rodents**

| Gene | Function | Type of inflammation | |
|---|---|---|---|
| | | Conventional | Germ-free |
| IL-10[13,14] | Anti-inflammation | Neutrophilic, severe, death | Negative |
| IL-2[16] | Proinflammation | Lymphocytic, severe, death | Mild, focal |
| HLA-B27/β2m[17] | Human leukocyte antigen/MHC β chain | Lymphocytic, severe | Negative |
| TCRα[18] | T cell receptor α chain | Lymphocytic | Negative |
| Gαi2[7] | Cellular signaling | Lymphocytic, plasmacytic | ND |
| Tgfβ1/Rag2[11] | Anti-inflammation/antigen receptor rearrangement | Granulocytic | ND |
| mdr1a[19] | ABC transporter | Lymphocytic, granulocytic | ND |
| K8[20] | Major intermediate filament protein | Lymphocytic | ND |
| Smad3[21] | Tgfβ signaling | Lymphocytic | ND |

ND: Not determined.

The pathogenic role of the normal enteric bacterial flora in the development of enterocolitis and colon cancer has been implicated in C57BL/6 IL-10-knockout mice. Probiotic Lactobacilli modify the enteric flora and are thought to have a beneficial effect on enterocolitis. Treatment of IL-10-deficient mice with the probiotic *Lactobacillus salivarius* ssp. *salivarius* UCC118 reduced the intensity of mucosal inflammation and the incidence of colon cancer from 50% to 10%. These effects were accompanied by significant reductions in fecal coliform, enterococci, and *Clostridium perfringens* levels[22]. This study exemplifies the effect of changes at the flora level on the development of inflammation, and supports the hypothesis that there are "protective" species and "harmful" species in the normal bacterial flora.

Human studies using culture techniques have linked populations of *Bacteroides vulgatus*, *Eubacterium rectale*, *Ruminococcus torques, Streptococcus hansenii, Bifidobacterium longum, Ruminococcus albus, Peptostreptococcus productus, Bacteroides stercoris, Bifidobacterium angulatum, Eubacterium eligens, Ruminococcus gnavus, Fusobacterium prausnitzii, Eubacterium cylindroids* to a high risk of colon cancer. The fact that *Bifidobacterium longum* and *Bifidobacterium angulatum* and the total concentrations of bifidobacteria also are significantly associated with a high risk of colon cancer is contrary to suggestions that the ingestion of *bifidobacterium* cultures acts to increase the numbers of intestinal floral bacteria that might offer increased protection against colon cancer[23-25]. *Lactobacillus* S06 and *Eubacterium aerofaciens* and total lactobacillus concentrations were significantly associated with a low risk of colon cancer[26].

Further studies of the population differences between normal and disease states might illuminate the contribution of specific flora changes to disease development.

### *The bacterial flora potentiates tumor formation independent of inflammation*

Mutation of the APC gene leads to the development of multiple intestinal neoplasia (Min), especially in the small intestine, with little inflammation[6,27]. Germ-free Min mice developed 50% fewer adenomas in the small intestine, although there were no significant differences in the remainder of the intestinal tract[28]. This model suggests that commensal bacteria are not required, but can potentiate tumor formation independent of inflammation.

### *Specific bacterial infection promotes colonic tumor formation in genetically susceptible mice*

Although resident enteric bacteria are necessary for the development of spontaneous colitis in many rodent models, not all bacteria have an equivalent capability to induce inflammation. Germ-free IL-10-deficient mice populated with bacterial strains, including *Bacteroides vulgatus*, *Clostridium sordellii*, *Streptococcus viridans*, *Escherichia coli, Lactobacillus casei, Lactobacillus reuteri, Lactobacillus acidophilus*, *Lactobacillus lactis,* a *Bifidobacterium* sp., and a *Bacillus* sp., did not exhibit significant colitis[4,14,29].

Conventional IL-10-deficient mice suffered from chronic enterocolitis[30]. In contrast, mutants kept under specific pathogen-free conditions developed only a focal inflammation limited to the proximal colon. These results suggest that the bowel inflammation in the mutants was stimulated by single or multiple specific bacterial species. *Citrobacter rodentium*, *Helicobacter hepaticus*, *Enterococcus faecalis* are examples of conditional cancer-causing bacteria that alone do not cause cancer, but are carcinogenic in certain genetically-engineered mice.

*Citrobacter rodentium* is a gram-negative bacterium that colonizes predominantly the distal colon of mice, causing a disease termed transmissible murine colonic hyperplasia (TMCH). This condition induces colitis and crypt cell proliferation, similar to that seen in human idiopathic inflammatory bowel diseases, including Crohn's disease and ulcerative colitis[31]. Infection with *C. rodentium* has not yet been associated with tumorigenesis, but TMCH promoted colon tumor development in mice administered the carcinogen DMH[32]. $Apc^{Min/+}$ mice infected with *C. rodentium* at 1 mo of age had a 4-fold increase in the number of colonic adenomas at 6 mo of age, as compared with uninfected Min mice[33].

*H. hepaticus* is a newly recognized bacterium associated with chronic active hepatitis, hepatic carcinoma, and inflammatory bowel disease in mice. *H. hepaticus* infection did not cause colon cancer in mice in the absence of an inflammatory trigger[34]. Germ-free and specific pathogen-free TGFβ1/Rag2-deficient mice were free of inflammation, hyperplasia, and cancer, but when reintroduced into a *H. hepaticus*-containing specific

pathogen-free room, developed colonic adenoma/carcinoma[11,35]. *H. hepaticus* in pure culture did not seem to induce IBD in IL-10 KO mice[36], suggestive of an essential collaboration between *H. hepaticus* and normal bacterial flora in the observed etiology.

*Enterococcus faecalis*, previously known as group D S*treptococcus* or *Streptococcus faecalis*, is an opportunistic pathogen that is found in the alimentary tract of both humans and animals. Its notorious capacity to acquire virulence factors and antibiotic resistance genes have made this opportunistic bacterium a major problem for patients and clinicians[37]. Inflammation, dysplasia, and rectal carcinoma developed in IL-10 KO mice colonized with *E. faecalis*, but not in germ-free mice[4].

### *Unusual bacterial infections associated with colorectal cancer in humans*

Although there is no established bacterial pathogen for human colorectal cancer, unusual infections might precede the clinical diagnosis of cancer in some instances.

*Streptococcus infantarius*, formally known as *Streptococcus bovis* or Non-enterococcal Group D S*treptococcus*, is a constituent of the human enteric flora. It is the causative agent in 5%-14% of endocarditis cases. Individuals with colon cancer had higher fecal carriage of *S. bovis* as compared to patients with nonmalignant enteric disease and healthy controls[38]. Panwalker reviewed 467 cases of adult *Streptococcus bovis* bacteremia[39]. Malignant colonic tumors were present in 62 of the 467 patients (13%). In some cases, the bacteremia will occur months or years after this species becomes established. It is not known whether the *S. bovis* carriage has any direct cause-and-effect relation to colon cancer. In azoxymethane-treated rats, administration of either *S. bovis* or its wall-extracted antigens promoted the progression of preneoplastic lesions through an increased formation of hyperproliferative aberrant colonic crypts, enhanced the expression of proliferation markers, and increased the production of IL-8 in the colonic mucosa, suggesting that *S. bovis* acts as a promoter of early preneoplastic lesions in the rat colon. It is interesting that bacterial cell wall proteins were more potent inducers of neoplastic transformation than were the intact bacteria[40]. When a cell wall protein fraction composed of 12 different proteins was applied to human epithelial colonic Caco-2 cells or the rat colonic mucosa, it was able to trigger the release of CXC chemokines (human IL-8 or rat CINC/GRO) and prostaglandin E2, which are correlated with an *in vitro* over-expression of COX-2. Moreover, these proteins were highly effective in the promotion of preneoplastic lesions in azoxymethane-treated rats. In the presence of these proteins, Caco-2 cells exhibited enhanced phosphorylation of MAP kinases. These data suggest that bacterial components possess both proinflammatory properties and procarcinogenic potentials, and support the hypothesis that colonic bacteria can contribute to cancer development, particularly in association with chronic infection/inflammation diseases where these bacterial components might interfere with cell function[41].

*Clostridium septicum* infections are rare, but are often associated with malignancy. This association has been discussed in a number of case reports[42]. In a review of 162 published cases of *C. septicum* infection in 1989, 81% had an associated malignancy, 34% had an associated colon carcinoma, while 40% had an associated hematologic malignancy[43]. A consequence of these close associations is that in patients for whom a *C. septicum* infection is diagnosed, a rigorous search for occult malignancy should be mounted. It is yet to be determined whether these associations represent a cause-and-effect relationship or a secondary phenomenon.

For both *S. bovis* and *C. septicus*, a question remains whether the bacteria induce bowel cancer or if the growth of the organisms is promoted by a preexisting carcinoma. Testing their carcinogenicity in genetically-engineered immunodeficient mouse models might shed light on our understanding of the role of bacteria in the development of human cancers.

## SUMMARY AND PERSPECTIVE

Traditional bacteriology is built upon concepts developed from studies of infectious diseases in which a pathogen can often be identified and pathogenesis explained by toxins or virulent factors. These concepts have clearly demonstrated their usefulness in the identification of etiologic agents of anthrax in the nineteenth century and *Helicobacter* gastritis more recently, among many others. Recent studies of tumorigenesis in rodent models have opened a new chapter in bacteriology, with the observation that the normal bacterial flora actively participates in the development of cancers. Searching for the responsible agents among normal flora bacteria, albeit not classic pathogens, is still a reasonable approach in the assessment of bacterial roles in chronic inflammatory disorders and related cancers. Support for this approach is found in evidence that certain bacterial species are required for tumorigenesis in genetically deficient rodent models, and in the association of specific bacterial species with human cancers.

The capacity for causing inflammation or cancers that is exhibited by a complex bacterial flora might depend on the aggregate activity of multiple constituents of the flora, rather than on a single species. This capacity might be enhanced or reduced as a function of significant changes in the species diversity and abundance within the flora. Thus, more detailed knowledge of how the bacterial flora is altered in association with disease conditions could significantly broaden our understanding of the etiology and pathogenesis of these diseases. In the past, the connection between a heterogeneous bacterial flora and a disease was often regarded as too complex to interpret. However, recent advances in 16S rDNA technology, DNA sequencing, and data analysis tools have made it possible to determine the differences between two diverse bacterial flora by defining and comparing the majority of bacterial species and their prevalence in each flora[2,44,45].

Alternatively, the host might also play a decisive role here. Colon cancers might develop in a genetically deficient host in the presence of a normal bacterial flora, without any requirement for specific bacterial species or alteration of the flora. No human counterparts of the critical gene

defects artificially created in rodents have been identified, but it is plausible that weak defects or polymorphisms of human genes that might not be aberrant enough to confer an overt clinical disease could, in collaboration with a normal bacterial flora, lead to cancers in a patient over a period of decades. Future investigations could seek to discover any relevant weak gene defects in human patients, and correlate them with long-term pathogenesis.

The present studies in rodent models of the role of the bacterial flora in tumorigenesis obviously raise some interesting possibilities in relation to human cancers. Can the concepts derived from bacterial flora in colon cancers be extrapolated to cancers in other anatomic sites where cancer development is related to chronic inflammation, such as gastric adenocarcinoma in *H pylori* gastritis, esophageal adenocarcinoma in reflux esophagitis, or oral squamous cell carcinoma in periodontitis? Can the natural history of cancer development be altered toward the benefit of hosts by manipulation of bacterial flora using probiotic and antibiotic therapies or vaccination? The potential contributions to improving human health make finding the answers to these questions a clear priority for future research.

## Abstract

Colorectal cancer is a major public health burden worldwide. There is clear-cut evidence that screening will reduce colorectal cancer mortality and the only contentious issue is which screening tool to use. Most evidence points towards screening with fecal occult blood testing. The immunochemical fecal occult blood tests have a higher sensitivity than the guaiac-based tests. In addition, their automation and haemoglobin quantification allows a threshold for colonoscopy to be selected that can be accommodated within individual health care systems.

**Key words:** Screening; Colorectal cancer; Fecal occult blood testing; Colonoscopy

## INTRODUCTION

Colorectal cancer is a major public health burden. It is the fourth most common form of cancer worldwide and the most frequent in North America, Australia, New Zealand, Argentina, and parts of Europe[1]. When colorectal cancer is detected at an early stage, the prognosis is excellent with a five year survival in excess of 97%[2]. The risk of nodal metastases and thus poorer prognosis increases as colorectal cancer develops with a risk of 2%-3% when confined to the submucosa compared with 8%-12% when confined to the muscularis propria[3,4]. The evidence that screening for colorectal cancer leads to earlier detection and improved survival is now incontrovertible and has led to a consensus that colorectal cancer screening will reduce mortality; however there is no consensus as to the best screening tool[5-11]. The four possible screening options currently cited are barium enema, fecal occult blood testing or fecal occult blood testing (FOBT), sigmoidoscopy, colonoscopy, or a combination thereof. Cost-effective analyses do not help distinguish between the strategies with the median incremental cost-effectiveness ratios being €9950/life-year saved, €13 200/life-year saved, and €10 000/life-year saved, for FOBT, sigmoidoscopy, and colonoscopy respectively compared with no screening[12].

Inadequate screening capacity is an important barrier to consider in colorectal cancer screening. Colonoscopy is the final pathway of all colorectal cancer screening. Depending on which fecal test is used, 2%-15% of participants will need a colonoscopy[13]. Between 5%-10% of participants undergoing screening flexible sigmoidoscopy screening will need a colonoscopy[14]. If colonoscopy is used as the screening option then potential annual demand for screening colonoscopy can be calculated at 45%-50% of those aged 50-70 years[15]. The endoscopy capacity of a health care system carries significant weight when deciding the best screening tool.

## BARIUM ENEMA

There are drawbacks to each of the screening options. Although double contrast barium enema is recommended for screening no published studies of its efficacy in this role exist. The sensitivity of barium enema for polyps > 1 cm is 48% and for colorectal cancer 82.9%[16,17]. Despite the presence of barium enema in screening guidelines, its place lies for those individuals who have had a failed colonoscopy rather than as a screening tool.

## SIGMOIDOSCOPY

Sigmoidoscopy is an attractive option as it takes only five minutes, requires no sedation and only a self-administered enema to clear the bowel. In a pivotal retrospective case controlled study those with colorectal cancer were less likely to have had a prior sigmoidoscopy than the control group with an odds ratio of 0.3[8]. Four flexible sigmoidoscopy trials were carried out on the strength of retrospective studies[10,18-20]. Long-term follow up was available from only one of these studies with a reduction in colorectal cancer incidence and mortality of 80% and 50% respectively over 13 years[10]. Much controversy has surrounded the question of right-sided colonic lesions missed by sigmoidoscopy. In men sigmoidoscopy failed to identify 29.7% of advanced colonic lesions and in women 65.3%[21,22]. As a consequence, a very persuasive argument against sigmoidoscopy has been the claim that screening flexible sigmoidoscopy is as illogical as screen-

ing only one breast during mammography[23]. In reality, just 2%-5% of asymptomatic individuals are believed to have isolated advanced proximal neoplasia[24]. The real concern surrounding sigmoidoscopy is its acceptance rate and its invasiveness as a screening test in asymptomatic individuals. In studies, which represent the ideal clinical situation, the acceptance rate varies from 33%-80%[10,18,19]. Screening sigmoidoscopy is an invasive procedure and is associated with risks which may not be acceptable in asymptomatic individuals: a perforation rate of 1 in 25 000, bleeding in 3.2%, and pain in 14%[25,26].

## COLONOSCOPY

Evidence-based guidelines place greatest weight on large-scale randomized trials, but the corroboration for colonoscopy comes from indirect evidence or small case-control studies. The US National Polyp Study and the Italian multi-center study showed a reduction in colorectal cancer incidence of 75%-90% over a follow-up period of 5.9 and 10.5 years respectively[9,27]. However, the primary aim of both studies was to determine the effects of resecting colorectal polyps on colorectal cancer incidence. Case-control studies have evaluated the feasibility of colonoscopy in colorectal cancer screening with advanced lesions detected in 10.5%-12.5% of asymptomatic individuals[28,29]. It should be born in mind that both studies enrolled individuals who wished to participate in colorectal cancer screening, and population-based studies reveal that the acceptance rate for colonoscopy is less than 20%[30,31]. For any screening test to be effective the acceptance rate must be over 60% and the acceptability of colonoscopy to the population may limit its usefulness as a screening tool. In addition, in clinical practice the yield from screening colonoscopy in average-risk individuals has been lower than case control studies with only 5.1% having a polyp > 9 mm[32]. The sensitivity of colonoscopy for colorectal cancer and polyps may have been over-estimated. In retrospective studies and prospective FOBT screening trials the sensitivity of colonoscopy for colorectal cancer is over 95%[17,33]. Back-to-back colonoscopy studies reveal that the miss rates for polyps > 1 cm is 0%-6%[34,35]. Virtual colonoscopy followed by colonoscopy reveals a miss rate of 12% for polyps > 1 cm[36]. Colonoscopy technique is of crucial importance in detection rates. In particular, the quality of bowel preparation and colonoscopy withdrawal times have been identified as factors impacting on colonoscopy detection rates[37-39]. Indeed, improving the quality of colonoscopy techniques is estimated to reduce interval cancers by up to 50%[40]. Finally as with sigmoidoscopy, colonoscopy is an invasive procedure and may not be acceptable as a screening tool in asymptomatic individuals. Although the risk associated with a single colonoscopy is small with a 0.2%-0.3% risk of serious complication and a 0.1% risk of death, the cumulative risk of repeat screening colonoscopy may outweigh the benefit obtained from screening colonoscopy[41].

## FECAL OCCULT BLOOD TESTING

The most robust evidence for the effectiveness of colorectal cancer screening lies with FOBT. Long-term follow up available in four randomized controlled trials of over 330 000 individuals and three non-randomized trials of just over 200 000 individuals reveals a reduction in colorectal cancer mortality of 12%-33%. Adjusting for compliance gives a 23% reduction in colorectal mortality with guaiac-based FOBT[5-7,42-44]. It is sometimes claimed that the mortality reduction in the American study is attributable to the high colonoscopy rate of 28%-38%[6]. However only 4% of individuals in the European studies, and just over 6% of individuals in the Chinese study underwent endoscopy[5,7,43].

The sensitivity of FOBT is often seen as a liability, and it is true that the once-off sensitivity of FOBT for colorectal cancer ranges from 26%-69%, and for adenomas ranges from 9%-36%[13,21,45]. Yet FOBT screening involves repeated testing at 1-2 yearly intervals and within this context the programme sensitivity of FOBT for detecting cancer is as high as 90%[6]. From an acceptability point of view FOBT is non-invasive, can be carried out at home, and does not necessitate any bowel preparation or taking time off work.

Guaiac-based FOBT depends on fecal blood to catalyze the phenolic oxidation of guaiac in the presence of hydrogen peroxide to produce a blue chromogen. Immunochemical FOBTs use antibodies specific for human haemoglobin and have a higher sensitivity of 66%-90% and a specificity > 90%[46,47]. Immunochemical FOBTs have evolved further with the development of quantitative results, thus allowing the positivity threshold to be varied and achieve an increased sensitivity with lowered specificity or a decreased sensitivity with an increased specificity[48,49].

## ALTERNATIVE SCREENING TOOLS

Virtual colonoscopy, despite improvements in technology, continues to show widely varying results with sensitivities for detecting polyps ⩾ 10 mm ranging from 55% to 92%[36,50]. As such it is still not ready for population screening. Fecal calprotectin failed to live up to its initial promise in subsequent studies[51]. Fecal DNA tests are affected by the relatively low frequency of single marker alterations in colorectal cancer. Even the use of a broad panel of markers in fecal DNA still fails to be convincing for population screening[52].

## CONCLUSION

Screening will reduce the mortality from colorectal cancer and should be implemented now. For those at average risk of developing colorectal cancer most evidence points towards screening with FOBT. Depending on which FOBT is used, between 2%-15% of individuals screened will need colonoscopy, a figure that can be accommodated without too much difficulty.

## Abstract

In the past, Crohn's disease (CD) has been understood primarily as an immunologic disorder characterized by an abnormal T-cell response. Recent *in vitro* and *in vivo* data suggests that CD may instead be precipitated by innate immune dysfunction resulting from a combination of genetic and environmental factors. Some reports have demonstrated a defective immune response in a variety of other cellular components, including neutrophils, monocytes and dendritic cells. Recent studies of granulocyte-macrophage colony-stimulating factor (GM-CSF) in CD, aiming to stimulate the innate immune system with the conception that an innate immune defect underlies the development of the disease, have been demonstrated a clinical benefit and reinforce this evolving understanding of the disease.

**Key words:** Crohn's disease; Innate immunity; Immunodeficiency; NOD2

## INTRODUCTION

Over a period of many years Crohn's Disease (CD) has been thought to result predominantly from excessive activation of type 1 helper T cells (TH1) with a characteristic cytokine profile including elevated interferon-γ and IL-2. However the pathways by which T cells became activated have remained an unsolved dilemma. Collectively recent studies using cell and animal models as well as studies of individuals with CD suggest that an aberrant innate immune response to luminal bacteria may be a critical initiating step in the development of the disease. These studies suggest that in at least some individuals with CD, innate immune responses are paradoxically impaired compared to normal controls.

## NOD2/CARD15 FUNCTION AND EFFECT OF ITS MUTATIONS

Improved, albeit still incomplete, understanding of the function of NOD2/CARD15 have been particularly key to an appreciation of the importance of innate immune dysfunction in CD. NOD2 is expressed constitutively in macrophages, neutrophils and dendritic cells[1], as well as in Paneth and epithelial cells[2]. NOD2 is a cytoplasmic protein that serves as a microbial sensor, and its leucine-rich repeat (LRR) domain is required for recognition of muramyl dipeptide (MDP), a fragment of peptidoglycan present in bacterial cell walls. The ligand MDP ultimately leads to activation of the transcription nuclear factor (NF-κB), and induction of proinflammatory cytokines[3,4]. Membrane recruitment of NOD2 is essential for NF-κB activation after the recognition of MDP in intestinal epithelial cells and is mediated by a motif comprising two leucine residues and a tryptophan in the COOH-terminal domain of NOD2[5]. Evidence that NOD2 may function as an antibacterial factor in intestinal epithelial cells was demonstrated in Caco-2 cells stably expressing wild type NOD2 when infected with *Salmonella typhimurium*. This protective effect was lost in cells expressing a most common mutant NOD2 associated with CD (3020insC)[6].

Specific mutations of the NOD2 gene have been definitively associated with increased susceptibility to ileal Crohn's disease in Western (but not Asian) populations: Arg702Trp, Gly908Arg, and leu1007fsinsC (a frameshift mutation that truncates the carboxy terminal 33 aminoacids)[7,8]. Heterozygous carriage of the risk alleles confers a 2-4 fold increased risk, and homozygotes or compound heterozygotes have a 20-40 fold increased risk [9]. More than 90% of all CD associated mutations are located in the LRR domain, suggesting that these may affect the function of NOD2 with respect to bacterial recognition and signaling. Transient transfection experiments indicate that CD-associated NOD2 mutants no longer activate NF-κB in response to MDP[3,10], which suggests that defective NF-κB activation facilitates infection of the lamina propia by enteric bacteria.

Abbott DW *et al*[11] demonstrated that NOD2 activation leads to ubiquitinylation of NEMO, a key component of the NF-κB signaling complex. They showed that NOD2-

dependent ubiquitinylation of NEMO is dependent on the scaffolding protein kinase RIP2. Crohn's disease-associated mutants of NOD2 exhibited a decreased ability to bind RIP2, and this decreased ability to bind RIP2 correlates with a decreased ability to ubiquitinylate NEMO.

NOD2 mutants produce selective functional defects in leukocytes of patients with CD as shown by van Heel *et al*[12] who analyzed cytokine expression of peripheral blood mononuclear cells after exposure to MDP. In PBMC from CD patients the NOD2 ligand induced little TNFα and IL-1β, but strong IL-8 secretion. Futhermore, monocytes isolated from CD patients carrying the 1007fs (3020insC) mutation were reported to exhibit defects in the production of the proinflammatory cytokines, TNFα, IL-6 and IL-8, as well as the anti-inflammatory cytokine IL-10[13]. Dendritic cells derived from CD patients homozygous for leu1007fsinsC also fail to up-regulate the costimulatory molecules CD80 and CD86 in response to MDP and lack production of cytokines such as TNF-α, IL-12 and IL-10[14].

## RELATION OF NOD2 AND TLR PATHWAYS

Intersection between TLR and NOD2 pathways is suggested by reports of synergistic induction of proinflammatory cytokines such as TNFα and IL-1β upon costimulation with MDP and specific TLR ligands[15,16]. MDP also substantially upregulated secretion of TNFα and IL-1β induced by ligands to five different TLR ligands, TLRs 2, 4, 5, 7 and 9: ($Pam_3CysSerLys_4$, LPS, Flagellin, MALP-2 and R-848, respectively). Of note, these effects were observed in the presence of the most common NOD2 mutants associated with CD. In studies using mice lacking NOD2, Watanabe *et al*[17] observed reduced responses to MDP, but enhanced responses to the TLR2 ligand, peptidoglycan e.g. increases in IL-12. They interpreted these findings to suggest that the NOD2 signaling pathways normally downregulate the TLR2 pathways. In their model, loss of function mutation of NOD2 together with TLR2 signals delivered by other bacterial products could result in enhanced cytokine responses to commensal bacteria by macrophages. These findings suggest that interaction between NOD2 and specific TLR pathways may represent an important modulatory mechanism of innate immune responses which is altered in some patients with CD.

However, controversy remains about the role of NOD2 and the interactions between NOD and TLR signaling pathways. While these results suggest that this NOD2 mutation may have enhanced responsiveness to bacterial peptidoglycan, interpretation of the significance of these findings remains controversial, because transient transfection assays using the CD-associated NOD2 mutants, as described above, have consistently shown defective cytokine responses to MDP and decreased activation of NF-κB[18]. In contrast to Watanabe *et al* Kobayashi and colleagues[19] did not find upregulation of TLR responses following disruption of NOD2. Kobayashi *et al* did find that mutations in NOD2 in mice affect the expression of small antibacterial proteins called cryptidins (α-defensins in humans) by intestinal epithelial cells. This data is consistent with the notion that NOD2 regulates the production of antibacterial peptides in Paneth cells in the intestinal crypts, and that this may contribute to local control of pathogenic bacteria (Figure 1).

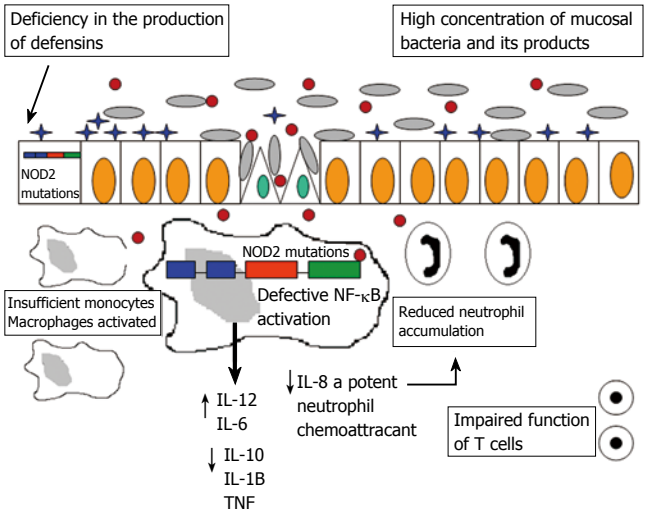

**Figure 1** Impairment of different innate immune mechanisms. These mechanisms play a central role in the homeostasis of intestinal barrier function. Identified environmental risks and genetic susceptibility may contribute to the innate immune dysfunction.

## OTHER POTENTIAL DEFECTS IN INNATE MUCOSAL DEFENSE MECHANISMS IN CD PATIENTS

### *Altered defensin expression in CD*

In general, α-defensins (1-3, 5 and 6) are induced in the colonic mucosa of CD and UC patients. However, NOD2 mutations in CD patients are associated with diminished mucosal α-defensin expression[20]. Decreased β-defensin 1 and the lack of induction of both inducible antimicrobial peptides β-defensins 2 and 3 in CD could result in enhanced bacterial survival and perhaps invasion[21].

### *Neutrophil function in CD*

Neutrophils act as a first line defense at the mucosal-microbial interface by killing and digesting bacteria within phagocytic vacuoles. Neutrophil-mediated clearance of mucosal microbes would prevent activation and recruitment of monocytes/macrophages. Several defects have been described in patients with CD, including impairment in migration of neutrophils[22]; complement dysfunction that produces impaired neutrophil recruitment[23]; decrease of phagocytic and bactericidal neutrophil function[24] and deficient superoxide generation in neutrophils[25].

A number of genetic syndromes with well described defects of the innate immune system may also provide insights into pathophysiology relevant to CD. Patients with glycogen storage disease (GSD) Ib[26,27], chronic granulomatous disease (CGD)[28], Chediak Higashi syndrome[29], Hermansky-Pudlak syndrome[30] leukocyte adhesion deficiency[31], Turner's syndrome[32], and

congenital[33], cyclic[34] and autoimmune[35] neutropenias can all manifest features of CD or CD-like phenotype[36]. Each of these syndromes comprises a quantitative or qualitative deficiency in the function of neutrophils, monocytes, or macrophages, suggesting that varied functional cellular deficiencies can result in a common intestinal phenotype of CD.

The finding that two murine lines with disruption of either CCAAT/enhancer binding protein (CEBP)-ε[37] and a cell-type specific disruption of the Stat3 gene in neutrophils and macrophages[38] develops enterocolitis, support the role of the neutrophil and the macrophage in the development of CD. Stat-3 disrupted mice show an immune response skewed toward Th-1 activity, demonstrating that neutrophil and macrophage dysfunction may eventuate in a Th-1 phenotype.

Thus a variety of studies and clinical insights have suggested that CD may result from an impaired mucosal innate immune response. In the context of these earlier findings, a recent study by Marks *et al*[39] support the hypothesis that the mucosal innate immune system plays a central role early in the development of CD. Marks *et al*[39] found a significantly decreased production of IL-8 and IL-1β (45% and 50% reduction respectively) from macrophages of patients with CD. This defect in the production of these cytokines was independent of the presence of NOD2 mutations and helps to clarify the controversy generated by Li *et al*[40] who reported that the presence of NOD2 mutations showed no induction (Leu1007finsC) or modest induction (Gly908Arg and Arg702Trp) of IL-8 and IL-1β). Macrophages from CD patients produce less IL-8 in response to pro-inflammatory agonists, suggesting that these cells may influence the acute inflammatory response. Impaired secretion of IL-8 appears to result in a failure of neutrophil migration. This finding was confirmed by normalizing neutrophil efflux after augmentation of endogenous IL-8 secretion by topical MDP. The authors suggest that in CD, reduced or delayed recruitment of neutrophils to sites where bacteria penetrate the intestinal wall may result in the persistence of bacteria and other debris in the tissue and lead to the chronic inflammation typical of this disease.

The data of Marks *et al*[39] suggests that CD patients possess a generalized impaired innate immune response as reflected by diminished response to intradermal injection of killed bacteria as well as trauma of the skin or the intestine. When killed bacteria were injected into the forearms of CD patients, there was less blood flow to the injection site than non-CD patients. They also found that CD patients had reduced neutrophil accumulation and interleukin-8 (IL-8) production at sites of tissue trauma in the intestine and skin. This study supports the idea that CD may in some way be associated with relative inability to mount an acute inflammatory response compared to normal individuals.

## THERAPEUTIC APPROACHES

Marks *et al*[39] suggest the provocative notion that IL-8 either by direct enteral administration or through synthesis by genetically modified gut organisms might have therapeutic value. Similarly, they propose that if diminished recruitment of neutrophils is a backdrop to CD, agents that increase blood flow such as long-acting phosphodiesterase-5 inhibitors might be useful in healing or preventing lesions in CD. In support of this possibility, they report that oral administration of sildenafil markedly increased blood flow to sites of bacterial injection in CD patients.

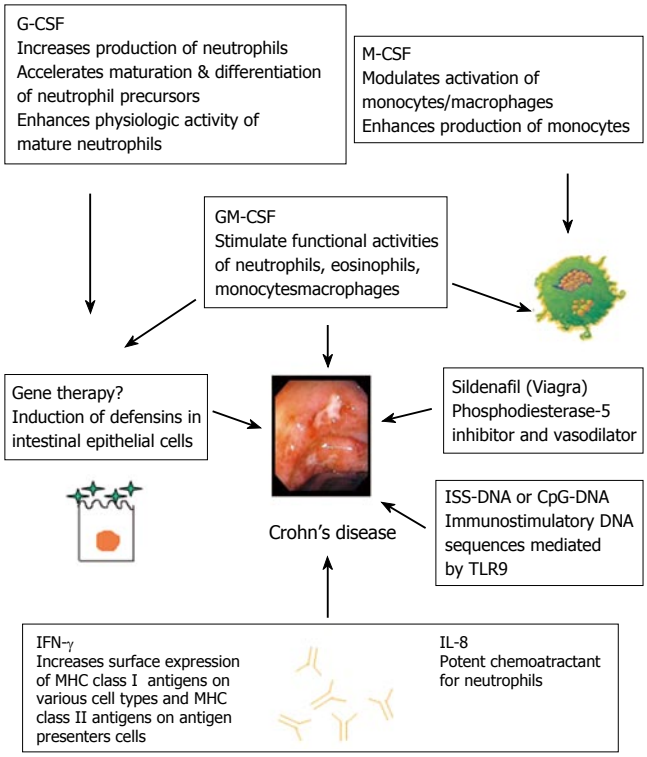

**Figure 2** Targets of immunostimulation therapy in Crohn's disease. Potential therapies encompass interventions focused on augmenting the intestinal innate immune function in different mechanisms of action.

Recent reports suggest that agents which act to enhance innate immune defenses can indeed confer therapeutic benefit. The endogenous growth factor granulocyte-macrophage colony-stimulating factor (GM-CSF) performs important functions in both the phagocytic and epithelial components of intestinal early innate immune defense. GM-CSF is expressed by both CD4+ T cells and Paneth cells in the intestine, and its receptors have been recently demonstrated to be present on intestinal epithelial cells which proliferate in response to GM-CSF *in vitro*[41,42]. Within the immune system, GM-CSF increases phagocytic cell function through its effects on oxidative burst, phagocytosis, and intracellular bacterial killing[43].

In the context of the evolving concepts of CD pathophysiology, these observations provided the rationale for clinical trials of granulocyte colony stimulating factor (G-CSF, specifically filgrastim) and GM-CSF (sargramostim). Both pilot studies suggested a benefit[44,45], though GM-CSF appeared more effective. A recent randomized controlled trial of 124 patients found a significant benefit in response at 100-point decrease in CDAI and in remission. The response was sustained for a mean of 8-10 wk after discontinuation of therapy[46].

While mechanistic studies were not included in the trial, recent translational studies[47] have demonstrated that GM-CSF can reverse several neutrophil impairments in cells obtained from individuals with CD (Figure 2).

In summary, mucosal innate immunodeficiency characterized by impaired dysfunction of neutrophils, monocytes and dendritic cells as well as intestinal epithelium play a critical early role in the development of CD. These defects may arise from a variety of genetic defects which are presumably worsened by environmental factors to culminate in decreased cytokine production and insufficient bacterial killing. Persistence of microbial derived stimuli subsequently leads to T cell activation, accounting for the T cell driven nature of the established disease. This concept would provide insight into why immunosuppression may be effective in some individuals by limiting the secondary, chronic T-cell response, while immune stimulation, possibly with GM-CSF, may also prove to be effective as a general strategy particularly in acute and early phases of the disease. A better understanding of the early initiating events in CD may result in even better therapeutic approaches that enhance the innate immune system.

## Abstract

The pathogenesis of liver damage associated with chronic hepatitis C virus (HCV) infection is thought to be largely immunomediated. However, some frequent histopathological features, such as steatosis, suggest a direct cytopathic effect of HCV. The direct responsibility of HCV in the pathogenesis of steatosis is shown by: (1) the association with HCV genotype 3 infection, suggesting that some viral sequences are involved in the intracellular accumulation of lipids; (2) the correlation between severity of steatosis and HCV replication levels; (3) association between response to treatment and disappearance of steatosis. Experimental studies have shown that the nucleocapsid protein of HCV (core protein) is capable and sufficient to induce lipid accumulation in hepatocytes. Moreover, the observation that chronic hepatitis C patients have reduced serum levels of ApoB suggests an interference with the very-low density lipoprotein (VLDL) assembly, although other mechanisms are possible. In patients with sustained virological response induced by antiviral therapy, such levels are normalized. Other observations suggest that the pathogenesis of steatosis in chronic hepatitis C is not solely due to HCV. The origin of the mild steatosis observed in most patients may be metabolic, since its severity correlates with body mass index and insulin resistance. Most studies have shown a correlation between presence and/or severity of steatosis and fibrosis stage, but it is unclear whether this effect is direct or mediated by the associated insulin resistance, increased susceptibility to apoptosis, or by inflammatory cytokines. Finally, steatosis negatively influences the rate of response to antiviral treatment, as confirmed by large clinical trials. Management of steatosis in chronic hepatitis C requires knowledge of its pathogenesis and may involve both life-style changes and pharmacological interventions, although the latter remain largely experimental.

## INTRODUCTION

The hepatitis C virus (HCV) is a major cause of chronic liver disease with an estimated 170 million people infected worldwide. The spectrum of severity of the liver disease associated with HCV varies widely from non-specific, minimal inflammatory changes to cirrhosis and hepatocellular carcinoma[1]. The rate of progression of chronic hepatitis C is also variable, depending on many cofactors, mostly host-related, such as age, gender, alcohol consumption, overweightness and coinfections[2,3]. Steatosis, defined as an increased fat content of the liver, essentially accounted for by triglycerides, has been recognized as one of these factors capable of influencing both liver fibrosis progression and the rate of response to interferon-alpha-based therapy. Steatosis is a common lesion associated with many conditions affecting the liver, some of which, like overweightness and alcohol consumption, being very frequent. Interestingly, however, the proportion of chronic hepatitis C patients with steatosis is higher than one would predict by simple chance association, suggesting a direct role of HCV, at least in some cases, in the intrahepatic accumulation of triglycerides. This proportion is indeed so high that, in the pre-serology era, steatosis has been used as a diagnostic tool to identify patients with non-A, non-B hepatitis[4,5].

The proper appreciation of fatty liver associated with chronic hepatitis C is important due to its clinically significant consequences. The scope of this review is to discuss the pathogenetic, clinical and therapeutic aspects related to steatosis in chronic hepatitis C patients.

## VIRAL STEATOSIS IN CHRONIC HEPATITIS C

The reported prevalence of steatosis in patients with chronic hepatitis C varies between 40% and 80%,

depending on the features of the population studied in terms of alcohol consumption, prevalence of overweightness/obesity, diabetes and other risk factors of fatty liver[6]. If all known factors of fatty liver are excluded, the prevalence of steatosis in chronic hepatitis C is still about 40%. This figure represents an approximately 2-fold increase compared to the prevalence of steatosis in another common chronic liver disease like hepatitis B (20%)[7,8]. This evidence alone suggests that HCV may directly cause steatosis, at least in some patients.

An early observation, later confirmed by nearly all reports that have addressed this issue, showed that steatosis was more frequent and more severe in patients infected with HCV genotype 3[9-13]. This added to the evidence linking HCV and fatty liver, because it hinted at the presence of "steatogenic" sequences across the genome of genotype 3. In other words, this viral genotype, more often and more significantly than other genotypes (albeit not exclusively, see below), would be directly involved in the accumulation of triglycerides in hepatocytes (so-called "viral" steatosis). This interpretation is supported by two additional observations. The first is that, especially in patients with genotype 3, the severity of steatosis correlates with the level of HCV replication, expressed as HCV RNA level in liver[10] or in serum[11]. Similar results have been reported measuring the level of HCV core protein expressed in the liver of chronic hepatitis C patients by immunoblot[14]. The second important observation is that the fatty liver is significantly reduced or disappears when patients are successfully treated with antivirals. This effect, again, is more evident in patients with genotype 3, while those with genotypes non-3 may remain steatotic even in case of sustained virological response[15,16]. A relapse after the end of therapy may result in the reappearance of steatosis in patients in whom it had disappeared while on-treatment[17].

The mechanism of triglyceride accumulation by HCV remains largely speculative. From a general standpoint, and based on currently available evidence, HCV may interfere with lipid metabolism at three levels: impaired secretion, increased neosynthesis, and impaired degradation (Figure 1).

Historically, impaired secretion of lipids from the infected hepatocyte has been the first proposed mechanism of HCV-induced steatosis. In fact, serum levels of apolipoprotein B (ApoB) and cholesterol are reduced in chronic hepatitis C patients in whom steatosis responds to antiviral therapy[18,19], suggesting that HCV may interfere with the very-low density lipoprotein (VLDL) assembly and/or secretion. The disappearance of fatty liver in sustained virological responders to antiviral therapy correlates with normalization of ApoB and cholesterol levels[16,18]. Hypocholesterolemia in patients with chronic hepatitis C has been reported to be specifically associated with genotype 3[19]. Thus, clinical data suggest that HCV may interfere with VLDL secretion, a defect corrected by antiviral treatment.

*In vitro* studies and the transgenic mouse model have both suggested that the HCV core protein is sufficient to induce a lipid accumulation in hepatocytes[20-23]. This viral protein is localized on the surface of lipid droplets, and its over-expression seems to further stimulate the formation of lipid droplets. These models have predominantly used genotype 1-derived constructs, but recent work has reported similar results using other viral genotypes, including type 3a, which seems to be the most efficient in terms of fat accumulation[24]. In fact, although some degree of intra-hepatocyte fat deposition occurs with all viral genotypes, the genotype 3 core protein expression results in about 3-fold fat accumulation with respect to genotype 1[24], in agreement with the clinical evidence. Based on the experimental model of the transgenic mouse, the HCV core protein seems to inhibit the microsomal triglyceride transfer protein (MTP) activity[23]. Since this enzyme plays a key, rate-limiting role in VLDL assembly, the consequence of its inhibition is the accumulation of triglycerides, i.e. steatosis. A direct interaction between core protein and MTP is unlikely, as it would require the secretion of the viral protein into the endoplasmic reticulum lumen, which has not been reported. However, the MTP inhibition may still be indirect. Strangely enough, transgenic mice for the HCV core protein have normal ApoB levels in serum[23]: Were it not for this discrepancy, this mouse model may be an ideal candidate to study the HCV-related steatosis seen in chronic hepatitis C patients. Recent data in human liver are, however, in agreement with this proposed mechanism, since the intrahepatic levels of MTP mRNA were reduced in patients with chronic hepatitis C, especially those with steatosis and/or genotype 3[25]. According to another experimental model, the HCV core protein may accumulate in the mitochondria and

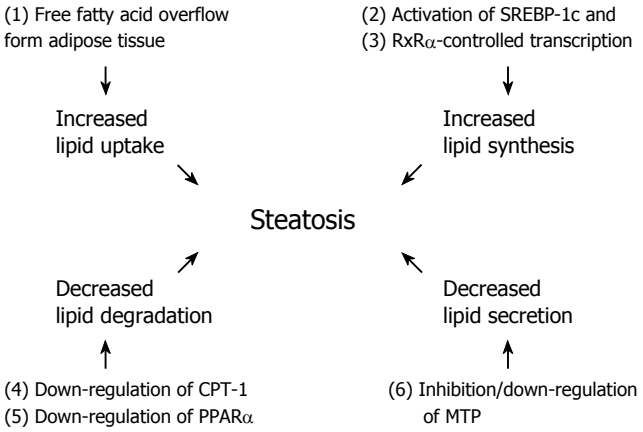

**Figure 1** Some of the major mechanisms leading to steatosis in patients with chronic hepatitis C. HCV, especially (but not only) genotype 3a, has been shown to be directly involved in triglyceride accumulation by several mechanisms: activation of fatty acid neosynthesis *via* SREPBP-1c (2) and RxRα (3), impaired degradation through down-regulation of CPT-1 (4) and PPARα (5), and inhibition and/or down-regulation of MTP (6). Another potential mechanism (not shown) is the cell damage inflicted by reactive oxygen species consequent to localization of the HCV core protein in the mitochondria. This may also trigger lipid peroxidation of microsomal membranes, leading to impaired VLDL secretion. In patients who are insulin resistant, the major mechanism leading to steatosis is the free fatty acid overflow from adipose tissue (1). Hyperglycemic/hyperinsulinemic states are also associated with activation of fatty acid neosynthesis *via* SREPBP-1c (2) and impaired degradation *via* down-regulation of CPT-1 (4). It has to be added that HCV may contribute to insulin resistance by impairing the IRS-1 signaling in hepatocytes by multiple mechanisms. Not shown in the figure are also the interference with ApoB synthesis and the activation of MTP reported in insulin resistant states: the latter phenomenon may be partially counterbalanced by the strong inhibition of MTP observed in patients with predominantly viral steatosis .

induce liver damage *via* the production of reactive oxygen species. These effects were prevented by a mitochondrial electron transport inhibitor[26]. In HCV transgenic mice, increased intrahepatic lipid peroxidation products occurred in response to carbon tetrachloride[27]. The subsequent production of ROS may result, among other effects, in the peroxidation of membrane lipids and structural proteins, such as those involved in the trafficking and secretion apparatuses. This would then block VLDL secretion, leading to steatosis. Furthermore, the intracellular accumulation of triglycerides would further contribute to the pathogenesis of steatosis by providing the fuel for continuing lipid peroxidation, in a typical free radical-driven amplification reaction.

HCV may also induce steatosis *via ex novo* synthesis of fatty acids. For example, HCV has been reported to upregulate the sterol regulatory element binding protein-1c (SREBP-1c) signaling pathway[28]. SREBP-1c is a transcription factor leading to the up-regulation of enzymes involved in *de novo* lipogenesis, an event that can favor intracellular accumulation of triglycerides. Chimpanzees experimentally infected with HCV show an increased intrahepatic activity of enzymes involved in lipogenesis, such as ATP citrate lyase, which are regulated by SREBP-1c[28]. The HCV core protein may additionally bind to and activate the DNA-binding domain of the retinoid receptor α (RxRα), a transcriptional regulator that controls many cellular functions, including cellular lipid synthesis[29-31]. On the other hand, accumulation of fat in hepatocytes transiently expressing the HCV core protein seems to depend on the presence of exogenous lipids, which indirectly decreases the likelihood of a significant fatty acids neosynthesis activated by this viral protein[24]. However, one cannot rule out that other viral proteins may activate the neosynthesis of fatty acids.

HCV may finally cause steatosis by impairing fatty acid oxidation. Transfection of hepatoma cells with the HCV core protein is followed by a reduced expression of peroxisome proliferators-activated receptor α (PPARα), a nuclear receptor regulating several genes responsible for fatty acid degradation[29]. These same authors have also reported a down-regulation of mitochondrial carnitine palmitoyl transferase-1 (CPT-1), the rate-limiting enzyme of mitochondrial β-oxidation, which is the main catabolic pathway of fatty acids, and of the acyl CoA oxidase (AOX)[29]. A reduced expression of CPT-1 in the liver of chronic hepatitis C patients has been reported recently[30]. However, the down-regulation of several genes, such as CPT-1 and AOX, is transcriptionally controlled by PPARα. Thus, the reported effects may be secondary to down-regulation of PPARα. PPARα mRNA is significantly reduced in the liver of patients infected with genotype 3 compared to genotype 1[32], and down-regulation of PPARα mRNA in chronic hepatitis C has been reported at least by another group[33]. Overall, the data support the hypothesis that HCV core protein may modulate the expression of various lipid degradation-associated genes, possibly *via* the down-regulation of PPARα.

The search for the viral sequences responsible for the genotype-specific effects on triglyceride accumulation has been so far elusive. No single mutation has been identified as being responsible for steatosis, suggesting that more complex mutation clusters may be involved in virally-driven steatosis[24]. The C-terminal signal sequence of the core protein appears particularly interesting. In this domain, the core protein of genotype 3a contains several unique mutations that, alone, or more likely in combination, may confer the steatogenic phenotype.

## STEATOSIS OF OTHER CAUSES OCCURRING IN HEPATITIS C

The HCV-induced steatosis may co-exist with a fatty liver due to other causes. In chronic hepatitis C patients who do not drink alcohol and are infected with non-3a genotypes, the most frequent correlate of fatty liver is an increased body mass index. Not only being obese, but also being merely overweight (BMI higher than 25 but less than 30) is an independent risk factor for hepatic steatosis in patients infected with HCV[8,11,16]. In genotype 1 infection, as observed in patients with non-alcoholic fatty liver disease (NAFLD), the fat distribution seems more important than total fat in determining steatosis. Visceral obesity, rather than merely increased BMI, seems to play a major role in the development of HCV-related steatosis[11]. In initial studies, when genotype was taken into account, it soon became clear that there was no association between BMI and the prevalence and the severity of steatosis in genotype 3 infected patients whereas, among patients with non-3 genotype, steatosis correlated with BMI[11,34]. These findings have been repeatedly confirmed and when patients with risk factors for NAFLD are excluded genotype 3 infection remains the single most important, independent predictor of steatosis[10,34].

This BMI-associated (or "metabolic") steatosis is not or very little modified by successful antiviral therapy[15,16]. However, a partial amelioration of steatosis is sometimes observed also in genotype non-3 infection following HCV eradication[16]. This implies that the assignment of either of the two types of steatosis (viral and metabolic) to a specific viral genotype should not be so clear-cut. Careful analysis of experimental and clinical data indicates that also HCV genotypes non-3 may induce some degree of viral steatosis, whereas metabolic abnormalities may be associated with a fatty liver also in genotype 3-infected persons. Thus, it is likely that the two types of steatosis can coexist in at least some chronic hepatitis C patients, although, in genotype 3 infection steatosis will be primarily of viral origin and in genotype non-3 primarily metabolic.

The most likely cause of metabolic steatosis in chronic hepatitis C, therefore preceding its appearance, is the insulin resistance that accompanies overweightness[35]. The mechanisms that underlie liver steatosis in the insulin resistant state are multiple (Figure 1). On the one hand, free fatty acid overflow from adipose tissue to the liver is a direct consequence of the failure to block lipoprotein lipase, resulting in increased uptake by peripheral tissues, including liver[36]. Second, the deregulated hyperglycemic/hyperinsulinemic state stimulates the expression of a variety of enzymes involved in fatty acid neosynthesis, while at the same time inhibit the

mitochondrial β-oxidation[36]. This imbalance between uptake, *ex novo* synthesis and degradation results in excess triglyceride accumulation within hepatocytes. In case of HCV infection, some degree of synergism may occur at the level of the above metabolic pathways, such as CPT-1 inhibition[29]. Moreover, insulin is a known down-regulator of ApoB synthesis[37]. However, recent data support the notion that chronic insulin resistant state may stimulate MTP activity in order to increase hepatocyte VLDL output[38]. If this is confirmed, two conflicting events would occur in insulin resistant chronic hepatitis C patients: MTP inhibition, directly-or indirectly-mediated by HCV, and MTP stimulation, mediated by insulin. Presumably, these two mechanisms may not operate in the same subgroups of patients. In those with genotype 3, who have the lowest levels of insulin resistance (see below), the viral inhibition of MTP would predominate, with hypotriglyceridemia, low ApoB serum levels and "viral" steatosis as a final consequence. In patients with genotype non-3 infection, hypertriglyceridemia may occur, but the inability to counterbalance the stimulation of fatty acid neosynthesis and the inhibition of mitochondrial β-oxidation would still result in "metabolic" steatosis. Clearly, further work is warranted to dissect the role of each of these metabolic changes in the pathogenesis of steatosis in hepatitis C.

Insulin resistance is a hallmark of the metabolic syndrome and, as such, proceeds independently of HCV. However, there is some good evidence that HCV may play a significant role in influencing the level of insulin resistance, and this irrespectively of the stage of liver disease. The fact that HCV-infected cirrhotic patients may present with type 2 diabetes more frequently than patients with cirrhosis of other origin was first reported in 1994[39], and has been later confirmed by several cohort and case-control studies, also in special populations like patients having received transplantation[40-48]. In particular, a retrospective analysis of 1117 patients with chronic viral hepatitis[40] reported that diabetes was diagnosed in 21% of HCV but only in 12% of HBV-infected patients. By multivariate analysis, HCV infection and age resulted in independent predictors of diabetes. In the same study, when 594 diabetics were compared with 377 patients evaluated for thyroid disturbances, 4.2% of diabetic patients were found to be infected with HCV as compared with 1.6% of controls[40]. In another study, conducted within the Third National Health and Nutrition Examination Survey (NANHES-III), a significant association with age was observed, i.e. chronic hepatitis C patients 40 years of age or older were more than three times more likely to have type 2 diabetes than those without HCV infection[46]. This raised the issue that diabetes may be due to the stage of liver disease rather than to the viral infection. However, Hui *et al*[49] have subsequently reported that 121 HCV-infected patients with stage 0 or 1 hepatic fibrosis had higher levels of HOMA scores compared with 137 healthy volunteers matched by sex, body mass index, and waist-to-hip ratio. This work also provided some evidence that the level of insulin resistance may be genotype-specific, since patients with genotype 3 had lower levels of HOMA scores than patients with genotype 1. Further evidence that HCV may provoke an insulin resistant state comes from some limited data on the correlation between the severity of insulin resistance and the HCV replication levels[50], and from the observation that insulin sensitivity may improve in patients who achieve HCV RNA clearance following antiviral therapy, while remaining unchanged in non-responders, despite a decrease in BMI[51]. However, further, independent confirmation of these data is warranted.

Experimental data suggest a direct interference of HCV with the insulin signaling pathway *via* proteasomal degradation of the insulin receptor substrate-1 and -2[52]. In addition, functional impairment of this signaling pathway may occur *via* increased levels of pro-inflammatory cytokines such as TNF-α[53] or other post-receptor defects[54]. It has been proposed that chronic hepatitis C patients with more severe liver disease may have an exaggerated intrahepatic TNF-α response, resulting in insulin resistance and a higher risk of developing diabetes[55]. In patients with genotype 3a, HCV may alter the intrahepatic insulin signaling through a down-regulation of PPARγ[32]. Interestingly, although interference with the insulin signaling shows some HCV genotype-specificity, as discussed above, insulin resistance has been reported to occur in all HCV genotypes[56].

Thus, HCV may induce liver steatosis by interfering with lipid metabolism in hepatocytes, and, indirectly, by influencing the level of insulin resistance. As a consequence, the metabolic steatosis, although largely due to disorders independent of the viral infection, may at least partially be ameliorated by antiviral therapy. It has to be noted, however, that as many as 30% of patients with fatty liver who do not drink alcohol and are infected with genotypes other than 3a have normal BMI and HOMA score[56], suggesting that other causes of fatty liver exist in hepatitis C.

A relatively new field is represented by the metabolic impact of cytokines secreted by adipose tissue, i.e. the so-called adipokines. As an example, an association has been reported for serum levels of adiponectin and HCV-related steatosis[57]. Adiponectin is a cytokine secreted by adipocytes with antilipogenic effects that may protect non-adipocyte tissues, such as liver, from fat accumulation. Chronic hepatitis C patients infected with genotype 3 have the lowest levels of adiponectin. Low circulating levels of adiponectin lead to increased serum free fatty acids, which are then taken up by hepatocytes. Further work is needed to fully appreciate the significance of adiponectin in steatosis associated with hepatitis C and more in general in the metabolic syndrome.

Apart from viral and metabolic factors, some specific host genetic polymorphisms may also play a role in the pathogenesis of steatosis. Hyperhomocysteinemia, by inducing endoplasmic reticulum (ER) stress, causes deregulation of the endogenous sterol response pathway *via* SREBP, leading to increased hepatic biosynthesis and uptake of cholesterol and triglycerides. This in turn leads to steatosis. It has also been suggested that hyperhomocysteinemia may increase oxidative stress by inhibiting the expression of several antioxidant enzymes, thus sensitizing hepatocytes to the cytotoxic effect of

pro-oxidant agents. Interestingly, a close association has been reported between the severity of steatosis and homocysteine serum levels in chronic hepatitis C patients[58]. The hyperhomocysteinemia-induced steatosis model may explain why only some, but not all, HCV-infected patients develop steatosis, and why only a minority of patients, e.g. those with higher homocysteine levels, accumulate a greater amount of fat in the liver. Hyperhomocysteinemia may result from a methylenetetrahydrofolate reductase (MTHFR) C677T polymorphism. In that study, it was shown that the polymorphism of the MTHFR gene at position 677, which has a prevalence of 12%-15% for the TT genotype in the general population, was associated with both hyperhomocysteinemia and a greater degree of steatosis in chronic hepatitis C patients. It was estimated that the relative risk of developing more severe steatosis was six-fold higher for patients with the CT genotype and 20-fold higher for those with the TT genotype[58].

## IS THERE A ROLE FOR STEATOSIS IN HCV REPLICATION?

HCV replication occurs entirely in the hepatocyte cytoplasm and, like many other plus-strand RNA viruses, proceeds in association with the endoplasmic reticulum membranes. Perturbation of host cell lipid and cholesterol metabolism can disrupt replication complexes by altering membranous structures where replication occurs. Thus, it is very likely that alterations brought about by HCV on lipid metabolism may affect its own replication.

The question that has been repeatedly raised is whether steatosis may play a role in the HCV life cycle, e.g. by stimulating HCV replication or facilitating cell-to-cell spread. Most models are currently highly speculative. For example, HCV is known for circulating bound to lipoproteins under the form of lipo-viro-particles (LPVs)[59]. Interestingly, binding LPVs to hepatocyte cell lines can be out competed by VLDL and LDL from noninfected controls and is blocked by anti-ApoB antibodies. Conversely, up-regulation of the LDL receptor increases their internalization[59]. Thus, low levels of circulating VLDL, as induced by HCV genotype 3a and, in general, in all patients with viral steatosis, may facilitate cell-to-cell spread of LPVs. This fascinating hypothesis needs, however further confirmation.

Another interesting aspect of the interaction between HCV replication and lipids comes from the observation that HCV RNA replication in hepatoma cells can be disrupted by treatment with lovastatin, a drug that decreases the production of mevalonate by inhibiting 3-hydroxy-3-methylglutaryl CoA reductase[60]. Mevalonate is a precursor of hydrophobic prenyl prosthetic groups, like the geranylgeranyl group, which are necessary to anchor various proteins to cell membranes. The inhibition of HCV RNA replication by lovastatin was overcome by the addition of geranylgeraniol, suggesting that HCV RNA replication requires one or more geranylgeranylated protein[60,61]. This protein has been recently identified as the FBL2 protein (F-box and leucine-rich repeat-containing protein[62]), which would form a stable complex with the non-structural protein 5A of HCV[63]. Knockdown of FBL2 mRNA was paralleled by inhibition of HCV replication *in vitro*[63]. It is interesting to add that several statins were recently shown to possess anti-HCV activity *in vitro*[64]. Fluvastatin exhibited the strongest anti-HCV activity, atorvastatin and simvastatin showed moderate inhibitory effects, whereas lovastatin had weakest anti-HCV activity. Moreover, the anti-HCV activities of statins were reversed by the addition of both mevalonate and geranylgeraniol[64]. If confirmed, these observations may have important consequences on the management of chronic hepatitis C.

Thus, the fatty acid content of the infected hepatocyte may be crucial to modulate the rate of viral replication. However, some caution is mandatory before hasty conclusions are drawn, based on these data. Fatty acids accumulated in the form of triglycerides as in the case of steatosis may not be available to replication complexes involving HCV, and their degree of saturation may also vary. It is known that, in patients with viral steatosis, the severity of the fatty liver correlates with HCV replication level: however, in these patients, replication precedes fatty accumulation, and not vice-versa, as shown by antiviral treatment data. Conversely, in patients with metabolic steatosis, in whom steatosis precedes viral infection and proceeds independently of it, the level of viral replication is not increased in parallel with the severity of fatty liver. Thus, further work is warranted to understand the relationship between steatosis and HCV life cycle, if any exists.

## STEATOSIS AS COFACTOR OF LIVER FIBROSIS PROGRESSION

The vast majority of cross-sectional[10,34,65,66-71] and longitudinal[11,66-68] studies have repeatedly shown an association between steatosis and progressing liver fibrosis in HCV-infected patients. At present, it is unclear whether the two types of HCV-associated steatosis (viral and metabolic) have a similar or different impact on fibrosis progression, because the reported data are controversial. It is likely that the two forms of steatosis act in an additive way. However, data are not unequivocal, as some studies suggest that steatosis may accelerate fibrosis only in genotype 3-infected persons[67-69], whereas others support an association in patients infected with genotype 1[70,71]. At least one study denies any association between steatosis and fibrosis[72]. Interestingly, as the disease progresses to advanced cirrhosis, steatosis tends to disappear[69], a phenomenon already observed in NAFLD[73]. Longitudinal studies are particularly important in emphasizing the role of steatosis in fibrosis progression. In a recent study on paired liver biopsies performed across a median interval of 61 mo in 135 untreated patients with chronic hepatitis C[66], steatosis was the only independent factor predictive of progression of fibrosis, and the probability of progression of fibrosis was significantly related to the percentage of hepatocytes with steatosis. The authors concluded by supporting the attitude of treating patients with mild

hepatitis and steatosis, regardless of HCV genotype.

The mechanisms by which HCV-related steatosis promotes liver fibrosis progression are far from being elucidated. Available data suggest that oxidative stress, pro-inflammatory cytokines, insulin resistance, and increased susceptibility to apoptosis may mediate the fibrogenic effect of steatosis. However, since virtually all studies are correlative, it is difficult to ascertain whether steatosis directly participates in the fibrogenic process, or whether it should be considered as an innocent by-product of another, directly fibrogenic mechanism.

The association between HCV and intrahepatic oxidative stress has been mentioned above[26,27]. It has been reported that in the presence of hepatic steatosis, oxidative stress is enhanced in HCV infection and may promote fibrogenesis, similarly to the second "hit" proposed in NAFLD. In a recent study, Kitase *et al*[74] detected by immunohistochemistry some protein adducts with lipid peroxidation end-products in the liver of chronic hepatitis C patients. Interestingly, areas positive for 4-hydroxy-2-hexenal-protein adducts, a good marker for oxidative stress, were larger in steatotic livers compared to non-steatotic. Thus, the authors concluded that steatosis in chronic hepatitis C may amplify the oxidative stress-driven lipid peroxidation by providing the necessary fuel[74]. There is also some limited evidence that antioxidant therapies may ameliorate the necro-inflammatory activity in chronic hepatitis C[75], although long-term effects on the fibrosis progression rate have not been reported so far.

Pro-inflammatory cytokines may mediate fibrogenesis in the steatotic liver, although it is unclear whether steatosis would facilitate this process. A recent meta-analysis (the HCV MAID study)[70], which included individual patients data of 3068 patients with chronic hepatitis C from 10 centers in five countries, demonstrated that liver steatosis is associated with increased liver inflammatory activity and accelerates the progression of liver fibrosis. This observation has been reported by others[34,71].

Insulin resistance is fibrogenic in the liver. However, in most studies, the relative contribution of steatosis and insulin resistance to fibrosis has not been determined. The HCV MAID Study has suggested that steatosis and diabetes are both independent factors of fibrogenesis in patients with genotype 1 infection[70]. However, when insulin resistance, an earlier and more sensitive parameter of glucose metabolism dysfunction, is added to a logistic regression analysis, the association between steatosis and fibrosis disappears[49]. A body of epidemiologic work suggests that the presence of diabetes and insulin resistance *per se* are risk factors of severe fibrosis and more rapid fibrosis progression in chronic hepatitis C[49,76,77]. The connective tissue growth factor (CTGF) is over-expressed in the liver of patients with non-alcoholic steatohepatitis as well as of diabetic Zucker rats[78]. In addition, both CTGF mRNA and protein are significantly increased when hepatic stellate cells are incubated with either glucose or insulin[78]. Similar mechanisms may operate in chronic hepatitis C[79], where the level of intrahepatic expression of CTGF was correlated with serum levels of leptin and the scores of steatosis and fibrosis. Since hepatic stellate cells possess leptin receptors[80], it is intriguing to speculate that leptin may represent the link between steatosis, insulin resistance and fibrosis in chronic hepatitis C.

Finally, hepatocyte apoptosis is a well recognized condition associated with both necroinflammatory activity and fibrosis in NAFLD[81]. In chronic hepatitis C, in the presence of steatosis, increased apoptosis is associated with activation of stellate cells and increased stage of fibrosis[82]. In addition, steatosis is associated with decreased Bcl-2 mRNA levels and an increase in the proapoptotic Bax/Bcl-2 ratio. It has also been reported that caspase activity, which controls apoptosis, is increased in both liver biopsy and sera from HCV patients[83] and is strictly correlated to the extension of steatosis. All these data seem to indicate a relationship between steatosis, apoptosis and development of fibrosis, although the fine pathogenetic mechanisms await clarification.

## HCV-RELATED STEATOSIS AND HEPATOCELLULAR CARCINOMA

Experimental data from the transgenic mice model have shown that HCV may play a causative role in the development of steatosis and hepatocellular carcinoma (HCC)[27,84]. It has been speculated that, among the possible mechanisms, reactive oxygen species may play a major role in mutagenesis[27,85]. In addition, the HCV core protein may interact with RxR$\alpha$[31], a transcriptional regulator that controls many aspects of cell proliferation and differentiation. A recent study has reported steatosis to be an independent risk factor for the development of HCC in chronic hepatitis C patients[85]. The authors prospectively followed 161 patients with chronic HCV infection for up to 15 years and found that the presence of steatosis was significantly associated with the incidence of HCC by multivariate analysis. Recently, however, a retrospective study including a smaller number of chronic hepatitis C patients did not confirm that steatosis may be a risk factor for HCC development[86]. Thus, further prospective studies are needed to assess the role of HCV-associated steatosis in liver carcinogenesis.

## HCV-RELATED STEATOSIS AND RESPONSE TO ANTIVIRAL TREATMENT

Steatosis has been recognized as a negative factor response to antiviral therapy for many years[87]. This observation has been repeatedly confirmed by data coming from large clinical trials[16,88,89]. The effect is significant for the steatosis seen among patients with non-3a genotype, hinting at the insulin resistance as the pathogenetic factor affecting responsiveness to interferon-alpha. This was confirmed by a recent study[51], where the sustained virological response rate was inversely correlated with the baseline HOMA score. Indirect evidence in favor of this negative association comes also from the reduced response to antivirals seen in African Americans, reportedly due to their high rate of visceral obesity and insulin resistance[90], and from the correlation between high levels of circulating TNF-$\alpha$, as seen in insulin resistance, and poor response to interferon therapy[90].

The molecular reasons for the correlation existing between insulin resistance and interferon-alpha resistance are still unclear. Chronic hepatitis C patients who do not respond to interferon-alpha may have increased levels of suppressor of cytokine signalling 3 (SOCS-3) in the liver, a factor promoting the proteasomal degradation of IRS-1[91]. Interestingly, members of the SOCS family are negative regulators of STAT-1, a factor involved in the transduction of the interferon-alpha signaling[92]. Thus, we cannot exclude that HCV activates some members of the SOCS family as a mechanism to inhibit the interferon-alpha signaling, with the simultaneous impairment of the insulin signaling just being a collateral effect.

## CONCLUSION

Steatosis is an established risk factor for disease progression in chronic hepatitis C. Furthermore, it has also been shown to impact significantly on the response to antiviral therapy. Thus, appropriate therapeutic strategies for HCV-related steatosis are required with the aim to improve both the natural history of chronic hepatitis C and its drug management. Ideally, it would be important to assess whether steatosis is mainly virally-induced (like in many cases of genotype 3 infection) or whether metabolic host factors play a predominant role, like in many patients infected with non-3 genotypes. In chronic hepatitis C patients with genotype 3, successful treatment is associated with disappearance or significant amelioration of fatty liver. Whether the efficacy of antivirals may be improved by specific interventions aimed at reducing the degree of steatosis remains to be proven. In patients with non-3 genotype infection, in whom insulin resistance may play a role as cofactor of disease and fatty infiltration of the liver, the first-line intervention is represented by those life-style modifications that may reduce body weight. In a recent study, a weight-reduction program followed by chronic hepatitis C patients was effective in reducing steatosis and improving liver biochemistry and fibrosis in the absence of effects on virological parameters and irrespectively of the infecting genotype[93]. One should be reminded that the diagnosis of viral and/or metabolic steatosis in any given patient should not be based solely on the infecting genotype, but should be corroborated by a whole set of clinical and laboratory parameters, including the assessment of the insulin resistance score. Finally, because alcohol, even at low doses, synergistically interacts with steatosis to promote fibrosis progression, it is mandatory to advise the patients to avoid its use. The additional role of drugs like metformin and thiazolidinediones, which improve insulin sensitivity, remains to be evaluated in carefully planned clinical trials. Of additional interest is the use of drugs that may inhibit the geranylgeranylation, a cellular enzymatic activity apparently essential for HCV replication. All these pharmacological strategies, however, remain experimental, for the time being, and should not be attempted in routine clinical practice until new data from controlled trials will be available.

## ACKNOWLEDGMENTS

The Author thanks Dr. Sophie Clément and Kathrin Overbeck for critically reading the manuscript. The author's experimental work is supported by the Swiss national Science Foundation grants no. 3347C0-108782 and 3200B0-103727.

## Abstract

**AIM:** To evaluate the growth inhibition efficacy of atofluding derivative N3-*o*-toluyl-fluorouracil (TFU) on human gastric carcinoma cell lines SGC-7901 and MKN-45.

**METHODS:** Cell growth inhibition by TFU was measured by MTT and clonogenic assays without or with liver microsomal enzymes. Xenografts of cancer cells in nude mice were employed to study the anti-proliferative effects of TFU *in vivo*.

**RESULTS:** TFU inhibited the growth of SGC-7901 and MKN-45 cells. However, the inhibitory effects of TFU on cell growth were not significant. The inhibition rates were enhanced in the presence of liver microsomal enzymes, ranging 4.73%-48.57% in SGC-7901 cells and 9.0%-62.02% in MKN-45 cells. *In vivo*, TFU delayed the growth of SGC-7901 and MKN-45 cells in nude mice. The inhibition rates were 40.49%, 63.24%, and 75.98% in SGC-7901 cells and 40.76%, 61.41%, and 82.07% in MKN-45 cells when the oral doses were 25, 50, and 100 mg/kg, respectively. TFU treatment was generally well tolerated by mice with less than 20% reduction in body weight.

**CONCLUSION:** TFU inhibits the growth of human gastric carcinoma cells. The inhibition rates are increased in the presence of liver microsomal enzymes. The efficacy of TFU may be associated with the sustaining release of 5-fluorouracil (5-FU) mediated by the enzymes.

**Key words:** N3-*o*-toluyl-fluorouracil; Gastric carcinoma cells; Pro-drug; Growth inhibition

## INTRODUCTION

5-fluorouracil (5-FU), a pyrimidine analog, has become a backbone in the therapy of gastric and colon cancer since its introduction in 1957. However, its clinically effective dosage is very close to its toxic dosage when given intravenously, resulting in strong toxicities to gastric and intestinal mucosa and bone marrow[1-3]. In addition, its plasma half-life is very short (15-20 min) and the drug is administered only as a continuous iv infusion[4-7]. In order to overcome these disadvantages, attempts have been made to design and synthesize new 5-FU derivatives. In the 1980s, a new oral 5-FU derivative, N1-acetyl-N3-*o*-toluyl-fluorouracil (atofluding), was developed[8]. Studies have shown that atofluding can effectively treat many types of tumor with few side effects. Nevertheless, the acetyl group on the N1 position of atofluding is not stable and prone to decompose, impairing quality control for the preparation. The pharmacokinetics showed that atofluding, N3-*o*-toluyl-fluorouracil (TFU), rather than atofluding itself could be detected in the serum after oral administration. TFU is the decomposition products of atofluding that hydrolyze the acetyl group by fluorine on C5 position (Figure 1). TFU is extracted and dissolved in acetone and water before its

determination by high-pressure liquid chromatography[8,9]. The results also showed that steady-state concentrations of TFU can remain in the body for 30 h[8]. These results have led us to the conclusion that TFU is stable in the preparation. Encouraged by these observations, the anti-tumor activities of TFU were studied and the inhibition efficacy of TFU on the growth of human gastric carcinoma cells was evaluated in the present study in order to replace the unstable atofluding.

## MATERIALS AND METHODS

### Cell lines and cell culture

Human gastric carcinoma cell lines, SGC-7901 and MKN-45 were obtained from the Division of Cancer Treatment, National Cancer Institute of China (Beijing, China). Cells were maintained in RPMI-1640 supplemented with 10% (v/v) heat-inactivated fetal bovine serum, penicillin-streptomycin (100 IU/mL-100 μg/mL), 2 mmol/L glutamine, and 10 mM Hepes buffer at 37℃ in a humid atmosphere containing 50 mL/L $CO_2$. Cells were fed every three to four days, and harvested by brief incubation in PBS containing 0.02% trypsin-EDTA.

### Chemical

TFU was synthesized by acylation of 5-FU with 2-methylbenzoyl chloride in pyridine at room temperature as previously described[8,9] and dissolved in dimethylsulfoxide (DMSO) for *in vitro* assay and in 5% amylum for *in vivo* study.

### MTT assay

Cells (2-5 × $10^4$ per well) seeded in 96-well plates (Corning Costar Corporation, Cambridge, MA, USA) for 12 h were treated with different doses of TFU for the required time period. The medium was then removed and the wells were washed with PBS. Cell viability was assessed by adding 20 μL of MTT [3-(4, 5-dimethylthiazol-2-yl)-2], 5 mg/mL 5-diphenyltetrazolium bromide (Sigma, USA) for 4 h[10]. Light absorbance of the solution was measured at 540 nm on the plate reader (TECAN, Grodig, Salzburg, Austria). The growth of experimental and control cells was compared. Experiments were performed in triplicate.

### Liver microsomal enzymes and preparation

SD male rats (150 ± 10 g) from the animal breeding house were treated with intra-peritoneal injections of phenobarbital (80 mg/kg body weight) daily for three consecutive days in 0.5 mL of peanut oil. The animals were sacrificed 24 h after the last injection. Livers were removed, washed with chilled 0.1 mol/L phosphate buffer (pH 7.4) and homogenized. Liver microsomal enzymes were prepared as described by Rastogi S *et al*[11]. The microsomal enzymes were resuspended in 0.1 mol/L phosphate buffer (pH 7.4) containing 10 mmol/L dithiothrietol, 10 mmol/L EDTA and 20% glycerol. Ten mL of the mixture of enzymes containing 1 mL of microsomes and 31.4 mg of nicotinamide adenine dinucleotide phosphate (NADPH; Merck, Darmstadt, Germany) was used[12]. The enzyme mixture (2 μL) was applied to each well of the 96-well plates after cells were seeded and TFU was added. Cell growth inhibition was measured as above.

### Clonogenic assay

Cells (250 to 300 per well) grown in 6-well plates (Falcon, Becton Dickinson, Franklin lakes, New Jersey, USA) for 12 h were treated with different doses of TFU at 37℃. After two weeks, colonies (greater than 50 cells) were stained with crystal violet and counted as previously described[10,13].

### In vivo inhibition of tumor growth

The *in vivo* efficacy of TFU was assessed in nude mice bearing tumors. Balb/c athymic (nu+/nu+) female mice, 4-6 wk of age, were purchased from the Experimental Animal Laboratory, Chinese Academy of Medical Sciences (Beijing, China). The research protocol was approved in accordance with the institutional guidelines of the Animal Care and Use Committee at Shandong University. Animals were housed under pathogen-free conditions. Cells (1 × $10^7$) were suspended in 100 μL of Matrigel (Collaborative Biomedical, Bedford, MA, USA) and injected subcutaneously into the right anterior flank of nude mice. After seven days, when tumor volume reached approximately 0.1-0.2 $cm^3$, the mice were divided into different groups ($n$ = 8) and orally administered 0, 25, 50, 100 mg/kg of TFU in 0.5 mL of 5% amylum[14]. Administrations were performed six days per week for three consecutive weeks. Tumor growth inhibition rates were defined as a ratio to the control tumor weight.

### Statistical analysis

Statistical significance was determined by the Student' s two-tailed $t$-test. The Kruskal-Wallis test was used to detect the percent of cell growth inhibition. $P < 0.05$ was considered statistically significant. Statistical analysis was performed with SPSS/Win11.0 software (SPSS, Chicago, IL, USA).

## RESULTS

### Growth inhibitory effects of TFU

To select optimal times for analysis of the relationship between treatment with TFU and cell growth inhibition, untreated cells were tested over six days. SGC-7901 and MKN-45 cells reached their confluence by d 6. We then selected d 5 within the linear growth period for concentration analysis and a 5-d period for the time course of treated cells (data not shown).

Gastric carcinoma cells were treated with TFU (0.1, 1, 10, 100, 1000 μg/mL) for up to 120 h and the viable cells were evaluated as described in MATERIALS and METHODS. As shown in Figure 2A, TFU showed its anti-proliferative effects on SGC-7901 cells in a dose- and time-dependent manner. Significant differences were seen across the doses tested (Kruskal-wallis H = 18.870, $P$ = 0.042). The growth inhibitory effects of TFU were significantly increased from 24 to 120 h of incubation (Kruskal-wallis H = 18.870, $P$ = 0.042). However, the inhibitory effects of TFU on cell growth were not high. Cells cultured with 10 μg/mL of TFU achieved only 11.09% of growth inhibition

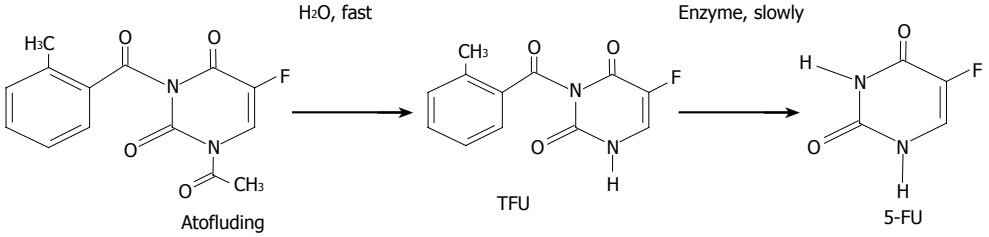

**Figure 1** Metabolism of atofluding to into TFU and 5-FU. The acetyl group on the N1 position of atofluding was hydrolyzed in the presence of $H_2O$ into TFU rapidly due to the influence of fluorine on the C5 position. 5-FU was transformed from TFU slowly and continually by the liver microsomal enzymes.

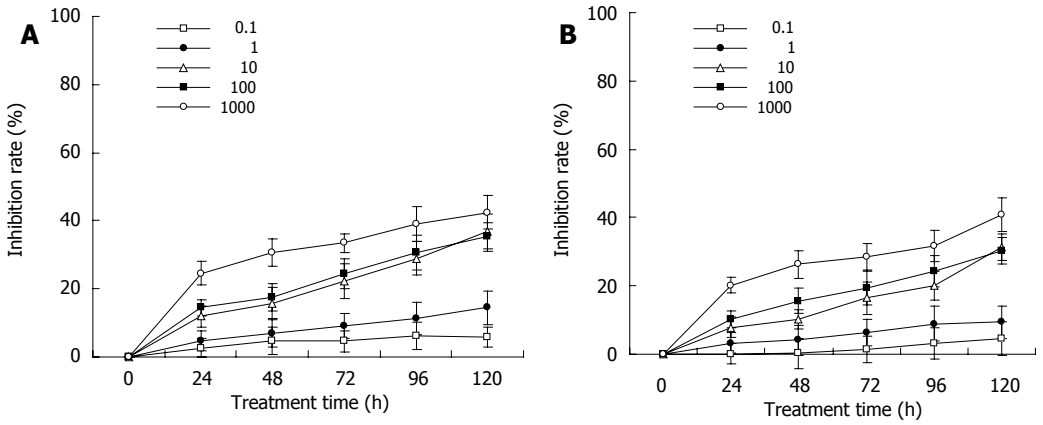

**Figure 2** TFU inhibits MKN-45 (**A**) and SGC-7901 (**B**) cell growth *in vitro*. Cells were treated with TFU (0.1, 1, 10, 100, 1000 μg/mL) for up to 120 h. Viable cell numbers were evaluated by the MTT assay and expressed as percentage of untreated controls at the concurrent time point. The bars indicate means ± SD ($n$ = 3).

**Table 1 Enhancement of TFU induces growth inhibition of SGC-7901 and NKM-45 cells in the presence of liver microsomal enzymes**

| Cell line | Time (h) | Inhibition (%) | | | | |
|---|---|---|---|---|---|---|
| | | 0.1 μg/mL | 1 μg/mL | 10 μg/mL | 100 μg/mL | 1000 μg/mL |
| SGC-7901 | | | | | | |
| | 24 | 4.73 | 8.21 | 11.92 | 14.84 | 24.08 |
| | 48 | 9.56 | 15.10 | 22.31 | 36.02 | 39.89 |
| | 72 | 17.29 | 24.35 | 30.75 | 40.03 | 43.72 |
| | 96 | 22.03 | 31.76 | 32.97 | 42.43 | 45.51 |
| | 120 | 37.67 | 36.67 | 35.24 | 45.86 | 48.57 |
| MKN-45 | | | | | | |
| | 24 | 9.00 | 18.38 | 20.00 | 36.99 | 42.02 |
| | 48 | 20.00 | 34.00 | 40.00 | 51.40 | 55.00 |
| | 72 | 45.09 | 52.63 | 57.11 | 58.18 | 60.16 |
| | 96 | 52.50 | 61.64 | 57.87 | 55.53 | 61.41 |
| | 120 | 59.19 | 62.02 | 59.12 | 55.84 | 53.98 |

Enhancement was calculated using the inhibition rate in the presence of microsomal enzymes minus the inhibition rate in the absence of enzymes at the same concentration.

at 24 h, 15.69% at 48 h, 22.24% at 72 h, 28.93% at 96 h and 36.86% at 120 h. The maximum inhibition rate was 42.51% at the concentration of 1000 μg/mL after 120 h treatment. MKN-45 cells expressed similar results (Figure 2B).

### *Enhancement of growth inhibition on human gastric carcinoma cells by liver microsomal enzymes*

The inhibitory effects of TFU on human gastric carcinoma cells were then examined in the presence of liver microsomal enzymes. The inhibition rates were significantly increased at all concentrations (0.1, 1, 10, 100, 1000 μg/mL) and treatment time points (24 to 120 h), being 4.73%-48.57% in SGC-7901 cells and 9.0%-62.02% in MKN-45 cells (Table 1). The growth inhibition was increased in a dose- and time-dependent manner (data not shown).

We also used a clonogenic assay to further test the sensitivity of SGC-7901 and MKN-45 cells to TFU over a relatively long culture period (two weeks). The anti-proliferative effect of TFU on clone formation was significantly increased in the presence of liver microsomal enzymes across the concentrations ($P < 0.01$, data not shown).

### *Inhibitory effects of TFU in vivo*

The effects of TFU on gastric carcinoma cell xenografts in nude mice were then examined. As shown in Table 2, TFU delayed the growth of SGC-7901 and MKN-45 cells after three weeks of treatment with 25, 50, and 100 mg/kg ($P < 0.01$). TFU treatment inhibited tumor growth in a dose-dependent manner. This inhibitory effect on the xenograft was more pronounced in MKN-45 cells than in SGC-7901 cells. Except for the 100 mg/kg group, TFU treatment was generally well tolerated by mice with less than 20% reduction in body weight ($P > 0.05$).

## DISCUSSION

In this report, we evaluated the efficacy of TFU, the pro-drug of 5-FU, on growth inhibition of human gastric carcinoma cells. The results showed that TFU had anti-proliferative effects on SGC-7901 and MKN-45 cell growth. The inhibition rates were increased significantly in the presence of liver microsomal enzymes.

Structurally, the difference between atofluding and TFU is that the former has an acetyl group on its $N_1$ position. Nevertheless, the acetyl group is prone to be hydrolyzed into TFU rapidly by fluorine on the C5 position, impairing quality control for the preparation. On the other hand, TFU is very stable *in vitro* and *in vivo*[8,9,15].

**Table 2 Growth inhibitory effects of TFU on SGC-7901 and MKN-45 cells in nude mice ($n = 8$)**

| Cell line | Dosage (mg/kg) | Body weight (mean ± SD, g) | Tumor weight (mean ± SD, g) | Tumor growth inhibition (%) |
|---|---|---|---|---|
| SGC-7901 | | | | |
| | 0 | 22.12 ± 2.31 | 2.30 ± 0.67 | |
| | 25 | 21.62 ± 1.96 | 1.21 ± 0.61 | 30.49 |
| | 50 | 20.28 ± 2.95 | 0.75 ± 0.17 | 53.24 |
| | 100 | 18.05 ± 2.40 | 1.23 ± 0.43 | 65.98 |
| MKN-45 | | | | |
| | 0 | 22.72 ± 1.75 | 1.84 ± 0.72 | |
| | 25 | 21.62 ± 1.96 | 1.09 ± 0.81 | 40.76 |
| | 50 | 20.28 ± 2.95 | 0.71 ± 0.40 | 61.41 |
| | 100 | 18.75 ± 1.44 | 0.33 ± 0.49 | 82.07 |

Differences were analyzed using the Student's two-tailed test.

Consistent results have been seen in our previous studies. The pharmacokinetic studies showed that TFU is detectable some minutes after oral administration of atofluding[8]. In this study, however, atofluding was not detected in the required time period, the steady-state concentrations of TFU in blood (9.97 ± 0.7 mg/mL) were achieved 30 h after multiple administrations. TFU was subsequently slowly metabolized to release 5-FU. Though the subsequent steady-state concentrations of 5-FU were lower than those of TFU, the concentrations could remain for up to 50-52 h[15], suggesting that TFU has good anti-tumor activities and low side effects. TFU would replace the unstable atofluding as the preparation. Sustained release of 5-FU from TFU is a catalytic procedure and enzymes are needed to mediate the bio-transformation[8]. In this study, liver microsomal enzymes promoted the activities of TFU, suggesting that the enzymes can mediate the metabolism.

However, the mechanism of the pathways is not known. Liver microsomal enzymes in a reaction mixture contain many forms of reductase and oxygenase[11,12,16,17]. It is presumed that TFU might transform into 5-FU by hydrolyzing in the presence of NADPH-dependent reductase[18]. The activity of reductase is initiated by donating electrons from NADPH consumption[11,12]. The bio-transformation slowly releases 5-FU into the blood to keep the relatively long steady-state concentrations. 5-FU is then converted to deoxynucleotide (5-FdUMP) mediated by phosphoribosyl transferase in tumor cells and competes with deoxyuridine monophosphate (dUMP) for thymidylate synthetase[19-23]. DNA synthesis decreases, thus leading to cell death. Liver microsomal enzyme assay is currently underway to analyze the metabolism of sustained release of 5-FU.

In conclusion, TFU inhibits the growth of gastric carcinoma cells by sustaining the release of 5-FU. Liver microsomal enzymes mediate this bio-transformation. Experiments on a broad-spectrum of cancer cell lines are in progress.

## Abstract

**AIM:** To investigate the inhibitory effects of taltobulin (HTI-286), a synthetic analogue of natural hemiasterlin derived from marine sponges, on hepatic tumor growth *in vitro* and *in vivo*.

**METHODS:** The potential anti-proliferative effects of HTI-286 on different hepatic tumor cell lines *in vitro* and *in vivo* were examined.

**RESULTS:** HTI-286 significantly inhibited proliferation of all three hepatic tumor cell lines (mean $IC_{50}$ = 2 nmol/L ± 1 nmol/L) *in vitro*. Interestingly, no decrease in viable primary human hepatocytes (PHH) was detected under HTI-286 exposure. Moreover, intravenous administration of HTI-286 significantly inhibited tumor growth *in vivo* (rat allograft model).

**CONCLUSION:** HTI-286 might be considered a potent promising drug in treatment of liver malignancies. HTI-286 is currently undergoing clinical evaluation in cancer patients.

**Key words**: Hepatocellular carcinoma; Antimicrotubule agent; HTI-286

## INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common tumor entity causing over one million deaths annually worldwide[1,2]. Most patients with HCC suffer two different diseases, namely a chronic and a malignant liver disease. More than 80% of all HCCs are developed in cirrhotic livers. Currently, only curative treatment options are surgical resection or liver transplantation. However, only a very few patients are eligible for these treatment options. Almost 80% of the newly diagnosed patients with HCC do not qualify for resection because of insufficient functional parenchyma or transplantation due to multi-centricity and/or other co-morbidities. Consequently, most patients unfortunately only qualify for a palliative treatment[3,4]. For these patients, a number of therapeutic interventions have been developed, termed as ablative procedures (transarterial chemoembolization, radio-frequency- or laser-induced thermo-ablation and percutaneous ethanol injection)[5]. Furthermore, several systemic chemotherapy regimes have been evaluated[6-8]. For all conservative therapies, randomised clinical trials are missing to date. Currently, chemotherapy in HCC is only applied in framework of clinical trails or arterial chemoembolization. To date, only one group has proven a survival benefit of chemoembolization in a specific subpopulation of HCC patients[9]. European Association for the Study of the Liver concluded in a consensus meeting for clinical management of HCC in 2001 that chemotherapy for HCC currently is negligible[5].

Microtubule (MT) function is essential for cell growth and interference of the dynamics of microtubule formation is considered a promising therapeutic approach in cancer treatment[10]. Unfortunately, inherent resistance

to anti-microtubule agents has been found in many tumor types and acquired resistance occurs during multiple cycles of therapy. Thus, great interest lies in identifying new anti-microtubule drugs that overcome various modes of resistance. Anti-microtubule agents have not been commonly tested against HCC since initial studies had shown inherent or acquired resistance to anti-microtubule agents because of high intrinsic activity of multidrug resistance gene (MDR) in HCC[11-13].

HTI-286 is a synthetic tubulin inhibitor and a hemiasterlin analogue. Hemiasterlin was originally identified as natural product from marine sponges. It is a potent inhibitor of cell growth, depolymerizes MTs and arrests cells in the $G_2$-M phase of cell cycle. Loganzo *et al*[14] have shown that HTI-286 retains potency in cellular models resistant to several chemotherapeutics like taxanes and vinca alkaloids. HTI-286 has been fount to inhibit growth of various human tumor xenograft models, such as colon, skin, prostate, brain and breast cancer, that are resistant to currently approved anti-microtubule drugs. Additionally, HTI-286 circumvents the P-glycoprotein-mediated resistance, which hampers efficacy of several anti-microtubule agents[14,15].

Accordingly, we hypothesised that HTI-286 has a promising potential in the treatment of HCC. We investigated the proliferation inhibiting effect of HTI-286 on hepatic tumor cell lines, such as like Morris hepatoma (MH), HepG2 and Hep3B, *in vitro*. Primary human hepatocytes (PHH) in culture were also exposed to HTI-286 to evaluate a possible cytotoxic effect. Furthermore, in a rat allograft model, *in vivo* effect of intravenous HTI-286 administration on tumor growth was studied. We found that HTI-286 markedly inhibited cell proliferation of hepatocarcinoma cells *in vitro* and tumor growth *in vivo*. Interestingly, no significant cell death appeared in PHH cell culture under HTI-286 exposure.

## MATERIALS AND METHODS

### Compound

HTI-286 (N, β, β- trimethyl- L- phenylalanyl- N-(1S, 2E)-3-carboxy-1-isopropylbut-2-enyl N, 3 dimethyl-L-valinamide), also known as taltobulin or SPA-110, was generously provided by Dr. Frank Loganzo (Wyeth, Pearl River, NY, USA). HTI-286 was dissolved in Dulbecco's modified Eagle's medium (DMEM) to make two stock solutions of 5 and 0.05 mmol/L, which were then diluted in culture medium to obtain the desired concentrations.

### Cell lines

Rat liver tumor Morris hepatoma 3924A (MH) cells were grown in RPMI 1640 with Glutamax I (Invitrogen) supplemented with 200 mL/L heat-inactivated fetal bovine serum (FBS) and 1% penicillin/streptomycin, gentamycin 50 μg/mL (Invitrogen).

Human hepatocarcinoma HepG2 cells were cultured in Minimum Essential Medium Eagle with glutamine (Sigma) supplemented with 0.11 g/L sodium pyruvate and 1.5 g/L sodium bicarbonate (pH 7.2), 100 mL/L heat-inactivated FBS and 1% penicillin/streptomycin, gentamycin 50 μg/mL.

Human hepatocarcinoma Hep3B cells were cultured in DMEM (4.5 g/L glucose), Glutamax I, NaPyr (Invitrogen), 100 mL/L FBS, 1% penicillin/streptomycin and gentamycin. Isolation of primary human hepatocytes was done by a co-research group and kindly provided to us. Primary human hepatocytes were cultured in William's medium E (Sigma) containing supplemented factors.

### Evaluation of cell doubling time and determination of 50% cell growth inhibition ($IC_{50}$)

Anti-proliferative activity of HTI-286 was determined *in vitro* using 3-(4, 5-dimethylthiazol-2-yl)-2, 5-diphenyl-tetrazolium bromide colorimetric method, also known as the MTT reduction assay. This assay is based on the ability of viable cells to reduce MTT-tetrazolium salt into MTT-formazan by the mitochondrial enzyme succinate-dehydrogenase[16].

Before initiating proliferation assay, cell doubling time of each tested cell line was evaluated with the MTT assay. Afterwards MH, Hep3B and HepG2 tumor cells were cultured in 96-well microtiter plates and seeded at densities predetermined. Ensuring cell confluence rates of > 50%, fresh medium with or without HTI-286 was added at different concentrations for 1, 2 or 3 doubling times. Then, 12.5 μL of an MTT solution in medium (5 mg/mL MTT; Sigma Chemical Co., St Louis, USA) was added for 3 h. The medium was removed and the MTT-formazan crystals were solubilized by adding DMSO (100 μL/well). Absorbance ($A_{562}$) was determined at 562 nm. Drug concentration inhibiting 50% ($IC_{50}$) growth compared to untreated cells was calculated.

### Proliferation assay

MH, Hep3B and HepG2 tumor cells were cultured in 96-well microtiter plates and seeded at densities predetermined after they were starved in growth factor-depleted medium for one doubling time. Ensuring cell confluence rates of > 50%, fresh medium with or without HTI-286 was added at different concentrations for two doubling times. MTT assay was processed as described above. Results were expressed as percentage of the control. The absorbance of the control (cell culture without any treatment) corresponds to 100% MTT reduction. Three independent experiments were performed for each cell line and data were presented as mean ± SD.

### DNA synthesis measurement using 5-bromodeoxyuridine (BrdU) incorporation

To evaluate the cell cycle arrest, MH cells were $A_{405}$ seeded at the same densities as used for proliferation assay, but BrdU, a labelled DNA precursor (5-bromo-2'-deoxyuridine), was applied for three and half hours. After removing the medium and according to the manufacturer's recommendations, absorbance was determined at 405 nm. The labelled precursor is incorporated into genomic DNA during the S-phase (synthesis) of the cell cycle and the detected amount is directly proportional to the rate of cell division occurring in the sample.

### Immunofluorescence assay

Morris hepatoma, Hep3B and HepG2 cells were plated on

cover slips placed in 6-well dishes. Two days later, different concentrations of fresh medium with or without HTI-286 were added to the wells for two cell doubling times. Cells were washed with phosphate-buffered solution (PBS), fixed for 15 min in methanol at 4℃ and incubated for 1 h at room temperature with 1:500 dilution of anti-α-tubulin antibody (clone DM 1A; Sigma) in PBS. After washing with PBS, cells were incubated with 1:100 dilution of FITC-conjugated F (ab') 2 fragment of goat anti-mouse IgG (Jackson Immunoresearch, West Grove, PA) for 30 min at room temperature in PBS. After washing, cells were mounted in one drop of Dako Faramount (DAKO Corporation, USA). Cells were examined with an Olympus B × 61 microscope and × 40 magnification objective.

### *In vivo study*

A total of 17 female American Cancer Institute (ACI) rats, weighing 120-145 g, were used. The official Animal Care Committee of the University of Bern approved all experimental procedures. The animals had free access to water and standard pelleted diet and were housed in a temperature-controlled room under constant 12 h light/dark cycles. Operations were carried out under anaesthesia using clean but not sterile technique. Rats were pre-anaesthetized with ether and then put under narcosis with a mixture of dormitor, climasol and fentanyl. As antidote a mixture of antisedan, sarmasol and narcan was used. The liver was exposed *via* a midline incision and a single cube (1-2 $mm^3$) of subcutaneously grown Morris hepatoma tumor was implanted between the right and left lobe. Tumors were allowed to grow for 10 d. Tumor growth was traced with magnetic resonance tomography (MRT). MRT was performed in a 1.5 Teele unit (Sonata, Siemens) using a phased array wrist coil. T2-weighted images (TSE; 3D; TRC200; TE 43 ms) in axial plane were acquired with continuous 1 mm slices (isotrope resolution).

The tumor volume was calculated according to a web-based volumetric calculator (S.D. Filip; Mississippi State University). After confirmation of successful tumor implantation, the animals were randomly divided into control and HTI-286-treated arms, each consisted of six animals, by a third person who was not involved in the study. HTI-286 was administered *via* tail-injection in a 0.12 mg/kg rat-weight concentration on d 1, 5, 9 and 15. The tumor growth was followed with MRI on d 7, 21, and 28 after tumor implantation. After the final MRI, animals were sacrificed under a deep narcosis.

### *Statistical analysis*

QuickCals calculator for scientists (GraphPad Software 2002) was used for statistical analysis. Student's *t* test was chosen to compare the means. Differences were considered statistically significant with two-tailed *P* values less than 0.05.

## RESULTS

### *Cell doubling time and $IC_{50}$*

To determine a test confluence in which active cell proliferation is permitted during the experiments and also a sufficient confluence for adding the drug, the cell doubling time of each tumor cell line was first evaluated using different initial seeding densities and by following the cell growth for 7 d (data not shown). The doubling times for MH, Hep3B and HepG2 tumor cells were found to be 22 h, 43 h and 59 h, respectively. For our experiments, we chose to add the drug for two cell doubling times.

We evaluated the required $IC_{50}$ concentration for each cell line with the MTT assay. All three hepatocarcinoma cell lines were exposed for 1, 2 and 3 cell doubling times to the drug. Sensitivity to HTI-286 was different in all cell lines. Mean $IC_{50}$ for all tested hepatic tumor cell lines was 2 nmol/L ± 1 nmol. At 1 nmol/L, HTI-286 inhibited MH cell growth by 50%. The $IC_{50}$ for Hep3B and HepG2 was 2 nmol/L and 3 nmol/L, respectively. HepG2 was the most sensitive and Hep3B the least sensitive cell line among the tested hepatocarcinoma cell lines.

### *Proliferation assay*

Ability of HTI-286 to inhibit cell proliferation was examined. Morris hepatoma, Hep3B and HepG2 cells were exposed at $IC_{50}$ concentration to HTI-286 for two cell doubling times. All three tested hepatic tumor cell lines were significantly inhibited compared to the controls with *P* values of 0.005, 0.001, and 0.002 for MH, HepG2, and Hep3B, respectively (Figure 1A-C).

In contrast, PHH did not show an obvious decrease in viable cells in the MTT assay after continuous exposure to HTI-286 for 24 or 48 h at concentrations between 1 nmol/L and 1 mmol/L (Figure 2).

These data suggest that hepatic neoplastic cells are more sensitive to HTI-286 than primary human hepatocytes. Furthermore, our data are consistent with the effects of HTI-286 on 18 different human tumor cell lines reported by Loganzo *et al*[14].

### *Effect of HTI-286 on cell cycle distribution*

Hemiasterlin arrests cells in mitosis and induces apoptosis. HTI-286-treated MH cells were analysed by 5-bromodeoxyuridine (BrdU) incorporation assay. Cells showed significant decrease in the S phase when being exposed to HTI-286 at 1 nmol/L for two cell doubling times. DNA synthesis was significantly reduced in the treated cells ($P = 0.02$) indicated by reduced BrdU incorporation compared to the untreated cells (Figure 3). With increasing concentration, more cells were found to be arrested into this phase (data not shown). Loganzo *et al*[14], using fluorescence-activated cell sorting analysis (FACS), identified the cell cycle arrest in the $G_2$-M phase. However, we did not have the possibility to perform a FACS analysis. These data are consistent with reported effect of hemiasterlin and HTI-286 on cell cycle and cell proliferation.

### *Effect of HTI-286 on microtubule structure and cell morphology*

The effect of HTI-286 on microtubule structure was examined by immunofluorescence microscopy using an antibody specific for α-tubulin. Untreated MH, Hep3B and HepG2 cells contained a dense and complex network

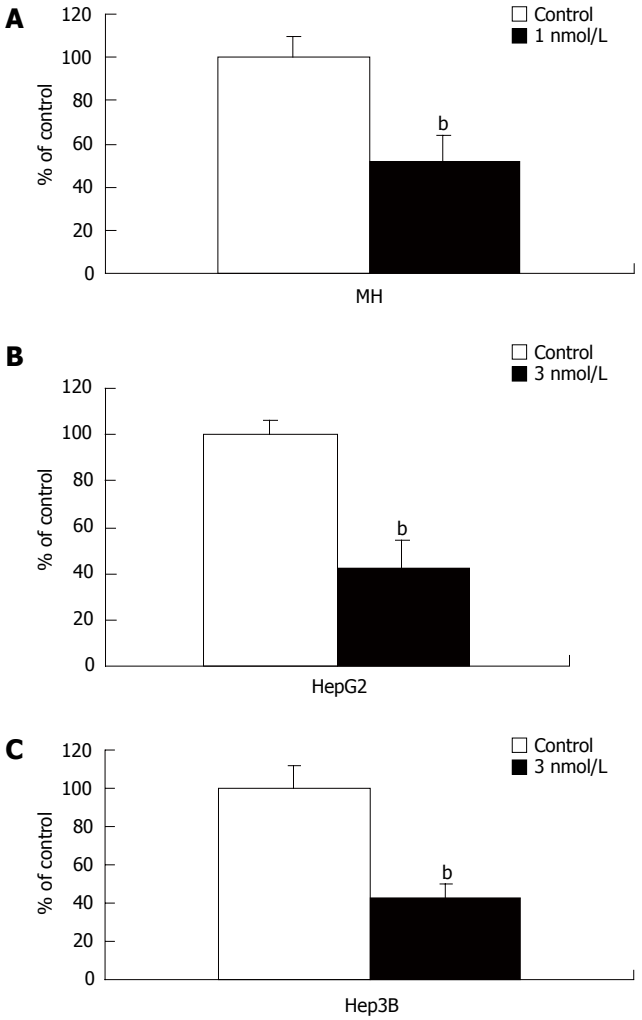

**Figure 1** Inhibitory effect of HTI-286 on proliferation of MH, HepG2, and Hep3B cells. Inhibitory effect upon HTI-286 treatment was highly significant in all three hepatic carcinoma cell lines. MH (**A**), HepG2 (**B**) and Hep3B (**C**) cells were exposed to 1, 3, and 3 nmol/L of HTI-286, respectively, for two cell doubling times. Student's *t* test analysis showed two-sided *P* values of 0.005, 0.002 and 0.001 for MH, HepG2, and Hep3B, respectively.

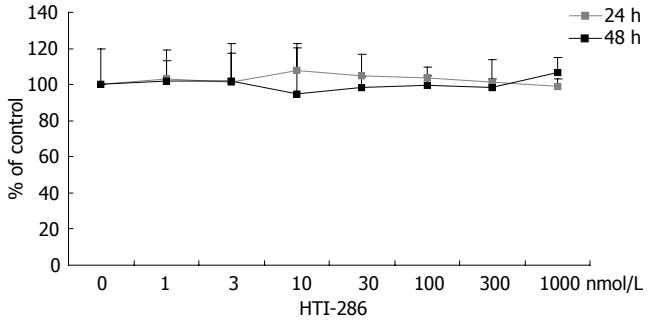

**Figure 2** Effect of HTI-286 on primary human hepatocytes. Human hepatocytes were exposed to HTI-286 for 24 and 48 h at concentrations between 1 nmol/L and 1 mmol/L. No significant decrease in viable cells was detected in MTT assay at any concentration.

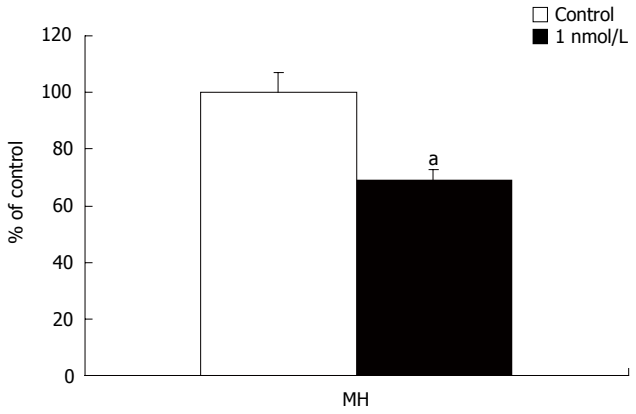

**Figure 3** BrdU incorporation in MH cells treated with 1 nmol/L HTI-286. Decrease in S phase was observed as BrdU incorporation decreased significantly ($P = 0.024$) in MH cells compared to the untreated cells when exposed to 1 nmol/L HTI-286 for two cell doubling times.

of MTs in general extending from the perinuclear region to the cell periphery. MH, Hep3B, and HepG2 cells were exposed to different concentrations (1 nmol/L-30 nmol/L) of HTI-286. Microtubule structure was disrupted by HTI-286 at low concentrations (Figure 4A and B). Furthermore, cell morphology changed during drug exposure. Cell rounding and swelling phenomena were the most significant attributes accompanied by a decrease in cell number. Accumulation of cells in metaphase was seen (data not shown). With increasing concentration of HTI-286, diffuse tubulin staining was evident with loss of cell adhesion, indicating a general disruption of cellular integrity. Additionally, multipolar spindles appeared, indicating disturbed spindle function in cells undergoing mitosis (Figure 4C). These data confirm that HTI-286 permeates hepatocarcinoma cells and modify MT structure and are consistent with the previous reported effect of HTI-286 on tubulin.

### *In vivo efficacy of HTI-286*

Morris hepatoma tumors were implanted into the liver of rats as described in methods. The perioperative mortality (tumor implantation) was zero percent. Successful tumor growth was seen in almost 70% of the animals on $10^{th}$ post-implantation day. Of those animals with good tumor development, 12 were randomized into two groups, each consisting of six animals. One group was given 0.12 mg/kg of HTI-286 intravenously on d 1, 5, 9 and 15. The dose was chosen according to advice by Wyeth. Rats tolerated intravenous HTI-286 treatment well. No clinical signs of hepatic or renal insufficiency were seen in the animals. The control group was not given any specific treatment but received the vehicle and the natural tumor progression was followed. The tumor volume at randomization did not differ between both groups ($P = 0.14$). Two animals from the control group died during the second MRI examination due to anaesthesia complications and were excluded from the analysis. By d 7, after only two doses of HTI-286, tumor growth was significantly inhibited in the treated group compared to the control group ($P = 0.04$). The last dose of HTI-286 was applied on d 15. The growth difference on d 21 reached high significance after completion of treatment (4 doses in total) in the HTI-286-treated group compared to the control group ($P = 0.0001$). Tumor growth was followed for one week more without application of HTI-286. On d 28, the MRI still revealed

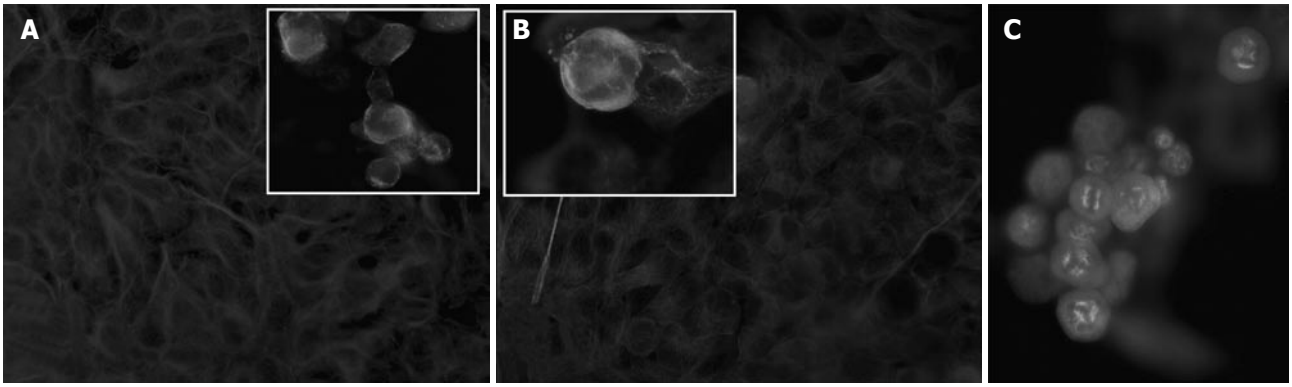

**Figure 4** Microtubule (MT) structure assessed by immunofluorescene microscopy with a specific α-tubulin antibody. **A** and **B**: Untreated Hep3B and HepG2 cells showed dense and complex MT network in the cytoplasm. Insets A and B represent cells after HTI-286 treatment at 3 nmol/L for two cell doubling times. Decreased cytoplasmic microtubule density and diffuse staining were observed. Magnification x 40 except for insets, which are magnified further to outline the morphological changes. **C**: MH cells treated with HTI-286 at 1 nmol/L for two cell doubling times showed multipolar spindles, indicating disruption of the microtubule network in mitotic cells.

smaller tumor in the treated group, indicating lasting inhibitory effect; however, the difference did not reach statistical significance ($P = 0.056$) (Figure 5).

## DISCUSSION

HCC is the most common cause of death due to cancer in some areas of Asia and with steadily rising incidence in Europe and USA as well. In Europe, it is already the primary cause of death in patients with cirrhosis[17]. Late presentation and lack of systemic therapy result in median survival of less than 12 mo. Less than 25% of HCC patients qualify for resection or transplantation[18]. To date, no chemotherapy regimen has been established for patients with unresectable HCC. Ultimately, the majority of HCC patients can only be treated symptomatically and they have dismal prognosis[19].

The few studies of anti-microtubule agents used for the treatment of HCC have shown high intrinsic multidrug resistance (MDR) gene activity, resulting in ATP-dependent export of chemotherapeutic drugs across the plasma membrane mediated by transporters of the MDR P-glycoprotein family (P-gp). Tubulin binding agents are typically good substrates for P-gp and may be partially responsible for the poor response rates observed in HCC patients[20-22].

Hemiasterlins are a family of potent cytotoxic peptides initially isolated from marine sponges. Anderson *et al*[15] have reported *in vitro* and *in vivo* anticancer activity of hemiasterlins and clarified underlying mechanisms of cytotoxicity. HTI-286 is a synthetic analogue of naturally occurring hemiasterlins and a potent antimitotic agent. In 18 different human tumor cell lines, HTI-286 has been proven as a potent inhibitor of cell proliferation and having substantially less interaction with P-gp than currently used taxanes and vinca alkaloids. HTI-286 has been shown significantly effective in tumors resistant to paclitaxel and vincristine. Furthermore, in human tumor xenografts, HTI-286 inhibited growth of tumors derived from colon, brain, skin, prostate, and breast[14].

It has been shown that neoplastic cells are either inherently refractory to tubulin binding agents (taxanes and vinca alkaloids) or acquire resistance during repetitive therapy[23-25]. Such resistance, whether inherent or acquired, is associated with induction of signal transduction pathways, expression of MDR, differential tubulin isotypes, tubulin mutations, interaction of tubulin with the cytoskeleton, and alteration of apoptosis-regulating proteins, such as p53, bcl family members, or survivin[10,26,27].

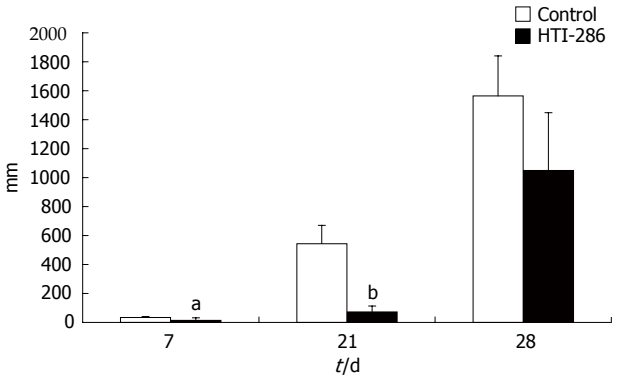

**Figure 5** *In vivo* inhibition of tumor growth under HTI-286 treatment. HTI-286 was injected on d 1, 5, 9 and 15. By d 7, tumor growth significantly differed between the control and HTI-286 group ($^aP = 0.042$; $^bP = 0.0001$). Two weeks after the last HTI-286 injection, the inhibitory effect was diminished between both groups ($P = 0.056$).

Our data demonstrate that HTI-286 is an effective inhibitor of hepatic tumor cell proliferation *in vitro*. The mean $IC_{50}$ of HTI-286 in our experiments (2 nmol/L ± 1 nmol/L) is consistent with the reported $IC_{50}$ of 2.5 nmol/L reported by Loganzo *et al*[14]. Anderson *et al*[15] reported $IC_{50}$ for hemiasterlin A and B of 0.5 and 2 nmol/L, respectively. With intravenous HTI-286 treatment, growth of Morris hepatoma tumors was also significantly inhibited. However, two weeks after the last intravenous dose, the inhibitory effect diminished. These findings are also consistent with the *in vivo* efficacy reported by Loganzo *et al*[14].

The data shown here demonstrate sensitivity of hepatic tumor cells to HTI-286. The observed differences in sensitivity and viability between the tested tumor cell

lines and PHH may be related to different tubulin isotype expression in malignant *versus* normal parenchymal cells. Although human hepatocytes do not proliferate in culture and lose their hepatic-specific metabolic activity and differentiation irreversibly after being maintained in culture for 5 to 7 d, our data suggest a less cytotoxic effect of HTI-286 on PHH compared with hepatic tumor cells[28,29]. Interestingly, no significant decrease in viable cells was observed at concentrations from 1 nmol/L to 1 mmol/L in PHH culture. In contrast, 50% growth inhibition was observed in MH, Hep3B, and HepG2 cells exposed to only 1-3 nmol/L HTI-286. However, the cell metabolism of human hepatocytes under HTI-286 has not been evaluated.

Six different alpha- and beta-tubulins have been described to date[30,31]. Furthermore, the six isotypes are sub-classified according to their C-terminal composition, which is highly divergent. In addition, post-translational modifications enhance the divergence[32,33]. Several studies have shown a positive correlation between expression of beta-tubulin isotype and resistance to paclitaxel and docetaxel. Accordingly, alterations of alpha-tubulin have been described resulting in resistance to tubulin binding agents as well[34-38]. Currently, only one study is available on expression of tubulin isotypes in HCC, response rate and resistance to vinca alkaloids and taxanes[39].

Microtubules are in dynamic equilibrium with the pool of soluble tubulin dimers in the cell, with constant incorporation and release of the dimers into the polymerized structures and back into the soluble tubulin pool[40]. Microtubule dynamic (MD) is the phenomenon of switching between growing and shortening states of MT ends. In proliferating and neoplastic cells, MD is increased[41,42]. Microtubule dynamic is suppressed by HTI-286[43]. Drugs targeting tubulin induce apoptosis. In the case of tubulin-binding agents, although the mechanisms have not yet been completely clarified, it seems that inhibition of MD is closely associated with changes in the expression profile and functional status of apoptotic/anti-apoptotic-regulatory molecules and MT-associated proteins[34,44,45]. Additionally, drug-resistance to tubulin-binding agents is also linked to cytoprotective and anti-apoptotic factors, such as p53, bcl-2, or bcl-xL. Current molecular understanding of the mechanisms of cell death by tubulin-targeting agents suggests that these agents inhibit MD and cell cycle $G_2$/M-phase transition, which triggers molecular signalling that induces mitochondrial permeability and the release of pro-death molecules into the cytosol inducing caspase-dependent apoptosis[46,47]. Giannakakou *et al*[48] showed suppression of MD with low concentrations of MT-targeting compounds enhancing microtubule-dependent trafficking and accumulation of p53 into the nucleus and activation of p53-downstream target genes as well as induction of p53-upregulated modulators of apoptosis. Evidence is strong that MDR1 expression is negatively correlated with p53, and MDR1 has been shown to be responsible for drug resistance to tubulin-binding agents[49]. HTI-286 is a very poor substrate for MDR1 encoded drug-efflux pump. p53 directly affects the MD by transcriptional regulation of proteins involved in modulation of microtubules, known as MT-associated proteins (MAPs). Bcl family members have been identified as transcriptional targets of p53. Anti-apoptotic function of bcl2 and pro-apoptotic function of bax depend on their dimerization status. Furthermore, anti-microtubule agents induce bcl2 inactivation through phosphorylation, which parallels their inability to form heterodimers with bax. Consequently, bax-bax homodimer levels rise and evoke apoptosis[50]. These findings are supported by the fact that bcl2 phosphorylation appears at $G_2$-M phase[51]. Microtubule-targeting drugs cause cell cycle arrest in $G_2$-M phase. Although the alteration of the molecular environment during HTI-286 exposure has not yet been evaluated, it is likely that the aforementioned molecular mechanisms leading to apoptosis also apply to HTI-286-induced cell death. HTI-286 inhibits proliferation at very low concentrations, suggesting that molecular events are impacted at low drug concentrations. Notably, suppression of MD is the most decisive factor in initiation of apoptosis and that all types of MT-targeting drugs, independent of their class (depolymerizing or polymerizing agents), modulate MD.

In addition to mitosis, tubulin plays an important role in the interphase cell in maintaining the celluar subcompartiments and distribution of organelles (mitochondria, Golgi, endoplasmis reticulum, lysosomes, endosomes and nucleus)[52-57]. This finding suggests a complex role for tubulin in signal transduction and transcription. Our $\alpha$-tubulin staining data implicate a complex network of MT in the interphase cell and a role in cellular organisation and metabolism.

In conclusion, our data suggest that HTI-286 is highly effective in inhibiting hepatic tumor cell proliferation *in vitro* and tumor growth *in vivo*. Primary human hepatocytes appear to be unaffected by high doses of HTI-286. Further investigation of HTI-286 in patients with advanced HCC or with primary unresectable HCC is warranted. Currently, HTI-286 is in clinical development.

## ACKNOWLEDGMENTS

The authors wish to express their gratitude to Philip Frost and Frank Loganzo, Oncology Research, Wyeth Research, Pearl River NY, USA, for their support and critical reading of the manuscript. The authors are also indebted to Wyeth Research for supplying the HTI-286 substance.

## Abstract

**AIM:** To study of the effect of caffeic acid phenethyl ester (CAPE) on the initiation period in a medium-term assay of hepatocarcinogenesis.

**METHODS:** Male Wistar rats were subjected to a carcinogenic treatment (CT) and sacrificed at 25$^{th}$ d; altered hepatic foci (AHF) were generated efficiently. To a second group of rats a single 20 mg/kg doses of CAPE was given 12 h before initiation with CT and were sacrificed at 25$^{th}$ d. We evaluated the expression of preneoplastic markers as γ-glutamyltranspeptidase (GGT) and glutathione S-transferase type pi protein (GSTp) by histochemistry, RT-PCR and Western blot analyses, respectively. We measured thiobarbituric acid reactive substances (TBARS) in homogenates of liver and used Unscheduled DNA Synthesis (UDS) assay by incorporation of [$^3$H] thymidine ($^3$HdT) in primary hepatocyte cultures (PHC).

**RESULTS:** At 25$^{th}$ d after CT CAPE reduced the observed increase of GGT$^+$AHF by 84% and liver expression of *ggt* mRNA by 100%. In case of the GSTp protein, the level was reduced by 90%. As indicative of oxidative stress generated by diethylnitrosamine (DEN) 12 h after its administration, we detected a 68% increase of TBARS. When CAPE was administered before DEN, it completely protected from liver TBARS induction. To have an indication of the sole effect of CAPE on initiation, two carcinogens were tested in a UDS assay in PHC, we used methyl-n-nitrosoguanidine as a direct carcinogen and DEN, as indirect carcinogen. In this assay, genotoxic damage caused by carcinogens was abolished at 5μM CAPE concentration.

**CONCLUSION:** Our results demonstrated that CAPE possesses anti-genotoxic and antineoplastic capabilities, by an anti-oxidative and free-radical scavenging mechanism.

**Key words:** Caffeic acid phenethyl ester; Antioxidant; Hepatocarcinogenesis; Initiation

## INTRODUCTION

CAPE (2-phenylethyl 3(3,4-dihdroxyphenyl)-2-propenoate), exhibits a broad spectrum of biological activities antibacterial[1], anti-inflammatory[2], antiviral[3], antiatherosclerotic[4], antiproliferative[5], neuroprotective[6-8] and antitumoral actions[9]. In *in vivo* models, CAPE has been identified as an experimental antineoplastic agent by inhibition of colon Aberrant Crypt Foci formation[10], mice skin tumor induction[11,12], intestinal tumor in Min/+ mice[13]; and, recently, we demonstrated that CAPE inhibits induction of AHF at a promotion stage of a chemical hepatocarcinogenesis model in rats[14].

The mechanism by which CAPE exerts its anti-carcinogenic effect is not completely known. In our previous work of the inhibition of promotion by this substance, we hypothesized that the activation of NF-kappaB induced by reactive oxygen species (ROS) generation produced by the metabolism of 2-acetamidofluorene (2-AAF) is inhibited by CAPE through its antioxidant capacity. This capacity has been interpreted as the mechanism which prevents oxidative

stress caused by different stimuli[12,15,16]. The inhibition of oxidative stress generated in ischemic-reperfusion conditions in different experimental models including rat and rabbit has been explained similarly[17-19]. The *in vitro* antioxidant activity of CAPE has also been shown, since it reduced the levels of intracellular $H_2O_2$ and oxidized bases in DNA, probably by selective scavenging activity[20,21].

At present, evidence has accumulated that electrophiles are generated by direct and indirect carcinogens. In our hepatocarcinogenesis system, DEN metabolism produces free-radical metabolites. Additionally, cytochrome isoform 2E1 (CYP2E1) is the main cytochrome responsible of DEN metabolism, and capable of generating a prolonged burst of ROS near the site of substrate oxidation[22]. The products of these events are involved as cellular oxidant participants in neoplastic development[23]. Since oxidative stress during carcinogen metabolism participates in the initiation of hepatocarcinogenesis in the rat and CAPE counteracts oxidative stress, the present study was designed to examine the effect of CAPE on the initiation stage, evaluating its possible antioxidative mechanism of action *in vivo* in a medium-term hepatocarcinogenesis model and *in vitro* using a PHC.

## MATERIALS AND METHODS

### Animals

Male Wistar rats (180-200 g) obtained from the Production Unit of Experimental Laboratory Animals (UPEAL-Cinvestav, México D.F., México), had access to food (PMI Feeds Inc., Laboratories Diet) and water at all times; food cups were replenished with diet three times weekly. During treatment, the rats were transferred to the holding room, under controlled conditions of 12-h light/12-h dark cycle, 50% humidity, and 21℃ temperature. All animals received human care according to the institutional guidelines for use of laboratory animals.

### Experimental hepatocarcinogenic protocol

Animals were treated as described by Carrasco-Legleu *et al*[14]. Briefly, animals were administered 200 mg/kg DEN intraperitoneally; one week later, 2-AAF was orally administered with a stainless steel feeding tube at doses of 20 mg/kg per day on 3 consecutive days before partial hepatectomy (PH). Animals were sacrificed 25 d after DEN administration[24] and the livers excised, quickly frozen in liquid nitrogen and stored at -80℃ until analysis. CAPE was obtained by esterification of caffeic acid with phenethyl alcohol as detailed previously[25], and dissolved in dimethylsulfoxide (DMSO) to evaluate its effect on initiation; it was administered IP at a dose of 20 mg/kg weight 12 h before DEN application (Figure 1).

### Histochemistry of GGT

Histological liver sections of 15 μm thickness were obtained with a cryostat (Slee cryostat MTC, Germany) and stained for GGT activity according to Rutenburg *et al*[26]. Images of the GGT positive ($GGT^+$) foci were captured with a digital camera (Color View 12, Soft Imaging System GmbH, Germany) and quantified with analysis software (AnalySIS Soft Imaging System GmbH, Germany). $GGT^+$ areas larger than 0.01 $mm^2$ were registered to avoid basal detection. Rat livers were sectioned in 5 mm slices, and 3 slices were randomly selected from each liver. Twenty histological sections were prepared from each liver slice and, randomly again, 4 out of the 20 were selected and prepared for computer analysis.

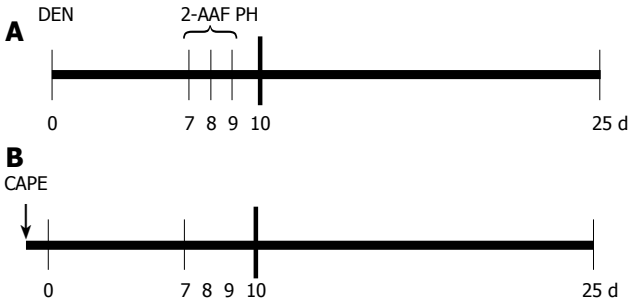

**Figure 1** CAPE administration protocol. **A**: Carcinogenic treatment (CT): at time 0 the rats were treated with 200 mg/kg of DEN; on d 7, 8 and 9, 2-AAF was administered by gavage at doses of 20 mg/kg per day, a PH was performed at d 10 and rats were sacrificed at d 25; **B**: CAPE (↓) was administered 12 h before DEN.

### RT-PCR analysis

Total RNA of liver tissue was isolated with the method developed by Chomczynski and Sacchi[27]. It was treated with RNase-free DNase 1 (Boehringer-Mannheim, Germany) and one microgram of RNA was reverse transcribed into cDNA using the commercial kit (Gibco BRL/Life Technology, Inc., Gaithersburg, MD) at a final volume of 12.5 μL. α-Actin was used as an internal reference gene. The 2 primer sequences of rat GGT and αactin used were: 5'-CTCTGCATCTGGCTACCCAC-3' 5' -GGATGCTGGGTTGGAAGAGG-3' and 5'-CCAAGG CCAACCGCGAGAAGATGAC-3' 5'-GGTACATGGTG GTGCCGCCAGAC-3' (sense and antisense), respectively. The mixture was heated at 45℃ for 30 min in a GeneAmp PCR System 2400 (Perkin-Elmer, Corp., CT). GGT and α-actin were amplified in 40 and 30 sequential cycles, the program was denaturation (94℃, 30 s), annealing (59℃, 45 s), and extension (70℃, 45 s). The PCR products were 418 bp and 586 bp, respectively. The amplified samples were visualized on 2% agarose gels, stained with ethidium bromide and captured with a digital camera (Kodak electrophoretic documentation and Analysis system 120).

### Western blot analysis

For detection of GSTp in the cytosolic fraction, liver homogenates were prepared with lysis buffer (Tris-HCl 10 mmol/L pH 7.4, NaCl 150 mmol/L and phenylmethylsulfonyl fluoride (PMSF) 1 mmol/L) and were spun at 9000 r/min in a microcentrifuge at 4℃ for 15 min. The cytoplasm protein concentration was measured with the bicinchoninic acid method[28]. SDS/PAGE was performed under reducing conditions on 12% polyacrylamide gels. Resolved proteins were transferred onto nitrocellulose sheets (Bio-Rad Lab., Hercules, CA), probed with a rabbit polyclonal anti-GSTp (Dako Corporation, Carpinteria, CA), treated with horseradish peroxidase-conjugated secondary antibody (Zymed, San Francisco, CA), detected by Enhanced Chemiluminescense

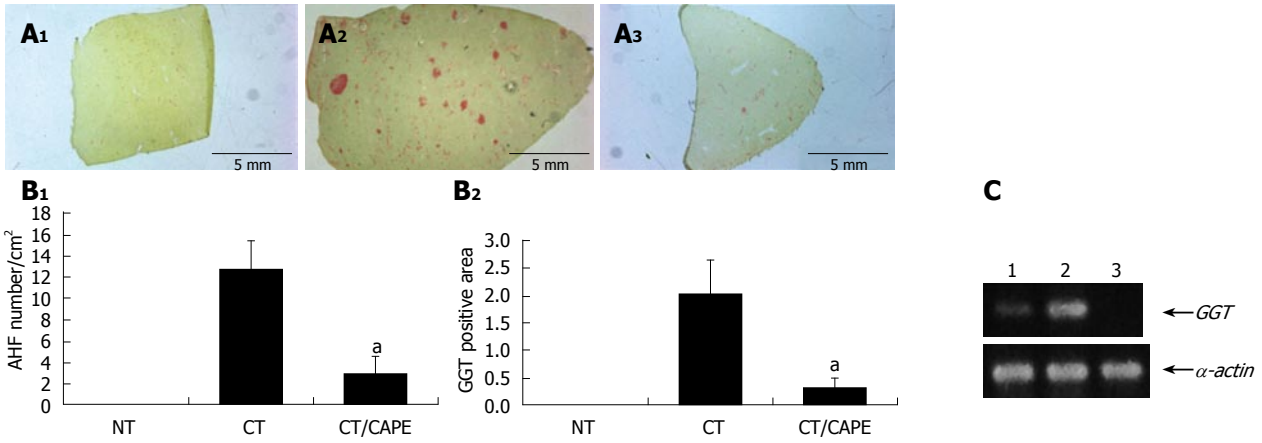

**Figure 2** Effect of CAPE on GGT expression. **A**: GGT histochemically stained sections (1) non-treated group (NT), (2) carcinogenic treatment group (CT), (3) CT plus CAPE before DEN; **B**: CAPE effect on number/cm$^2$ of AHF and percentage of GGT$^+$ area/tissue. The differences of AHF number and area after the effect of CAPE in these groups were compared with the respective control group (CT + vehicle) and obtained values were significant by *t* with $^aP < 0.05$. Twelve histological liver sections per rat from each treatment were randomly selected. NT ($n = 3$), CT ($n = 4$), CT plus CAPE ($n = 7$); **C**: The RT-PCR assay was used to determine *GGT* mRNA expression. L1: Control NT; L1: CT group; L1: CT plus CAPE. The series of the extreme right represents α-actin transcripts as control. This experiment was performed with a pool of total RNA isolated from 3 animals.

detection reagent (Santa Cruz Biotechnology Inc., Santa Cruz, CA) and developed with Konica Film (Tokyo, Japan.). These membranes were then re-probed with anti-α-actin monoclonal antibody (Cinvestav, Mexico City) used as loading control.

### *Thiobarbituric acid reactive substances*

Samples of frozen liver were homogenized in a buffer containing 10 mmol/L Tris, PMSF and NaCl, and protein was determined. Lipid peroxidation (LPX) was measured as TBARS, a widely used method, according to Buege and Aust[29]. Briefly, 600 mg of protein liver homogenates plus 300 μL of 0.4% thiobarbituric acid in 20% acetic acid, pH 3.0, were mixed and heated at 100℃ for 45 min. Next, the samples were cooled, added with 200 μL of 1.2% KCl, 0.5 ml of 1:15 pyridine/butanol and centrifuged at 7500 r/min for 10 min. The resulting solution was determined at *A*532 nm, and using the extinction coefficient, $E = 1.56 \times 10^5$, TBARS were expressed as nmoles of malonyldialdehyde as mg of proteins.

### *Unscheduled DNA synthesis assay in primary hepatocyte cultures*

PHC were prepared from male Wistar rats (180-200 g) by the collagenase perfusion method as previously described[30], and three replicates of $8 \times 10^5$ cells were seeded onto 35 mm culture dishes. PHC were seeded in DMEM supplemented with 10% bovine fetal serum (HyClone, Laboratories Inc., Logan Utah) and 5 μg insulin/mL (Eli Lilly, México, DF) and placed in a 37℃ humidified incubator in an atmosphere of 90% air/10% $CO_2$.

After 2 h of incubation, the medium was removed and replaced by one ml of serum-free medium containing 10 μmol/L HU, 5 μCi of $^3$HdT from Amersham Life Science (Cleveland, OH) and 4 μL of DMSO as control. DEN, CAPE or MNNG were dispensed from 0.625 to a final concentration of 10 μmol/L per dish. Control dishes received the corresponding vehicle of CAPE and carcinogens. PHC were incubated for 4 h with their respective treatment. To account for variation in the number of cells between dishes, results were normalized as a function of DNA concentration. For this purpose DNA hydrolysate was obtained with the method by Leyva and Kelly[31] as described by Pérez-Carreón[32]. Incorporation of $^3$HdT in dpm per μg DNA was determined and the results were expressed, as percent of control incorporation.

### *Statistical analysis*

Number and area of GGT$^+$ AHF and GSTp protein expression of the group treated with CAPE were compared with the respective control group (CT plus vehicle). Results were analyzed by *t*. Differences were considered statistically significant at $P < 0.05$.

## RESULTS

### *In vivo assays*

**Protective effect of CAPE on hepatocarcinogenesis initiation:** In this *in vivo* medium-term hepatocarcinogenesis assay, CAPE was tested on initiation. Rats which received the CT (DEN, 2-AAF and PH) were sacrificed 25 d after initiation. At this time, copious liver GGT$^+$ AHF were histochemically detected, and their average-quantity was considered 100%. The CT animal group that received a single dose of CAPE before initiation clearly showed a decrease of GGT$^+$ AHF formation, resembling that of the non-treated (NT) group (Figure 2A). Quantification of this phenomenon showed a drastic decrease in number and area of GGT$^+$ AHF. CAPE had a protective effect of 84% and 91%, respectively (Figure 2B). Differences were considered significant when $P < 0.05$. We also evaluated the expression of transcripts of the GGT protein by the RT-PCR assay, and observed a decrease of transcripts due to the CAPE effect (Figure 2C)

**CAPE decreases the expression of the GSTp protein:** The protective effects of CAPE with respect to GGT were toward its activity and its mRNA expression. GSTp is another marker related to the hepatocarcinogenesis model. We analyzed if CAPE modulates this marker at protein

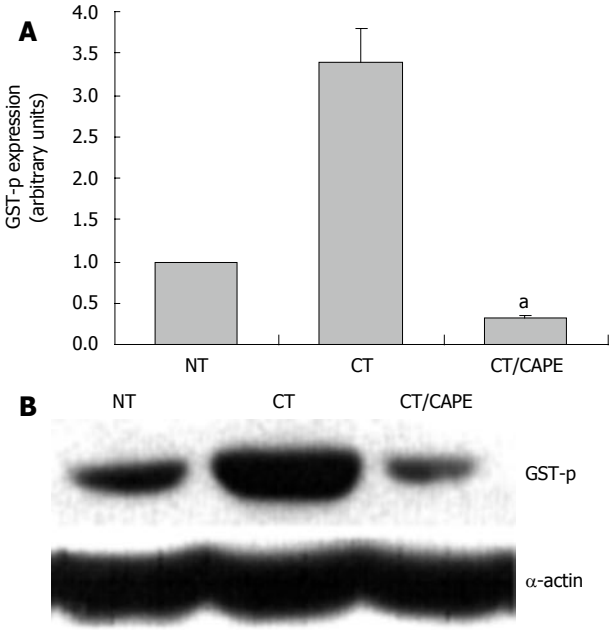

**Figure 3** The effect of CAPE on GSTp protein expression. Western blot was used to analyze the expression of the GSTP protein marker. **A:** Densitometric analysis of GSTP in: Control NT, CT and CT plus CAPE given before DEN. Results were statistically significant with $^{a}P < 0.05$; **B:** Representative Western blot.

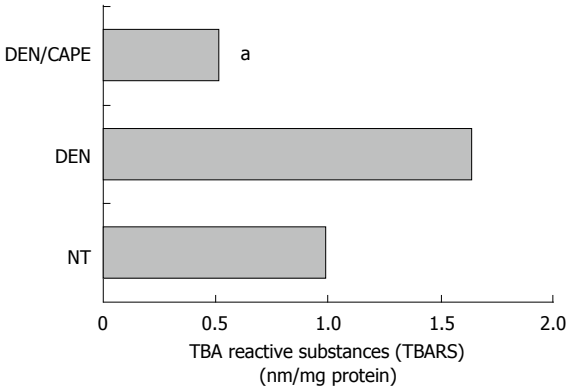

**Figure 4** Effect of CAPE on LPX levels induced by DEN. LPX was determined by detection of malonyldialdehyde concentration and expressed as TBARS. DEN increased TBARS levels detected at 12 h. CAPE administered 12 h before the initiator, clearly reduced the TBARS induced by DEN. Six hundred microgram of liver homogenates of each treated group were used, group NT, DEN (12 h after) and DEN plus CAPE (24 h after CAPE administration). Results were statistically significant with $^{a}P < 0.05$.

level. By Western blot we detected that CAPE drastically decreased the expression of the GSTp protein by 90% at d 25 (Figure 3). These results, in congruence with those related to GGT, showed the same protective profile of CAPE.

**DEN-generated lipid peroxidation was decreased by CAPE:** Since our laboratory previously has shown that LPX is an expression of oxidative stress in cells[33], we determined the TBARS as a global approach to measure LPX, and compared their levels obtained 24 h after administration of CAPE before initiation. Twelve hours after initiation with DEN, an increment of LPX of 68% above control level was observed (Figure 4). The administration of CAPE 12 h before administration of DEN importantly prevented full expression of LPX. CAPE decreased it to 52% with respect to the NT group of rats.

In sum, these *in vivo* results showed that a single dose of CAPE, in addition to the protective effect on induction of $GGT^{+}$ AHF, transcription of *GGT*, and expression of GSTp, produced a very important protective effect against oxidative stress.

### *In vitro assay*

**Protective effect of CAPE *in vitro*:** The genotoxic alteration produced by carcinogens, one of the first measurable effects involved in initiation, can be analyzed with the UDS assay. This assay was used to test if CAPE protects against the genotoxic effect induced by 2 carcinogens with different mechanisms of activation: DEN, an indirect carcinogen that is activated by CYP2E1 and generates electrophylic species as well as ROS, and MNNG, a direct carcinogen that produces electrophylic proximal carcinogens by hydrolysis. The effect of CAPE on DEN-treated PHC of Wistar rats was analyzed; the incorporation of $^{3}$HdT in presence of vehicle (water or DMSO alone) was defined as control. Figure 5A shows that DEN at 1.25 μmol/L induced an increment of $^{3}$HdT incorporation of 60% above control level. CAPE alone at 1.25 and 2.5 μmol/L did not induce incorporation above control level (data not shown). The CAPE concentrations (0.625 to 5 μmol/L) abolished increments in $^{3}$HdT incorporation caused by 1.25 μmol/L DEN in a concentration-dependent form. We also analyzed if the action of CAPE is due to its free-radical scavenging abilities, MNNG being a mutagenic electrophylic species generator by hydrolysis. CAPE protected from the genotoxic damage to DNA produced by MNNG. The increment of $^{3}$HdT incorporation induced by MNNG was more pronounced than that induced by DEN. The maximum evoked response was 182% above control level at 0.625 μmol/L MNNG concentration. CAPE was tested at 5 μmol/L for its protective effect, and this concentration abolished the carcinogenic effect of 0.625 to 10 μmol/L MNNG and decreased $^{3}$HdT incorporation between 20 and 40% below control level (Figure 5B). CAPE inhibited the genotoxicity induced by both carcinogens tested, DEN and MNNG, suggesting that its protective mechanism is probably its capacity as scavenger of electrophylic molecules and not as inhibitor of carcinogenic activation in our system.

## DISCUSSION

Present results clearly show a protective effect of CAPE when a single dose was given before initiation in the rat hepatocarcinogenesis model. CAPE decreased the induction of both, area and number of $GGT^{+}$ AHF, GGT transcripts and of the GSTp protein. Our results showed a protective effect against induction of preneoplastic lesions and are an addition to previously reported data[11-14]. These effects are in accordance with the effective chemoprotective antioxidant activity reported for CAPE[34,35] and are further supported by *in vitro* evaluation, in mouse epidermal cells, where CAPE was found to be

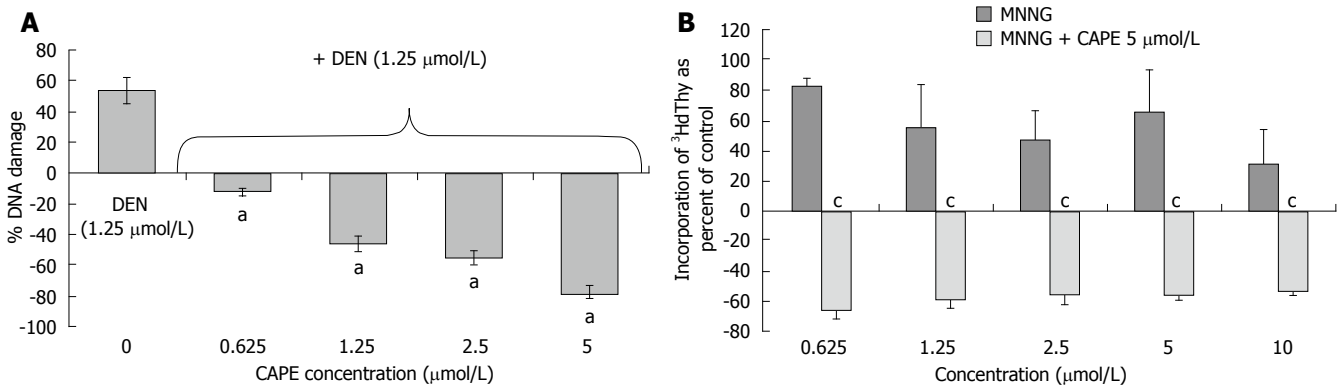

**Figure 5** CAPE protects from genotoxic damage caused by DEN and MNNG in PHC. **A**: DEN at 1.25 μmol/L concentration induced $^3$HdT incorporation and this dose was tested with several concentrations of CAPE (0.625, 1.25, 2.5, 5 and 10 μmol/L). CAPE decreased DEN genotoxic damage to levels even below the control; **B**: Curve concentration of MNNG from 0.625-10 μmol/L. One dose of 5 μmol/L of CAPE protects from genotoxic damage caused by MNNG in PHC. Data incorporation of $^3$HdT was estimated as dpm/mg of DNA and results are expressed as percent of control samples, the zero data represent $^3$HdT incorporation of basal level of control group. Results were obtained from 3 replicates of at least 3 animals. $^a P < 0.05$ *vs* DEN only; $^c P < 0.05$ *vs* MNNG only.

one of the four better chemo-protective agents among 25 well-known substances with this activity[36].

In this context, it has been postulated that overproduction of ROS and oxidative DNA damage play a major role in cancer development. Increased concentrations of active oxygen, organic peroxides and radicals can promote initiated cells to neoplastic growth, inducing alterations in DNA structure or producing epigenetic mechanisms[23,37]. This justified the investigation of the effect of CAPE during the early stages of liver carcinogenesis, where we had specifically demonstrated the obligated participation of oxidative stress in the production of preneoplastic lesions during initiation in our medium-term hepatocarcinogenesis model. We had previously shown that ROS importantly participate in our model of hepatocarcinogenesis, and quercetin, an antioxidant molecule, prevents the appearance of AHF and drastically decreases LPX induced by DEN[33]. These results are in accord with observations in another system where CAPE decreased LPX levels[38]. Our proposition is that many, if not all, protective effects of CAPE have a common mechanism, which is its anti-oxidative and free-radical scavenging abilities that involve several cellular pathways.

Present *in vitro* UDS assay results in PHC with two carcinogens, one indirect and the other a direct, support our hypothesis. The protective effect of CAPE against DEN involves at least two possible explanations: (1) CAPE intercepts electrophylic metabolites and ROS formed through the CYP2E1 activity and, in this way, blocks their interaction with DNA and prevents induction of DNA damage, or (2), CAPE inhibits CYP2E1, as is the case of the chemoprotector molecule, sulforophane[39], and prevents formation of DEN electrophylic metabolites, which prevents UDS. Prevention of MNNG-induced UDS could be explained only by the CAPE anti-oxidative and free-radical scavenging ability since MNNG electrophylic metabolites are generated without participation of cytochrome enzymes and ROS generation. Moreover, it has been shown that tea polyphenols prevent MNNG induction of gastric cancer[40]. A stronger evidence in this context has been obtained in Swiss mice treated with MNNG; garlic, tomato or neem leaf extracts prevent the induction of micronuclei and the increment of LPX in bone marrow, as well as enhanced GSH-dependent antioxidant activities[41,42]. Even though, in the case of DEN, we cannot discard the possibility that the mechanism by which CAPE prevents AHF is via CYP2E1 inhibition, the fact that the MNNG genotoxic effect is prevented by CAPE, supports the notion that the protective mechanism of CAPE is due to its anti-oxidative and free-radical scavenging activities. This proposition is also supported by results in a cell-free assay used to evaluate antioxidant and free-radical scavenging activities of several chemopreventive agents[43]. In these studies, CAPE revealed the third highest antioxidant activity after caffeic acid and α-tocopherol, and the second highest free-radical scavenging activity after rosmarinic acid. This evidence together with previous studies in models that show that the protective effect of CAPE against cancer in rodents is related to its anti-oxidant activity support our proposal[11-13,44].

The chemoprotective effect of CAPE in our medium-term model of hepatocarcinogenesis diminished *ggt* mRNA expression, drastically decreases the number and area of GGT$^+$ AHF, and the GSTP protein expression; it abolished LPX and, in addition, it prevented the UDS induced by DEN or by MNNG in PHC. In conclusion, we suggest that the protective effects of CAPE at initiation as shown *in vivo* and *in vitro* are due to its anti-genotoxic, anti-oxidative and free-radical scavenging abilities.

## Abstract

**AIM:** To evaluate the effect of combination treatment with the interferon (IFN) and angiotensin-converting enzyme inhibitor (ACE-Ⅰ) on several fibrotic indices in patients with refractory chronic hepatitis C (CHC).

**METHODS:** Perindopril (an ACE-Ⅰ; 4 mg/d) and/or natural IFN (3 MU/L; 3 times a week) were administered for 12 mo to refractory CHC patients, and several indices of serum fibrosis markers were analyzed.

**RESULTS:** ACE-Ⅰ decreased the serum fibrosis markers, whereas single treatment with IFN did not exert these inhibitory effects. However, IFN significantly augmented the effects of ACE-Ⅰ, and the combination treatment exerted the most potent inhibitory effects. The serum levels of alanine transaminase and HCV-RNA were not significantly different between the groups, whereas the plasma level of transforming growth factor-β was significantly attenuated almost in parallel with suppression of the serum fibrosis markers.

**CONCLUSION:** The combination therapy of an ACE-Ⅰ and IFN may have a diverse effect on disease progression in patients with CHC refractory to IFN therapy through its anti-fibrotic effect.

**Key words**: Interferon; Angiotensin-converting enzyme inhibitor; Liver fibrosis; Chronic hepatitis C; Transforming growth factor-β

## INTRODUCTION

The goal of therapy for chronic hepatitis C (CHC) is the eradication of the hepatitis C virus (HCV)[1]. In the recent decade, anti-viral therapy against HCV has been markedly improved, especially treatment with ribavirin and peg-interferon (IFN)[2]. However, the overall sustained viral response (SVR), defined as undetectable HCV-RNA 6 mo after the end of treatment, even with the combination of peg-IFN and ribavirin is still unsatisfactory, since many patients have not achieved SVR yet. It is well known that continuous inflammation associated with HCV infection slowly results in liver fibrosis development, and eventually leads to hepatocellular carcinoma (HCC). Accordingly, one of the clinical goals in the treatment of refractory CHC is to prevent the progression of liver fibrosis development[3]. It has been reported that the prognosis and clinical management of chronic liver diseases depend on the extent of liver fibrosis, as complications mainly develop in the advanced stages, which is also applicable to HCV infection[1]. Also, it has been shown that the degree of fibrosis development correlates with the incidence of HCC[4]. Collectively, it is likely that the effective anti-fibrotic therapy will significantly improve the prognosis of patients, especially in non-SVR refractory CHC.

Recent studies have shown that long-term IFN could exert beneficial effects in patients with refractory CHC[5]. Apart from the anti-viral effect, several evidences suggested that IFN could improve liver fibrosis. However, the histological improvement of liver fibrosis could be observed only in the SVR patients[6]. It has been reported that IFN inhibited the collagen promoter activity in the activated hepatic stellate cells (HSC), which play a pivotal role in liver fibrosis development[7]. Furthermore, it is well

known that the combination treatment with different anti-fibrotic agents may provide synergistic rather than additive effects. Alternative strategies with other safe agents in the non-SVR patients should be used.

Recent studies have revealed that the renin-angiotensin system (RAS) plays an important role in the liver fibrosis development[8]. Angiotensin-Ⅱ (AT-Ⅱ) induces the proliferation of the activated HSC, and the local RAS components were significantly up-regulated during the liver fibrosis development[9]. It has been reported that inhibition of RAS by the clinically used angiotensin-converting enzyme inhibitor (ACE-Ⅰ) and AT-Ⅱ type-1 receptor blocker (ARB) significantly attenuated liver fibrosis development in several experimental models[10,11]. In the clinical practice, these RAS-inhibitory agents also exerted anti-fibrotic effects in several types of chronic liver diseases, including CHC[12,13]. We previously reported that the combination treatment with IFN and ACE-I exerted a more potent inhibitory effect on murine liver fibrosis development than either single agent[14]. In a preliminary study, we also demonstrated that the combination treatment with IFN and ACE-I suppressed the serum fibrosis markers in CHC[15].

In the current study, we investigated whether this combination treatment would exert a more potent anti-fibrotic effect than either single agent in patients of refractory CHC. To elucidate the possible mechanisms, we also examined the serum transforming growth factor-β (TGF-β) level, which is known as a key cytokine in the liver fibrogenesis.

## MATERIALS AND METHODS

### Patients and methods

In the current study, we examined a total 40 patients with CHC refractory with mild hypertension from July 2002 to December 2005 at Nara Medical University Hospital. The refractory CHC is defined as CHC that failed to respond to IFN mono-therapy. The patients were randomly divided into 4 groups of matching clinical background (e.g., age, sex), HCV status, and serum fibrosis markers. The treated groups were given either single or combination of oral ACE-I (perindopril: 4 mg/d) and an intramuscular injection of IFN (natural IFN: 3 MU/L; 3 times a week) for 12 mo, whereas the control group received neither agent. We recommended all patients to stop alcohol intake completely. This protocol was approved by the Institutional Review Board (IRB) of Nara Medical University, and the study was conducted in conformity with ethical and humane principles.

### Evaluation of laboratory data

The serum fibrosis markers; namely, hyaluronic acid, type IV collagen 7S (7S-collagen), and amino-terminal peptide of type-Ⅲ pro-collagen (P-Ⅲ-P) were measured before and after the treatment in all patients by latex agglutination, enzyme immunoassay (EIA), and radioimmunoassay (RIA) respectively, with routine laboratory methods. The serum level was measured by ELISA kit (R&D systems, Tokyo, Japan) according to the manufacturer's instructions as described previously[14]. The serum HCV status was measured by using the quantitative or qualitative reverse transcription-polymerase chain reaction (RT-PCR) analysis. Other serum biochemical markers, such as alanine transaminase (ALT), were measured by the routine laboratory methods.

**Table 1 Characteristics in patients of refractry chronic hepatitis C**

| | Control | IFN | ACE-Ⅰ | IFN+ACE-Ⅰ |
|---|---|---|---|---|
| No. of patients | 10 | 7 | 7 | 11 |
| Mean age ± SD (yr) | 60 ± 7 | 60 ± 9 | 58 ± 9 | 62 ± 8 |
| Sex (M/F) | 6/4 | 3/4 | 4/3 | 5/6 |
| Serum HCV-RNA[1] (M copies/L) | 632 ± 120 | 641 ± 131 | 620 ± 106 | 628 ± 108 |
| Genotype (1 b/others) | 9/1 | 6/1 | 7/0 | 10/1 |

[1]Data represent mean ± SD.

### Statistical analysis

To assess the statistical significance of the inter-group differences in the quantitative data, Bonferroni's multiple comparison test was performed after one-way analysis of variance (ANOVA). This was followed by Barlett's test to determine the homology of variance.

## RESULTS

### Patient characteristics

The characteristics of the refractory CHC patients in all groups are shown in Table 1. There were no significant differences in the patient's clinical background among the groups. Most patients in all groups had high titer of HCV of genotype 1b, which is known for its resistance to the IFN based anti-viral therapy[2].

### Serum fibrosis markers

All medications were well tolerated by all patients. To examine the therapeutic effects of IFN and/or ACE-I on the progression of liver fibrosis in patients with refractory CHC, we compared several serum fibrosis markers before and after the respective treatment. As shown in Figure 1A, there were differences in the serum hyaluronic acid among the groups. Without treatment, the mean serum hyaluronic acid level was increased (1.2% ± 1.1%) at the end of the study as compared with the starting level. Both IFN- and ACE-I treated-groups had decreased mean serum hyaluronic acid level at the end of study (-4% ± 2.2% and -9% ± 3.4%, respectively). However, only ACE-I exerted a significant difference as compared with the untreated control group ($P < 0.01$). The combination treatment of ACE-I and IFN (IFN + ACE-Ⅰ) exerted the most potent suppressive effect (-21% ± 5.9%) among all groups, and the inhibitory effect of this combination was more potent than that in the ACE-I -treated group ($P < 0.01$) (Figure 1B). Similar results were observed in the 7-S-collagen and P-Ⅲ-P levels (Figures 2 and 3, respectively).

### Biochemical markers and serum TGF-β level

We next examined the changes in several biochemical

**Table 2 Changes of seveal markrs in patients of refractry chronic hepatitis C (mean ± SD)**

markers. The ACE- I - and IFN + ACE- I -treated groups showed improvement in the serum ALT level at the end of the study (Figure 4A). However, in contrast to the serum fibrotic markers, there were no marked differences between both groups (Figure 4B). These results indicated that the improvement of fibrosis markers induced by ACE- I and/or IFN were not due to the non-specific cytoprotective effects. Also, the viral status of HCV and serum creatinine (Cre) did not significantly change before and after the study in all groups. The mean blood pressure decreased in the ACE- I - and IFN + ACE- I -treated groups, although, similar to ALT, there was no difference between both groups (Table 2). Since TGF-β is known as a key cytokine in the liver fibrosis development, we next measured the TGF-β level in all experimental groups. The alterations of the TGF-β level were almost parallel to those of the fibrosis markers. The IFN + ACE- I treatment significantly attenuated the TGF-β level at the end of the study (-20% ± 5.6%) (Figure 5).

## DISCUSSION

In the current study, we showed that the combination treatment with ACE- I and IFN significantly suppressed

several serum fibrosis markers along with inhibition of TGF-β in patients with refractory CHC.

After evolvement of the combination therapy with peg-IFN and ribavirin, a significantly higher SVR rate has been achieved as compared with the IFN mono-therapy[2]. Even in the genotype 1b patients, almost half of the patients could reach the SVR status. However, from the opposite aspect, about half of the patients are still resistant

to the IFN-based anti-viral therapy. Also, it is well known that this combination regimen frequently exerts several adverse effects as compared with the IFN mono-therapy, such as hemolytic anemia and potential teratogenecity. Accordingly, an alternative strategy should be developed for patients with both refractory CHC and intolerance to the combination therapy of peg-IFN and ribavirin. One of the clinical goals to be achieved for these patients is prevention of progression to liver cirrhosis and HCC[5]. It has been reported that the improvement of fibrosis stage led to suppression of hepatocarcinogenesis [4]. Taken together, it is likely that the effective anti-fibrotic therapy will significantly improve the prognosis of the patients with refractory CHC.

In addition to the anti-viral effect, several evidences suggested that IFN is also effective in curtaining liver fibrosis both in the experimental animal models and in the clinical practice[6,14]. It has been reported that IFN significantly suppressed the HSC, and it also inhibited the promoter activity of pro-collagen gene[7]. However, in the clinical practice, fibrosis improvement with IFN-based therapy could be observed only in the virological responders[6]. Since it has been reported that the combination treatment with different anti-fibrotic agents exerted a more potent inhibitory effect than single agent therapy, alternative strategies such as combination therapy with other safe agents are required.

It is well known that TGF-β is a central key cytokine in the liver fibrosis development[16]. We previously reported that the clinically used ACE- I even at a clinically comparable low dose significantly attenuated the experimental liver fibrosis development along with suppression of TGF-β[10,17]. In the clinical practice, a retrospective study on liver transplanted patients with CHC, re-infection with HCV revealed that the patients receiving RAS inhibitors, such as ACE- I , had significantly less fibrosis progression than those receiving other types of drugs[12]. In the current study, we found that the combination treatment with ACE- I and IFN significantly suppressed the several serum fibrosis markers along with TGF-β inhibition as compared with ACE- I alone. We have shown similar results in a previous experimental study[14]. The combination treatment with ACE- I and IFN attenuated the liver fibrosis development along with suppression of the activated HSC, pro-collagen mRNA, and TGF-β. It is well known that the activated HSC play a pivotal role in the liver fibrogenesis, and that the activated HSC are one of the main cells producing TGF-β and collagen[16]. The exact mechanism of the inhibitory effect in the current study is still obscure at this time. However, we observed that the serum TGF-β, P-Ⅲ-P, and 7-S-collagen were suppressed almost in parallel by this combination regimen, whereas ALT and HCV status were not altered. These results indicated that, as in the experimental study, the anti-fibrotic effect of this combination regimen was, at least partly, mediated through inhibition of the activated HSC.

It is now widely recognized that angiogenesis plays an important role in many biological phenomena, including fibrosis development[18]. It has been shown that neovascularization significantly increased during the development of liver fibrosis[19]. We previously reported that ACE- I and IFN exerted an anti-angiogenic activit[20]. It would be possible that the anti-fibrotic effect of this combination treatment is, to some extent, mediated by suppression of neovascularization in the liver.

From the clinical point of view, liver biopsy is still considered the "gold standard" to assess the fibrosis development[16]. However, liver biopsy is associated with potential morbidity and mortality and has several limitations, including sampling error and inter-observer variability[21]. Recent studies have shown that evaluation of the serum fibrosis markers can predict the degree of fibrosis to an extent similar to that of liver biopsy[22]. Although we did not perform liver biopsy in the current study, further studies are required in the future to examine the histological and immunohistochemical markers, such as smooth muscle α-actin which is known as a marker of the activated HSC, and to make comparison with the serum fibrosis markers. Furthermore, in the next step, we have to examine whether this IFN+ACE- I regimen is also effective for the CHC patients refractory to the combination therapy of peg-IFN and ribavirin.

In summary, we found in our present study that the combination treatment with ACE- I and IFN significantly attenuated the serum fibrosis markers along with suppression of TGF-β in patients with refractory CHC. This combination treatment may become a new strategy to prevent disease progression in the patients with refractory CHC through its anti-fibrotic effect.

## Abstract

**AIM:** To compare the prevalence of hepatitis viral markers among soldiers from Turkey, blood donors from Northern Cyprus, and soldiers from Northern Cyprus.

**METHODS:** Hepatitis B surface antigen (HBsAg), anti-HCV and anti-human immunodeficiency virus (HIV) seroprevalence, HBV DNA, HCV RNA and HCV genotyping among soldiers from Turkey (group Ⅰ), civil blood donors from Northern Cyprus (group Ⅱ), and soldier candidates from Northern Cyprus (group Ⅲ) were studied and compared to one another. In total, 17545 cases (13546 males and 3999 females with a mean age of 34.5 ± 10.3 year, group Ⅰ = 11234, group Ⅱ = 5057, and group Ⅲ = 1254) were included into the study.

**RESULTS:** Among all cases, HBsAg positivity rates were 2.46%, anti-HCV was 0.46% and anti-HIV was 0.00%. HBV DNA was 2.25%, HCV RNA was 0.33% in all groups. HBsAg positivity rates were 2.16% in group Ⅰ, 3.00% in group Ⅱ and 2.71% in group Ⅲ. There was a significant difference between group Ⅰ and group Ⅱ ($\chi^2$ = 6.11, $P$ = 0.047 < 0.05). Anti-HCV positivity rates were 0.45% in group Ⅰ, 0.45% in group Ⅱ, and 0.56% in group Ⅲ. Genotypes of HCV were 1b and 1a in group Ⅰ, 1b, 1a and 2 in group Ⅱ, and 1b, 1a in group Ⅲ. HBsAg carrier rates were 2.20% in females and 2.53% in males. Anti-HCV prevalence was 0.38% in females and 0.48% in males. HBsAg positivity rates were 2.53% in individuals younger than 50, and 1.47% in older than 50. There was a significant difference between the two groups ($\chi^2$ = 23.48, $P$ = 0.001).

**CONCLUSION:** Prevalences of HBsAg, HCV and HIV infections in Northern Cyprus population are similar to those of Turkey.

**Key words:** Cyprus; Donor; Healthy adults; Hepatitis B; Hepatitis C; Human immunodeficiency virus

## INTRODUCTION

Worldwide, two billion people have been infected with hepatitis B virus (HBV), 360 million have chronic infection, and 600 000 die each year from HBV-related liver disease or hepatocellular carcinoma[1]. Meanwhile, hepatitis C virus (HCV) infection is the most common chronic blood borne infection in the World. An estimated 3.9 million persons are currently infected and it is responsible for approximately 8000 to 10000 deaths each year in the United States[2]. Both diseases cause serious mortality, morbidity and financial costs, continuing thus to be a major health problem[3]. In addition, prevalence of human immunodeficiency virus (HIV) is increasing everyday and it has become a disaster for humankind in some areas. Prevalence studies of these blood-borne diseases show certain risky groups and risky attitudes that should be studied further. Northern Cyprus population shares many characteristics with Turkey's population. Turkey is among the moderate endemic countries and rates of HBV carriers are 4.4%-12.5% and of HCV positivity 0.3%-4.0%[4,5]. Acquired immune deficiency syndrome (AIDS) is one of the most important mortality causes in the world although it is not endemic in Turkey and Cyprus[6,7]. There is an increasing risk in recent years in this area of this disease. Seroepidemiological studies about blood-borne diseases could have provided us with the opportunity of learning basic knowledge about

epidemiology of these diseases in the community. The aim of this study was to determine prevalence of HBV, HCV and HIV infections among normal population and Turkish soldiers in Northern Cyprus.

## MATERIALS AND METHODS

### Study population

Population of Northern Cyprus is about 175 000 and it has close relation with Turkey. Ethical permission was obtained from Afyon Kocatepe University Human Ethics Committee.

### Study samples

A cross-sectional study was performed using the data of blood centers of two hospitals (Nalbantoglu General Hospital, Nicosa and Akcicek Military Hospital, Kyrenia) in Northern Cyprus between January 2000 and January 2001. There were three different groups in this study: group Ⅰ, Turkish soldiers who came from Turkey and their results represent Turkish population; Group Ⅱ, civilian blood donors who applied to the hospitals from Northern Cyprus and who were inhabitants there, and donors with any history of jaundice in the past were eliminated from the study; Group Ⅲ, Northern Cyprus inhabitants who applied for soldier recruitment and were screened for these diseases.

### Serology

The blood samples were screened for hepatitis serology [Hepatitis B surface antigen (HBsAg), anti-HCV] and anti-HIV. HBsAg, anti-HCV and anti-HIV positivity were investigated by microparticle ELISA (Axsym, Abbott) in blood samples.

### HBV and HCV molecular diagnosis

We screened HBV DNA and HCV RNA markers by reverse transcription polymerase chain reaction (RT-PCR) (7700 Sequence Detection System, AB).

### HCV genotyping

HCV-RNA sequences were amplified by RT-PCR that targeted the 5' non-coding region of the viral genome and were genotyped by line probe assay using INNO-LIPA HCV Ⅱ kit.

### Collection of serum samples

Blood samples were obtained from different groups and stored at -20℃ until use. Prior to RNA extraction, sera were tested on INNO LIA HCV Ab Ⅲ (Innogenetics NV, Antrewp, Belgium) to confirm the presence of anti-HCV antibodies.

### HCV RNA extraction

HCV RNA was extracted from serum or EDTA-plasma. To avoid carryover contamination, the steps of the protocol were carried out at four separate locations. Cotton-plugged tips were generally used, and all buffers, primers, and dNTPs were divided into single-use aliquots. Fifty microliters of serum were mixed with 150 μL of Trizol LS Reagent (Life Technologies Gent, Belgium) at room temperature. After lysis and denaturation, 40 μL of $CHCl_3$ was added. The mixture was vigorously shaken, incubated for 15 min at room temperature, and centrifuged, and the minute amounts of viral RNA were precipitated from the colorless aqueous phase with 20 μL of 1 μg Dextran T500 (Pharmacia, Brussels, Belgium) per μL and 100 μL of isopropanol. The RNA pellet was washed with 200 μL of ethanol and collected by centrifugation. Finally, the RNA pellet was briefly air dried. If the procedure was interrupted at this stage, the RNA was stored at -20℃ as a pellet instead of being dissolved in water.

### cDNA synthesis and PCR amplification

The RNA pellet was dissolved in 15.1 μL random primers (20 mg/L, $pdN_6$; Pharmacia). After denaturation at 70℃ for 10 min, 4.9 μL of a cDNA mixture was added which was composed of 4 μL of 5 × avian myeloblastosis virus reverse transcriptase buffer (250 mmol/L Tris HCl [pH 8.5], 100 mmol/L KCl, $MgCl_2$, 25 mmol/L dithiothreitol), 0.4 μL of 25 mmol/L dNTPs, 0.2 μL or 25 U of RNase inhibitor (HPRI; Amersham, Gent, Belgium), and 0.3 μL or 8 U of avian myeloblastosis virus reverse transcriptase (Stratagene, La Jolla, Calif.). cDNA was synthesized at 42℃ for 90 min. PCR was performed in a volume of 50 μL. Other PCR amplified the cDNA over 40 cycles (1 min at 94℃, 1 min at 50℃, and 1 min at 72℃). One microliter of product was amplified with nested PCR primers for another 40 cycles with the same thermal profile. All primers were tagged with a biotin group at the 5' end.

### Preparation of LIPA strips

A poly (dT) tail was enzymatically added to the 3' end of each oligonucleotide as previously described[8]. The tailed probes were precipitated and washed with ice-cold ethanol. Probes were dissolved at their respective specific concentrations and applied as a positive control (LIPA line 1). The oligonucleotides were fixed to the membrane by baking at 80℃ for 12 h. The membranes were then sliced into 4-mm-wide strips.

### LIPA

Equal volumes (10 μL each) of the biotinylated PCR fragment and the denaturation solution (400 mmol/L NaOH, 10 mmol/L EDTA) were mixed in test troughs by pipetting and incubated at room temperature for 5 min, after which 2 mL of the prewarmed (37℃) hybridization solution (3 × SSC [1 × SSC is 0.15 mol/L NaCl plus 0.015 mol/L sodium citrate], 0.1% sodium dodecyl sulfate) was added, followed by the addition of one strip per trough. Hybridization occurred for 1 h at 50℃ ± 0.5℃ in a closed water bath with back-and-forth shaking. The strips were washed twice with 2 mL of wash solution (3 x SSC, 0.1% sodium dodecyl sulfate) at room temperature for 20 s and once at 50℃ for 30 min. Following this stringent washing, strips were rinsed twice with 2 mL of a standard rinse solution. Strips were incubated on a rotating platform with an alkaline phosphatase-labeled streptavidin conjugate diluted in a standard conjugate solution for 30 min at 20℃ to 25℃. Strips were then washed twice with 2 mL of rinse solution and once with standard substrate buffer, and color development was initiated by addition

**Table 1 Distribution of HBV and HCV markers in various population**

| Group | *n* | HBsAg | HBV DNA | Anti-HCV | HCV RNA |
|---|---|---|---|---|---|
| | | *n* (%) | *n* (%) | *n* (%) | *n* (%) |
| Turkish soldiers | 11234 | 243 (2.16)[a] | 223 (1.98) | 50 (0.45) | 35 (0.31) |
| Civil donors | 5057 | 154 (3.00) | 150 (2.90) | 23 (0.45) | 13 (0.25) |
| Northern cyprus soldiers | 1254 | 34 (2.71) | 23 (1.83) | 7 (0.56) | 5 (0.39) |
| Total | 17545 | 431 (2.46) | 396 (2.25) | 80 (0.46) | 53 (0.33) |

[a]$P = 0.047$ *vs* the group of civil donors (group Ⅱ).

**Table 2 Distribution of HCV genotyping in various population**

| Group | HCV RNA | Genotype 1b | Genotype 1a | Genotype 2 |
|---|---|---|---|---|
| | | *n* (%) | *n* (%) | *n* (%) |
| Turkish soldiers | 35 | 34 (97.1) | 1 (2.8) | |
| Civil donors | 13 | 11 (84.6) | 1 (7.7) | 1 (7.7) |
| Northern Cyprus soldiers | 5 | 4 (80.0) | 1 (20.0) | |
| Total | 53 | 49 (92.4) | 3 (5.7) | 1 (1.9) |

of 5-bromo-4-chloro-3-indolylphosphate (BCIP) and nitroblue tetrazolium to 2 mL of substrate buffer. After 30 min at room temperature, the color reaction was stopped by aspiration of the substrate buffer and addition of distilled water. Immediately after drying, the strips were interpreted[8].

### *Statistical analysis*

The differences between groups were analyzed by the Chi-square test. $P < 0.05$ was taken as significant.

## RESULTS

Totally 17 545 individuals, aging 20-56 (mean ± SD, 34.5 ± 10.3) years, of whom 13 546 were men and 3999 were women were included into the study. HBsAg positivity rate was 2.46%, anti-HCV was 0.46%, anti-HIV was 0.00%, HBV DNA was 2.25% and HCV RNA was 0.33% in all groups. HBsAg positivity was the lowest in group I (2.16%) among all groups. There was a significant difference between groups I and Ⅱ for HBsAg positivity rates ($\chi^2 = 6.11$, $P = 0.047$). There were no significant differences between groups for anti-HCV prevalence ($\chi^2 = 0.32$, $P = 0.852$) (Table 1).

Three different genotypes were determined such as 1b, 1a, and 2 genotypes. Number and ratios of 1b, 1a, and 2 types were 49 (92.4%), 3 (5.7%), 1 (1.9%), respectively (Table 2). There was no significant difference in the distribution of HCV genotypes with respect to age, sex and transfusion history ($P > 0.05$).

HBsAg prevalence was higher in males (2.53% *vs* 2.20%). There was no significant difference between the groups for HBsAg prevalence ($\chi^2 = 1.42$, $P = 0.234$). Anti-HCV positivity was higher in males (0.48% *vs* 0.38%). There was no significant difference between two groups for anti-HCV prevalence ($\chi^2 = 0.75$, $P = 0.387$) (Table 3).

Positivity of HBsAg had a close relation with age. The HBsAg carrier rate was highest in the 40-49 year old group (3.42%) and there was a significant difference between older and younger than 50 years groups (2.53% in younger than 50 years, and 1.47% in older; $\chi^2 = 23.48$, $P = 0.001$). Anti-HCV prevalence was higher in younger age groups than in the older age groups, however, there was no significant difference among different age groups for anti-HCV prevalence ($\chi^2 = 0.99$, $P = 0.803$) (Table 4).

## DISCUSSION

Epidemiological studies about blood-borne diseases such as hepatitis B, C and HIV are important for revealing the risk groups and risk factors for these infections. Evaluation of the prevalence among blood donors and army recruits is a common and easy method to obtain the epidemiology of these infections in a community. There are some differences between normal population and blood donors or soldiers, however, this approach is very common for screening studies. Screening these groups helps us to solve difficulties in collecting information among healthy populations[9,10].

Northern part of Cyprus has very close relationship with Turkey and both peoples share similar demographic features. At the same time, there is similar close relationship between Southern Cyprus and Greece. Prevalence of HBsAg in Greece has low endemicity level and seropositivity is lower than 1% among volunteer blood donors and military recruits[11,12]. In contrast, HBsAg positivity is reported between 4% and 10% among civil blood donors according to a study including over 10 000 individuals in Turkey[9,10]. Many studies showed that the incidence of HBsAg has a moderate level in Turkey. These data suggest that epidemiology of HBV in Northern

Cyprus population is similar to Turkey. On the other hand, Papaevangelou[13] showed that the carrier rate of HBsAg in the blood donor and army recruit samples ranged between 0.77% and 1.01% in Southern Cyprus. Therefore, Southern Cyprus results are similar to Greece and other south European countries.

At the beginning, our expectation was that the results of Northern Cyprus might have been between Turkey and Southern Cyprus. However, the result has suggested that prevalence of hepatitis B in native population of Cyprus is not lower than in Turkish soldiers. In the last ten years, the intensive efforts on vaccination and prevention precautions might have been effective on prevalence of the disease in Turkey. Our results could be attributed to good infection control and vaccination program against hepatitis B in Turkey. In contrast, there is no effective prevention program against hepatitis B in Northern Cyprus[14].

The incidence of HCV is about 0.01% in North Europe and 1%-1.5% in South Europe[15]. In Turkey, HCV prevalence is between 0.1% and 1.5% in blood donors[9,10,16]. It could be seen easily that HCV prevalence in Turkey and Greece is similar to that of other South European countries. In this study, the incidence of anti-HCV in Northern Cyprus is similar to Turkey and Greece results. In Turkey, prevalence of HCV is increasing in older age.

On the basis of its extensive genetic heterogeneity, HCV has been divided into six major genotypes and at least 100 subtypes. Genotypes 1, 2 and 3 are found throughout the world; but the other genotypes are common in particular geographic regions (genotype 4 is common in North Africa and the Middle East, genotype 5 is common in South Africa, and genotype 6 is common in Southeast Asia)[17]. The predominant genotype in patients with chronic HCV infection in Turkey is genotype 1, followed by genotype 2 and 3[18]. Predominant molecular techniques used (hybridization and direct DNA sequencing) are based on nucleotide differences in the highly conserved 5' UTR among genotypes[17]. The widely used INNO-LIPA HCV Ⅱ assay (Innogenetics, Ghent, Belgium) uses PCR products from the 5' UTR that hybridize to type-specific probes embedded on a nitrocellulose strip[17].

Abacioglu's study showed that the predominant genotype was 1b (75.3%), followed by 1a (19.1%), 2 (3.4%) and 4 (2.2%). In that study, HCV RNA sequences were amplified in the 5' non-coding region and were typed by restriction fragment length polymorphism analysis[19]. These results, together with the results of two previous studies, indicate that HCV genotypes 1, 2, 3 and 4 are prevalent at different frequencies in the Turkish population. In the present study, three different genotypes were determined such as 1b, 1a, and 2 genotypes. There was no significant difference in the distribution of HCV genotypes with respect to groups, age, sex, transfusion history ($P > 0.05$) (Table 2).

In this study, male gender had a higher rate for HBsAg carrier status but the difference was not significant (2.20% in females *vs* 2.54% in males). Koulentaki's[20] study from Greece showed that a greater number of males than females were HBsAg positive (0.41% *vs* 0.28%, respectively). In many studies, males are more frequently exposed to HBV and become carriers more often than females. For HCV, an opposite gender trend was reported that females being infected more frequently than males (0.49% in females *vs* 0.37% in males). In our study, prevalence of HCV was higher in males.

Another agent, which has similar transmission ways to HBV, is HIV. There is a potential hazard for everybody in the world because of the characteristics of the diseases. Although we did not detect any HIV positive case in this study, Cyprus is a sensitive area because of visitors from other countries. There is a young population and many sea workers, and individuals are not well informed about the subject, and drug-users may increase.

In conclusion, seroprevalence of blood-borne disease in Northern Cyprus is similar to Turkey. This study suggests that it is necessary to investigate risk factors and risk groups for these infections in Northern Cyprus. In the light of this result, an effective control and training program for soldiers and civilians should be implemented.

## Abstract

**AIM:** To determine if novel bile acid transporters may be expressed in human tissues.

**METHODS:** *SLC10A1* (NTCP) was used as a probe to search the NCBI database for homology to previously uncharacterized ESTs. The homology search identified an EST (termed *SLC10A4*) that shares sequence identity with *SLC10A1* and *SLC10A2* (ASBT). We performed Northern blot analysis and RT-PCR to determine the tissue distribution of *SLC10A4*. *SLC10A4* was cloned in frame with an epitope tag and overexpressed in CHO cells to determine cellular localization and functional analysis of bile acid uptake.

**RESULTS:** Northern analysis revealed that *SLC10A4* mRNA is ubiquitously expressed in human tissues with the highest levels of mRNA expression in brain, placenta, and liver. In *SLC10A4*-transfected CHO cells, immunoblotting analysis and immunofluorescence staining demonstrated a 49-kDa protein that is expressed at the plasma membrane and intracellular compartments. Functional analysis of *SLC10A4* showed no significant taurocholate uptake in the presence of sodium when compared to untransfected CHO cells.

**CONCLUSION:** To date, we have shown that this protein has no capacity to transport taurocholate relative to *SLC10A1*; however, given its ubiquitous tissue distribution, it may play a more active role in transporting other endogenous organic anions.

**Key words:** *SLC10A4*; Bile acid transport; Biliary epithelium; Taurocholate; Plasma membrane

## INTRODUCTION

Bile acids, the major solute in bile, are physiologically important for promoting bile flow and facilitating the absorption of dietary lipids[1,2]. Bile acids are also involved in cholesterol homeostasis, xenobiotic excretion, as well as apoptotic and cell signal transduction pathways[1-6]. Unlike most other biliary solutes, bile acids are efficiently conserved and cycle in the enterohepatic circulation (EHC). This EHC is maintained by the vectorial transport of bile acids *via* specific bile transport proteins located on the plasma membranes of liver and intestinal epithelia[1].

Within the liver, hepatocytes express the sodium dependent taurocholate transporting protein (*SLC10A1*) and several sodium independent organic anion-transporting proteins at the sinusoidal membrane[6-9]. On their canalicular membrane, hepatocytes express the bile salt export pump (*ABCB11*)[10]. Cholangiocytes, the epithelial cells that line the bile ducts, express the apical sodium dependent bile acid transporter (*SLC10A2*) on lumenal surface[11]. Rat cholangiocytes express a truncated form of ASBT, that may export bile acids across the basolateral membrane[12]. To complete the EHC of bile acids, the enterocytes of the distal ileum express *SLC10A2*[13]. After *SLC10A2*-mediated uptake, bile acids are directed across the ileal enterocyte and secreted into the portal circulation, allowing for efficient recycling of the bile acids from the intestine to the liver[13].

Given the redundancy of biological systems, we hypothesize that additional bile acid transporters may exist within the human genome. In this study, we identified a novel member termed *SLC10A4* of the SLC10A family of sodium bile acid symporter related proteins. We also examined the expression of *SLC10A4* mRNA presence in human tissues and have over expressed this protein in CHO cells.

## MATERIALS AND METHODS

### Materials

All chemicals were of highest commercially available purity and were purchased from Sigma, St. Louis, MO Chemical C. (St. Louis, MO) unless otherwise indicated.

### Cell culture

Cells were maintained at 37℃ in a humidity-controlled incubator with $CO_2$. The cholangiocarcinoma cell-lines (Witt, KMC, and KMCH) were grown in Dulbecco's modified Eagle's medium containing F12 (Sigma, St. Louis, MO) supplemented with 5% (v/v) FBS (Mediatech, Herndon, VA), Penicillin (100 U/mL)/Streptomycin 100 μg/mL (Sigma, St. Louis, MO), and 2 mmol/L-glutamine (Sigma, St. Louis, MO). H69 cells are SV40 transformed normal human biliary epithelial cells (a gift from Dr. Douglas Jefferson, Tufts University) and were grown as previously described. T84 cells, derived from a human adenocarcinoma, were grown in Dulbecco's modified Eagle's medium containing F12 (Sigma, St. Louis, MO) supplemented with 5% (v/v) FBS (Mediatech, Herndon, VA), Penicillin (100 U/mL)/Streptomycin 100 μg/mL (Sigma, St. Louis, MO). Chinese hamster ovary (CHO) cells were grown in Dulbecco's modified Eagle's medium containing F12 (Sigma, St. Louis, MO) supplemented with 10% (v/v) FBS (Mediatech, Herndon, VA), Penicillin (100 U/mL)/Streptomycin 100 μg/mL (Sigma, St. Louis, MO), 1 × MEM vitamin solution (Sigma, St. Louis, MO), and 2 mmol/L L-glutamine (Sigma, St. Louis, MO).

### Identification of the SLC10A4 EST

To initially identify novel members of the SLC10 family of proteins, a bioinformatic approach was used. Amino acids 1-200 of *SLC10A1* (GenBank accession no. AAA36381) were used to perform a tBlastN search of the NCBI database. The candidate EST (Htm1-361F, GenBank accession no. BE39690) sequence was then used for BlastN and BlastX database searches to confirm that it had not been previously identified and as a template to design PCR primers.

### RNA isolation

Total RNA was extracted from the tissue culture cell-lines using Tri-Reagent (Sigma, St. Louis, MO). The cells were lysed using 1 mL of Tri-Reagent/1.0 × $10^6$ cells and stored for 5 min at room temperature. Next, 0.1 mL of 1-bromo-3-chloropropane was added, the samples were vortexed, incubated at room temperature for 15 min, and centrifuged at 12000 × *g* for 15 min at 4℃. RNA was subsequently precipitated with isopropanol. The RNA pellet was resuspended with RNA Secure (Ambion, Austin, TX), and the concentration and purity was assessed by spectroscopy.

### Reverse transcription-polymerase chain reaction and pCRII cloning

5 μg of total RNA was reverse transcribed using a SuperScript™ II reverse transcritpase (In Vitrogen, Carlsbad, CA). The reaction mixture contained total RNA, 10 mmol/L deoxynucleotide triphosphates and random hexamers in a final volume of 10 μL. This mixture was incubated 5 min at 65℃. Reverse transcription buffer, 25 mmol/L $MgCl_2$, 0.1 mmol/L dithiothreitol (DTT), and RNase inhibitor was then added to the reaction mixture and incubated for 2 min at 25℃. Finally, the reverse transcriptase was added to the reaction mixture and incubated for 50 min at 42℃. The reverse transcriptase reaction was terminated at 70℃ for 15 min and chilled on ice. The *SLC10A4* cDNA was PCR amplified using *SLC10A4* specific primers; sense (5'-GGCAATCTCTC CAATCTTATGTC-3') and antisense (5'-CAGTTGGTG GAGATGAAGAGAGT-3'). The 441 bp PCR amplicon was electrophoresed on a 1% agarose gel and the bands were visualized by ethidium bromide staining. The PCR amplicons were then cloned into the pCRII dual promoter vector (In Vitrogen, Carlsbad, CA) according to the manufacturers protocol. Briefly, 2 μL of the PCR product was mixed with 10 × ligation buffer, 50 ng of pCRII vector, water, and T4 DNA ligase. The ligation reaction was incubated overnight at 14℃ and transformed into competent *Escherichia coli* (*E. coli*). Following the isolation of plasmid DNA, the pCRII (*SLC10A4*) was sequenced to confirm identity of the DNA insert (Mayo Molecular Core Facility, Rochester, MN).

### Random priming and Northern blot analysis

The pCRII (*SLC10A4*) plasmid was linearized and random primed using radiolabeled [α-$^{32}$P] dCTP. The random primer protocol was followed per manufactures (In Vitrogen, Carlsbad, CA) directions. Briefly, 25 ng of pCRII (*SLC10A4*) template DNA was denatured by boiling for 5 min and cooled on ice. To the template DNA, the following was added; 2 μL of dATP, 2 μL of dGTP, 2 μL of dTTP, 15 μL of random primer buffer, 5 μL of [α-$^{32}$P] dCTP (10 Ci/L). This reaction mixture was brought up to 49 μL. The 1 μL of Klenow fragment was added, mixed, and centrifuged briefly. This reaction mixture was incubated for 1 h at 25℃. Following the incubation, 5 μL of stop buffer was added and the $^{32}$P-labeled *SLC10A4* cDNA probe was purified using a NAP-25 column. Next, the Human MTN Blot (Clontech, Palo Alto, CA) and the Human Digestive System MTN Blot (Clontech, Palo Alto, CA) was prehybridized in ExpressHyb solution (Clontech, Palo Alto, CA) for 30 min at 68℃ and then 1 × $10^6$ cpm/mL of the labeled probe was added and incubated for an additional 60 min at 68℃. Following hybridization, the blots were washed several times and exposed to x-ray film (Kodak, Rochester, NY) and developed. Subsequently, the membranes were stripped with 0.5% SDS at 95℃ for 10 min and reprobed with β-actin to normalize for mRNA loading.

### Cloning the open reading frame (ORF) of SLC10A4

We obtained IMAGE clone 3502817 (ATCC, Manassas, VA) that contains the complete ORF of *SLC10A4* in the pOTB7 vector. The IMAGE clone was used as template DNA for PCR to delete the stop codon using specific PCR primers; sense (5'-GGATCCCCAAGTAACTATAACGG TCC-3') and antisense (5'-GAATTCGTATCTCCACAT TTGGAGAGAAGTCTG -3'). This fragment was cloned into pCRII (In Vitrogen, Carlsbad, CA) using the method

described above. The pCRII (*SLC10A4*) was digested with *Eco*RI and *Bam*HI restriction enzymes, the *SLC10A4* fragment was isolated by gel purification, and subcloned into the *Eco*RI and *Bam*HI sites of pcDNA4 V5-HisA (In Vitrogen, Carlsbad, CA), a mammalian expression vector which expresses the V5 epitope tag. The *SLC10A4* insert was sequenced to confirm identity of the DNA insert (Mayo Molecular Core Facility, Rochester, MN).

### Transfection of CHO cells

Transfections were performed using Lipofectamine reagent (In Vitrogen, Carlsbad, CA) according to the manufactures directions. The day of transfection, the CHO cells were 50%-80% confluent. The media was replaced with Optimem (In Vitrogen, Carlsbad, CA) and the cells were transfected with 3 μg of pcDNA V5-HisA (*SLC10A4*) or empty vector pcDNA V5-HisA plasmid DNA for 4 h after which the transfection media was replaced with complete CHO media. After 48 h, Zeocin (500 μg/mL) was added to the complete media and the cells were selected. Individual stable clones were isolated using cloning cylinders and confirmed by RT-PCR and immunoblotting to confirm the expression of *SLC10A4*.

### Immunofluorescent staining

CHO cells were grown on collagen-coated coverslips and fixed by 0.1 mol/L PIPES, pH 6.95, 1 mmol/L ethylene glycolbis (β-amino-ethylether-N, N, N', N'-tetra acetic acid (EGTA), and 2% paraformaldehyde in 1X phosphate buffered saline (PBS) for 20 min at room temperature. The cells were then permeabilized in 0.2% Triton for 2 min and incubated for 1 h with V5 epitope tag (1:500; In Vitrogen, Carlsbad, CA) monoclonal antibody. The cells were washed with PBS and subsequently incubated Texas Red-conjugated goat anti-mouse secondary antibody (Molecular Probes, Eugene, OR). The coverslips were washed with PBS and then mounted using Prolong Antifade mounting medium (Molecular Probes, Eugene, OR) and analyzed using a confocal microscope.

### Immunoblotting for the V5 epitope tag

For the immunoblotting assay, cell lysates and mixed plasma membranes were prepared as previously described[14]. Cell lysates and MPM were heated to 95℃ for 10 min in sample buffer containing 0.8 mol/L dithiothreitol (Sigma, St. Louis, MO) and 10% SDS (Sigma, St. Louis, MO) for protein denaturation and solubilization. These protein samples were subjected to sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and transferred to nitrocellulose membranes. After blocking, blots were incubated with the V5 epitope tag antibody (1:2000 dilution; In Vitrogen, Carlsbad, CA) and incubated over night at 4℃. The blots were washed and incubated for 1 h at room temperature with horseradish peroxidase conjugated secondary antibody (1:2000 dilution), and bands were detected using the enhanced chemiluminescent plus detection system (ECL Plus; Amersham, Arlington Heights, IL). Autoradiographs were obtained by exposing the nitrocellulose to Kodak XAR film (Rochester, NY).

### Bile Acid Uptake Study

Uptake experiments were performed in triplicate using un-transfected, empty vector transfected or *SLC10A4*-transfected CHO cells. CHO cells transfected with *SLC10A1* was used as the positive control for the uptake experiments. [$^3$H]Taurocholate (specific activity 2.0 Ci/mmol) of > 95% purity was purchased from PerkinElmer (Boston, MA). The uptake experiments were performed as previously described[15].

## RESULTS

### Identification of SLC10A4 and sequence analysis

Using a bioinformatics approach, numerous expressed sequence tags (EST), including (Htm1-361f [GenBank accession no. BE439690] and Htm1-302f [GenBank accession no. BE439637]) were identified within the NCBI database. Upon further analysis it was determined that these ESTs represented a novel gene (*SLC10A4*) belonging to the sodium bile acid symporter family. The DNA and deduced amino acid sequence are shown in Figure 1. The human *SLC10A4* cDNA encodes a protein of 437 amino acids with a predicted molecular mass of 46.5 kDa. The cDNA encompasses a consensus methionine start codon[16] and an in-frame stop codon (Figure 1). The cDNA also encompasses a 5' untranslated region (UTR) of 183 bp and a 271 bp 3' UTR which contains a poly A tail. Kyte-Doolittle hydropathy analysis suggests that SLC10A4 contains 8 putative transmembrane domains (Figure 1). Furthermore, the amino terminus is predicted to contain three potential N-linked glycoslylation sites.

### Comparison of SLC10A4 with other species and with other members of the sodium bile acid symporter family

The *SLC10A4* deduced amino acid sequence for human compared to rat (accession no. XP_579196) share the greatest evolutionary conservation of *SLC10A4* with 89% identity (Figure 2A). In contrast the amount of identity shared between human compared to mouse (XP_775579) or bovine (XP_591836) was equal, 73%.

To further our understanding between the relationships of *SLC10A4* and the other members of the SLC10 family, we performed multiple amino acid alignments and examined the evolutionary relationship between the SLC10 proteins. At the amino acid level, *SLC10A4* shares 30% identity with *SLC10A3* (P3; a SLC10A family member of unknown function), 27% identity with *SLC10A5*, 27% identity with *SLC10A2*, and 24% identity with *SLC10A1* (Figure 2B). We have also looked for relationships of this *SLC10A4* protein compared with anion transporters but no conservation was found (data not shown).

### RT-PCR amplification of the SLC10A4 fragment

RT-PCR was performed using *SLC10A4*-specific primers and cDNA prepared from human colon, T84 cells, and cholangiocyte cell lines. This analysis identified *SLC10A4* mRNA in T84 cells, a normal human cholangiocyte cells (H69), and the cholangiocarcinoma cell-lines Witt, KMC and KMCH (Figure 3). In each case, the PCR amplicon was sequenced to confirm the identity of the PCR product.

**Figure 1** Analysis of the *SLC10A4* DNA and protein sequence. Nucleotide and deduced amino acid sequences of *SLC10A4* cDNA. The nucleotide sequence is numbered on the left and the amino acid sequence is numbered on the right. The 5' UTR encompasses nucleotides (1 to 183) and the initiator methionine lies in an appropriate Kozak sequence (underline). The transmembrane domain is highlighted in bold font. The location of the stop codon is indicated by the asterisk.

### *Tissue distribution of SLC10A4 mRNA*

The *SLC10A4* transcript was detected by Northern blot analysis in a wide variety of human tissues (Figure 4A). The highest *SLC10A4* mRNA expression was observed in brain, placenta, and pancreas. Lower levels of expression were also observed in liver and kidney. While the major *SLC10A4* transcript is approximately 2.4 kb, an additional prominent 0.7 kb transcript was observed in pancreas, and a minor 1.4 kb transcript was observed in liver and kidney. β-actin expression appears to be comparable in each tissue suggesting equal loading of mRNA (Figure 4B).

### *Analysis of SLC10A4-transfected CHO cells*

CHO cells lacking endogenous expression of *SLC10A4* were stably transfected with the human *SLC10A4* cDNA. Figure 5A shows that the pcDNA V5-HisA (*SLC10A4*) transcript is expressed in the stably transfected CHO cells. In contrast, the *SLC10A4* mRNA was not detected in non-transfected CHO cells or in CHO cells transfected with the expression vector (pcDNA4 V5-HisA) alone.

### *Subcellular localization of SLC10A4-V5 in transfected CHO cells by immunofluorescent staining*

To address the cellular localization of this novel protein, transfected cells were stained using an affinity-purified mouse monoclonal antibody raised against the V5 epitope tag. We observed strong staining for *SLC10A4* in the transfected CHO cells, confirming its expression (Figure 5B). The transfected V5-epitope tagged *SLC10A4* protein was expressed primarily in intracellular compartments and to a lesser degree on the plasma membrane.

### *Immunoblot analysis of the SLC10A4-V5 protein*

Protein extracts from untransfected CHO cells, empty vector transfected CHO cells, and *SLC10A4*-transfected CHO cells were fractionated into mixed plasma membranes and an intracellular fraction and used for immunoblotting analysis. This analysis detected a 49-kDa protein and larger apparent aggregate, possibly a glycosylated form of this protein, in the *SLC10A4*-transfected cells, whereas no protein was detected in the non-transfected or empty

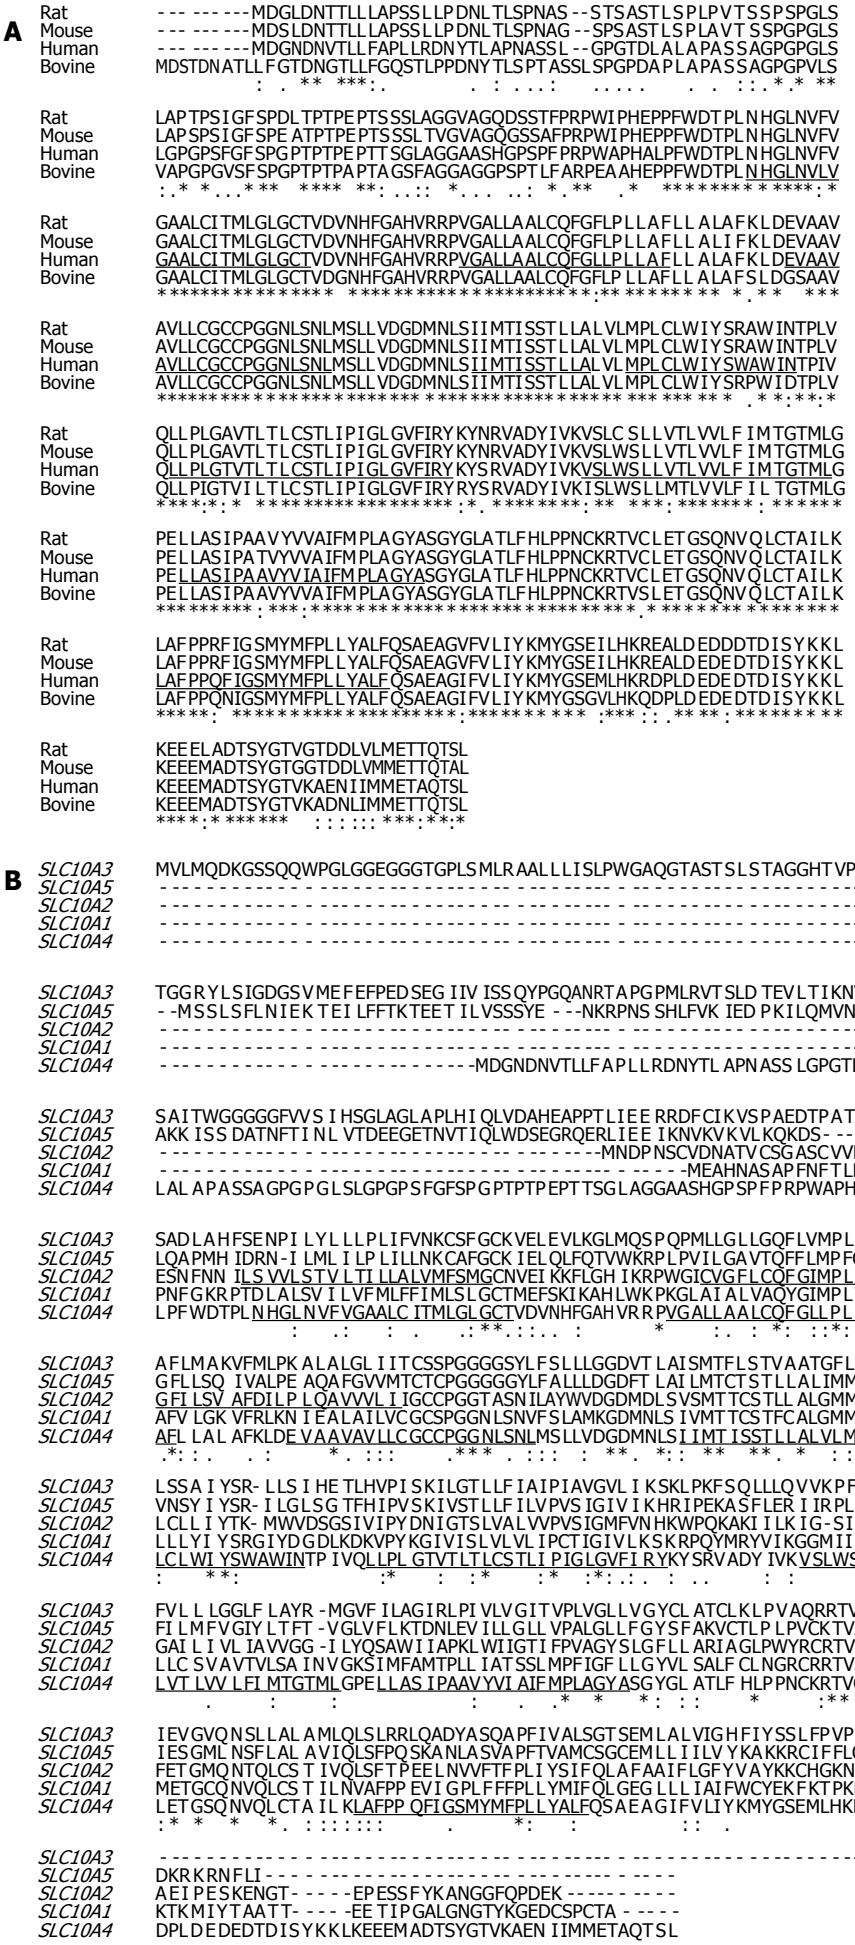

**Figure 2** Multiple alignment of the deduced amino acid sequence for SLC10A4 with sequences from rat (XP_579196), mouse (XP_775579), and bovine (XP_591836) and sequences with other SLC10A4 family members (**A**). The deduced amino acid sequence of *SLC10A4* was aligned with human *SLC10A3* (P09131), human *SLC10A5* (XP_376781), human *SLC10A2* (NP_000443) and *SLC10A1* (AAH74724)(**B**). The SLC10A4 putative transmembrane domains are underlined.

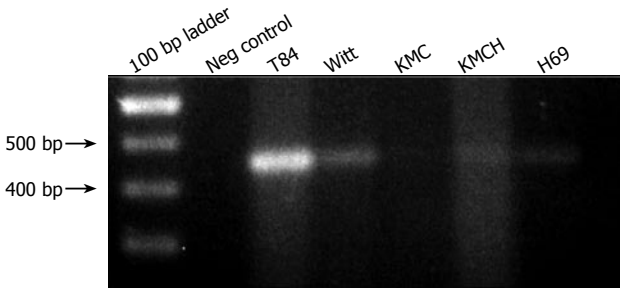

**Figure 3** Expression of *SLC10A4* mRNA in cultured cholangiocyte. Positive bands were detected in normal human cholangiocytes (H69) cells, in cholangiocarcinoma cell-lines (Witt, KMC, and KMCH) and the positive control (T84 cells). No bands were detected in the negative control (i.e., no template cDNA).

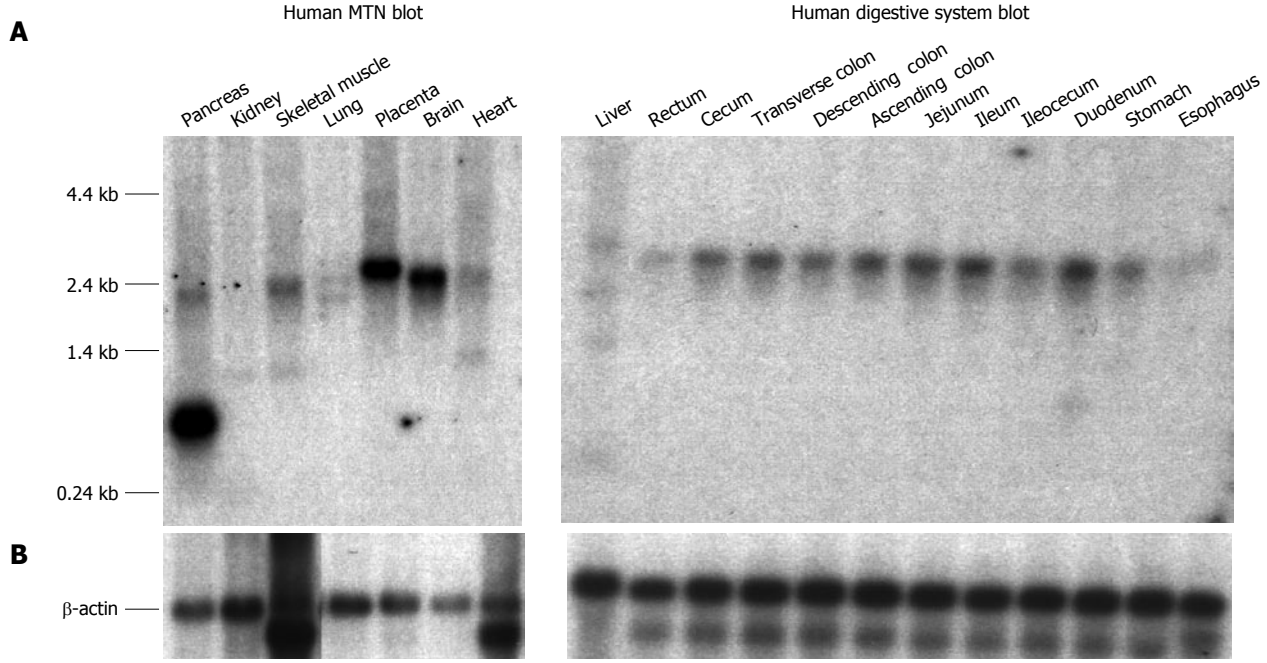

**Figure 4** Northern blot analysis of *SLC10A4* mRNA expression in human tissues. (**A**) The Human MTN and Human Digestive System blots contain 2 μg and 1 μg of poly A+ mRNA per lane, respectively. Each blot was hybridized with a $^{32}$P-labeled *SLC10A4* specific probe. (**B**) Hybridization using a $^{32}$P-labeled β-actin specific probe to confirm equal loading of mRNA.

vector-transfected CHO cells (Figure 5C). The 49-kDa band was detected in the lysate, plasma membrane and vesicles of the *SLC10A4*-transfected CHO cells.

### *Taurocholate functional uptake study*

To examine the possible functional capability of *SLC10A4*, we performed taurocholate uptake studies using stably transfected CHO cells (Figure 6). In functional uptake the positive control, namely, CHO cells stably transfected with *SLC10A1*, exhibited an approximate seven fold increase in taurocholate uptake compared to untransfected and empty vector transfected cells in the presence of sodium (Figure 6). In the same experiment, *SLC10A4*-transfected cells showed no significant increase in taurocholate uptake when compared to the untransfected cells (Figure 6). In the absence of sodium, neither transporter (i.e. *SLC10A1* or *SLC10A4*) showed a significant bile acid uptake when compared to control cells (Figure 6).

## DISCUSSION

The major findings described here are: (a) *SLC10A4* shares amino identity with other members of the sodium bile acid symporter family (*SLC10A2*, *SLC10A1*, *SLC10A3*, and *SLC10A5*); (b) the *SLC10A4* mRNA is widely expressed in human tissues, including cultured human cholangiocytes; and (c) the *SLC10A4* protein is expressed in intracellular compartments as well as on plasma membrane in transfected CHO cells.

As a result of the recent sequencing of the human genome, many novel genes have been identified through the cloning of ESTs (i.e., G protein coupled receptors)[17-20]. We utilized a bioinformatic approach to identify a novel SLC10A family member, termed *SLC10A4*. Prior to the completion of this work, two cDNA clones (accession no. AAH 12048 and AAH19066) have been sequence and listed in the NCBI database as SLC10a4 derived from neuroblastoma brain tissue. To date, only minimal bioinformatics observations have been made regarding *SLC10A4*[21]; however to our knowledge this is the first report to have experimentally analyzed *SLC10A4* mRNA distribution in various tissues, including cholangiocytes. Furthermore we have expressed the *SLC10A4* protein in a CHO cell-line to determine its subcellular localization.

The *SLC10A4* amino acid sequence is conserved amongst various mammalian species. This suggests that this protein may have an important role in substrate transport within various mammal species. *SLC10A4* protein

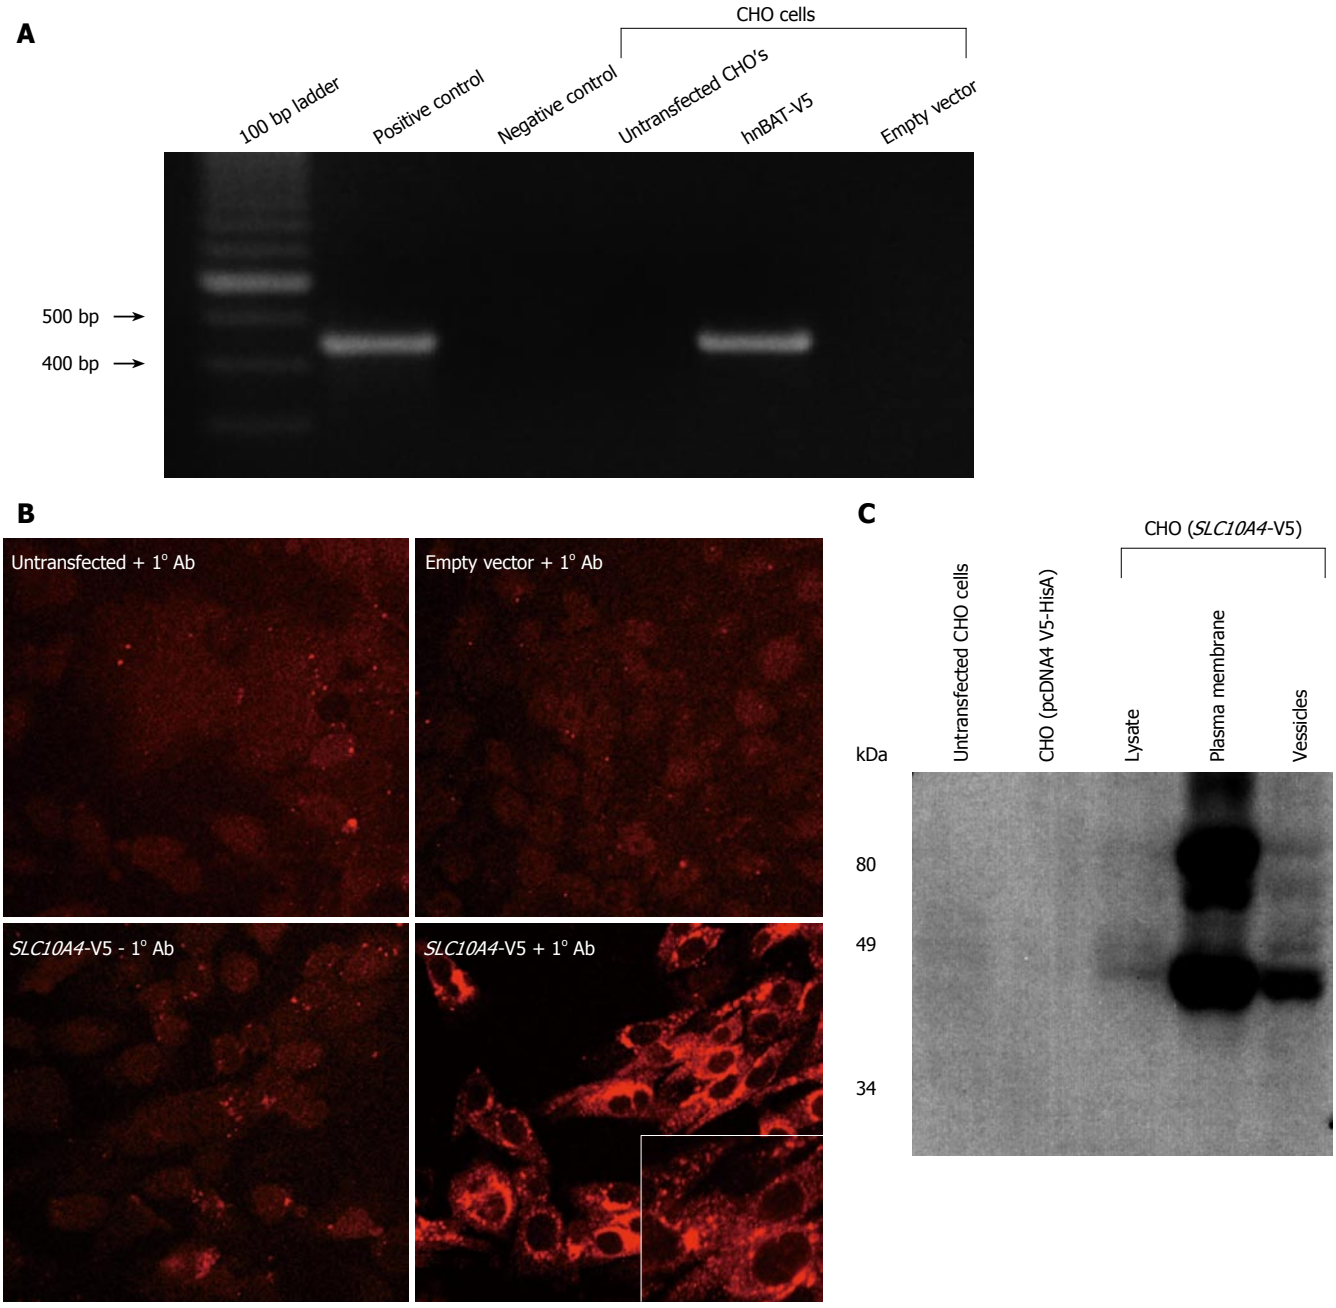

**Figure 5** Analysis of the *SLC10A4* stably transfected CHO cells. (**A**) Expression of *SLC10A4* mRNA in transfected CHO cells. *SLC10A4* mRNA was detected by RT-PCR in the *SLC10A4* transfected cells but not in untransfected CHO cells or the negative control (i.e., no template cDNA). (**B**) Protein expression of *SLC10A4* in stably transfected CHO cells. No staining was found in untransfected CHO cells or CHO cells stably transfected with the empty vector (pcDNA4 V5-HisA) alone in the presence of the affinity-purified monoclonal V5 antibody, or in the CHO cells transfected with *SLC10A4* in the absence of the primary antibody. Robust staining was detected in CHO cells transfected with *SLC10A4* in the presence of the V5 antibody (× 40). (**C**) Immunoblotting analysis of *SLC10A4* in transfected CHO cells. *SLC10A4* is detected in the cell lysate (20 μg), mixed plasma membranes (40 μg) and vesicle (40 μg) fractions of the cells. No bands were seen in cell lysates (40 μg) from untransfected CHO cells or empty vector (pcDNA4 V5-HisA) stably transfected CHO cells.

has a long extracellular amino terminus (shared amongst species) relative to that of *SLC10A1* and *SLC10A2* which may suggest a unique physiological process and role that this protein may have.

*SLC10A4* shares many characteristics of the human sodium dependent bile acid symporter family members. The SLC10 family is composed of five family members that show approximately 30% identity at the amino acid level. Within the SLC10 family, *SLC10A1* and *SLC10A2* share the greatest amino acid identity (about 36%) and are the only proteins shown to transport bile acids. From an evolutionary perspective, *SLC10A4* appears to be an intermediate between *SLC10A1* and the uncharacterized *SLC10A5* protein. To this end, the exon structure of the sodium dependent bile acid symporter family is of interest. *SLC10A5* has 1 predicted exon; *SLC10A4* and *SLC10A3* are composed of 3 predicted exons, *SLC10A1* is encoded by 5 exons, and *SLC10A2* is encoded by 6 exons. The simpler genomic organization of *SLC10A4*, *SLC10A5* and *SLC10A3* allows us to hypothesize that the genes may be ancesteral in nature. SCL10A4 is composed of 437 amino acids compared to *SLC10A1* and *SLC10A2* that are made of 349 and 348 amino acids, respectively. Furthermore, *SLC10A1* and *SLC10A2* are glycosylated and *SLC10A4*

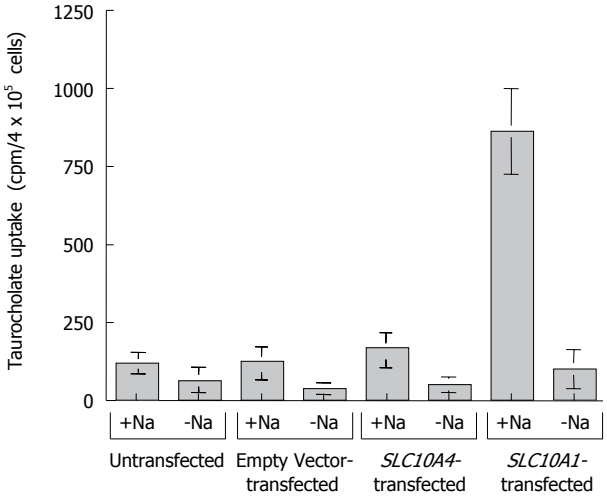

**Figure 6** Taurocholate uptake studies by *SLC10A4*. The cells were exposed to 200 μmmol/L of taurocholate (a mixture of [$^3$H]taurocholate and unlabeled taurocholate) in the presence or absence of $Na^+$. After 5 min at 37℃, the cells were washed with ice-cold wash solution, lysed, and the amount of [$^3$H] taurocholate was measured. The results are expressed as mean ± SE ($n$ = 3).

is predicted to have numerous glycosylation sites on the amino terminus. The predicted size of *SLC10A4* is slightly smaller than the experimental molecular weight, which may be due to addition of the V5 epitope tag on its carboxyl terminus. Additionally, the immunoblot shows a larger band of about 80 kDa that is possibly due to the glycosylation of the native protein, which is expected to occur based on the bioinformatics predictions. In contrast to *SLC10A1* and *SLC10A2*, the hydropathy plot for *SLC10A4* suggests eight potential transmembrane-spanning domains whereas the more characterized models of *SLC10A1* and *SLC10A2* have only seven again suggesting that this protein may have diverged from the well studied *SLC10A1* and *SLC10A2* genes. This discrepancy will require further experimental analysis to determine the actual number of transmembrane domains that reside in *SLC10A4*. The major sodium bile acid symporters involved in the secretion and absorption of bile acids are *SLC10A1* and *SLC10A2*. *SLC10A1* is primarily found in the liver where it is localized in the hepatocytes[6]. Within the hepatocytes, the *SLC10A1* protein resides on the sinusoidal membrane[6]. In contrast, *SLC10A2* mRNA has been shown in the cholangiocytes, ileal enterocytes, and in the proximal tubular cells of the kidneys[11,15,22,23]. *SLC10A2* is an apical oriented protein in the afore mentioned cells. Both *SLC10A1* and *SLC10A2* have been shown to transport various bile acids in a sodium dependent manner[6,15,22,23]. Much less is known about the remaining members of the SLC10 family of sodium bile acid symporters. *SLC10A3* is ubiquitously expressed in tissues and has been localized to various ESTs including placenta[21] (GenBank accession no. BX377672, brain (GenBank accession no. BM559383), lung (GenBank accession No. BM981524), kidney (GenBank accession no. BG249893) and stomach (GenBank accession no. BM747336). Far less is known for *SLC10A5* mRNA tissue distribution that has been limited to fetal brain (GenBank accession no. XM_294493)[21]. *SLC10A4* is also ubiquitously expressed in all tissues we have tested. Interestingly, *SLC10A4* mRNA shows slight difference in mRNA size amongst tissue by Northern blotting suggesting that this may be the result of tissue specific alternative transcription.

To our knowledge, the protein localization and substrate specificity have not been determined for either *SLC10A3* or *SLC10A5*, and these genes remain orphan transport proteins. In CHO cells expressing *SLC10A4*, we were not able to show transport of taurocholate, suggesting that *SLC10A4* is also orphan transport protein.

We have found that the *SLC10A4* mRNA is widely expressed in human tissues and is comparable to distribution pattern of *SLC10A3*. In fact, both *SLC10A3* and *SLC10A4* mRNA are expressed in similar tissues, suggesting both proteins may serve a ubiquitous function in the cell machinery. To define the localization of *SLC10A4* in CHO cells we created a chimeric protein in which the coding sequence of *SLC10A4* was cloned in frame with the V5-epitope tag. This construct was stably transfected in CHO cells to characterize the *SLC10A4* protein. We found that the novel protein localizes to both intracellular and plasma membrane of CHO cells. The intracellular localization infers that the protein is a regulated protein by some intracellular messenger. It has been shown the *SLC10A1*-GFP is regulated by cAMP when this construct was transfected into HepG2 cells[24]. It is possible that *SLC10A4* is regulated in a similar manner as *SLC10A1*. *SLC10A4* may be a regulated protein that requires an agonist to translocate the protein to the plasma membrane.

The physiological relevance of this novel transporter is currently unclear. Although the protein does not transport taurocholate and chenodeoxycholic acid, we cannot rule the transport capacity of other bile acids or other polar solutes. Nevertheless, *SLC10A4* protein shares homology with *SLC10A1* and *SLC10A2*. We have cloned and characterized the human *SLC10A4* in hoped that they data will improve our understanding on the phylogeny, origin and evolution of the SLC10A family of transport proteins which may provide important insight into which protein regions are involved in substrate specificity.

## Abstract

**AIM:** To examine the influence of dexamethasone on pancreatitis-associated protein (PAP) gene expression using both *in vitro* and *in vivo* models of acute pancreatitis and to study how PAP gene expression correlates with severity of pancreatitis.

**METHODS:** *In vitro*, IL-6 stimulated pancreas acinar AR42J cells were cultured with increasing concentrations of dexamethasone and assayed for PAP expression (RT-PCR). *In vivo*, pancreatitis was induced in rats by retrograde injection of 40 g/L taurocholate into the pancreatic duct. Animals were pretreated with dexamethasone (2 mg/kg) daily or saline for 4 d. Pancreata and serum were harvested after 24 h and gene expression levels of PAP Ⅰ, Ⅱ and Ⅲ were measured by RT-PCR. Severity of pancreatitis was based on serum amylase, pancreatic wet weight, and histopathological score.

**RESULTS:** *In vitro*, dexamethasone and IL-6 induced a marked transcription of PAP Ⅰ, Ⅱ and Ⅲ genes in AR42J cells at 24 h ($P < 0.05$ for all comparisons). *In vivo*, pancreas mRNA levels of PAP Ⅰ, Ⅱ or Ⅲ increased by 2.6-fold, 1.9-fold, and 1.3-fold respectively after dexamethasone treatment, compared with saline treated animals. Serum amylase levels and edema were significantly lower in the dexamethasone group compared with the saline group. Histopathologic evaluation revealed less inflammation and necrosis in pancreata obtained from dexamethasone treated animals ($P < 0.05$).

**CONCLUSION:** Dexamethasone significantly decreases the severity of pancreatitis. The protective mechanism of dexamethasone may be *via* upregulating PAP gene expression during injury.

**Key words:** Pancreatitis; Pancreatitis-associated protein; Pancreatitis-associated protein; Dexamethasone

## INTRODUCTION

Acute pancreatitis is an acute inflammatory response to pancreatic injury and induces important changes in the expression of a number of genes in the pancreas[1,2]. Among these, the most profound change is that of the pancreatitis-associated protein (PAP) family, the expression of which is very low in the normal pancreas and becomes strongly overexpressed after even mild pancreatic inflammation[1,3-5]. Multiple functions have been ascribed to PAP. It has been shown to be antibacterial, anti-apoptotic, and mitogenic *in vitro*, and sequence analysis of PAP reveals the presence of a carbohydrate recognition domain in the protein, suggesting that PAP Ⅰ might act as a carbohydrate-binding lectin and can aggregate bacteria in suspension[6]. Therefore, PAP may function as an endogenous anti-bacterial agent and be protective against infectious complications of pancreatitis, which can otherwise lead to severe disease with a high mortality. In addition, PAP expression is upregulated by free radicals or cytokines, and such upregulation confers cellular resistance to apoptosis[7]. Previous results from our laboratory also showed that reg Ⅲ (PAP) isolated from cow is mitogenic for pancreatic-derived cells, thus implicating PAP in the proliferative response of pancreas to injury[8]. An anti-inflammatory effect of PAP has been found which protects the lung from leukocyte-induced injury[9]. In addition, we recently demonstrated that antisense knockdown of PAP gene expression exacerbates the severity of pancreatitis, suggesting a protective function of PAP in acute pancreatitis[10].

Pancreatitis is an important clinical problem, for which

**Table 1 Taqman primers and probes for real-time quantitative PCR**

| Gene (Accession No.) | Primer/Probe sequences (Forward/Reverse/Probe) | Position (nt No.) | Size (bp) |
|---|---|---|---|
| PAP Ⅰ | F 5'-AAAATACCCTCTGCACGCATTAG-3' | 153-171 | 67 |
| (NM_053289) | R 5'-GGGCATAGCAGTAGGAGCCATA-3' | 219-198 | |

| PAP Ⅱ | F 5'-CCAGAAGGCAGTGCCCTCTA-3' | 240-259 | 67 |
| (L10229) | R 5'-GCAGTAAGAACGATAAGCCTTGGA-3' | 306-283 | |
| | P 5'-FAM-ACGAACCAGCTGCCCCATGG-TAMRA-3' | 261-280 | |
| PAP Ⅲ | F 5'-TGTGCCCACTTCACGTATCAG-3' | 121-140 | 64 |
| (L_20869) | R 5'-GGCATAGCAATAGGAGCCATAGG-3' | 184-162 | |
| | P 5'-FAM-TGCCCCAAGGGCTCGCG-TAMRA-3 | 143-159 | |
| β-actin | F 5′-TTCAACACCCCAGCCATGT-3′ | 379-397 | 68 |
| | R 5′-GTGGTACGACCAGAGGCATAC A-3′ | 446-425 | |
| | P 5′- FAM-CGTAGCCATCCAGGCTGTGTTGTCC-MGBNFQ-3′ | 399-422 | |

treatment remains largely supportive. Corticosteroids have been shown to be beneficial in treatment of acute pancreatitis[11-19]. Although it is thought that steroid administration exerts an anti-inflammatory effect of the inflamed pancreas, the mechanism of how this occurs remains unclear. We postulate that during acute pancreatitis, the pancreas turns on a defense mechanism that includes expression of PAP and other stress proteins that enable the survival of pancreas under conditions of acute stress and that corticosteroid treatment augments the PAP response.

In the present study, the influences of dexamethasone on PAP Ⅰ, Ⅱ and Ⅲ gene expression using both *in vitro* cellular analysis and an *in vivo* model of acute pancreatitis were examined and correlated with severity of pancreatitis. It is our hypothesis that dexamethasone mediates protection against acute pancreatitis *via* PAP gene induction.

## MATERIALS AND METHODS

### Materials

IL-6 (1-10 MU/L) stimulated pancreas acinar AR42J cells were cultured with dexamethasone (100 nmol/L) and assayed for PAP expression. Sprague Dawley rats obtained from Harlan Sprague Dawley (Indianapolis, IN) and weighing 175-200 g at onset of studies served as subjects. They were fed standard laboratory chow, given water *ad libitum*, and randomly assigned to control or experimental groups.

### Pancreatitis induction and dexamethasone treatment

Pancreatitis was induced in rats by retrograde injection of 40 g/L sodium taurocholate (NaT) (Sigma, St. Louis, MO) into the pancreatic duct as previously described[20-21]. Briefly, under pentobarbital (Abbott Laboratories, North Chicago, IL) anesthesia (50 mg/kg ip), a midline incision was performed. The common bile duct was identified and cannulated in an antegrade direction with PE-10 tubing (Fisher Scientific, Pittsburgh, PA) so that the proximal end of the tube was beyond the ampulla of Vater in the duodenum. The bile duct was then ligated to prevent the flow of bile and 40 g/L NaT in sterile saline was infused into the pancreatic duct at a rate of 1 mL/kg over 10 min[22]. Animals were pretreated with daily intraperitoneal injection of dexamethasone (2 mg/kg) or saline for 4 d prior to pancreatitis induction ($n$ = 8 per group). Pancreata and serum were harvested 24 h after pancreatitis induction. Severity of pancreatitis was based on serum amylase, pancreatic wet weight, and histopathological score. All animal studies have been approved by the Division of Animal and Laboratory Resources, SUNY Downstate Medical Center.

### Biochemical analysis and evaluation of pancreatic morphology

Serum amylase activity (U/L) was measured using 4,6-ethylidene ($G_7$)-*p*-nitrophenyl ($G_1$)-$\alpha_1$D-maltoheptaoside as the substrate[23]. The extent of pancreas edema was quantitated by the ratio of pancreas wet weight over rat's total (mg/g) body weight[21]. For morphologic analysis, 5-μm-thick paraffin sections of pancreas samples were stained with HE. Ten randomly chosen microscopic fields were examined for each tissue sample, and inflammation as well as necrosis, were scored as follows: none = 0; mild = 1; moderate = 2; and severe = 3[24].

### Analysis of PAP gene expression

PAP Ⅰ, Ⅱ and Ⅲ levels were measured, *in vitro* and *in vivo*, by real-time quantitative reverse transcription-polymerase chain reaction (RT-PCR), based on the fluorogenic 5'-nuclease assays previously described[25,26]. The assay, which confers very high specificity, was carried out using a GeneAmp 5700 sequence-detection system (Applied Biosystems, Foster City, CA), with β-actin as an internal control to standardize the amount of sample RNA added to a reaction. Primers and probes were designed using Primer Express software (PE Biosystems). Sequences for all primers and probes used in these analyses are listed in Table 1.

All primers and probes and other reagents for real-time quantitative PCR were purchased from Applied Biosystems. One hundred ng of total RNA was used to set up 25-μL real-time quantitative PCRs that consisted of 1 X TaqMan Universal PCR Master Mix, 500 nmol/L forward and reverse primers, and 200 nmol/L TaqMan probe. PCR amplification was carried out with the following temperature profile: 30 min at 48℃; 10 min at 95℃;

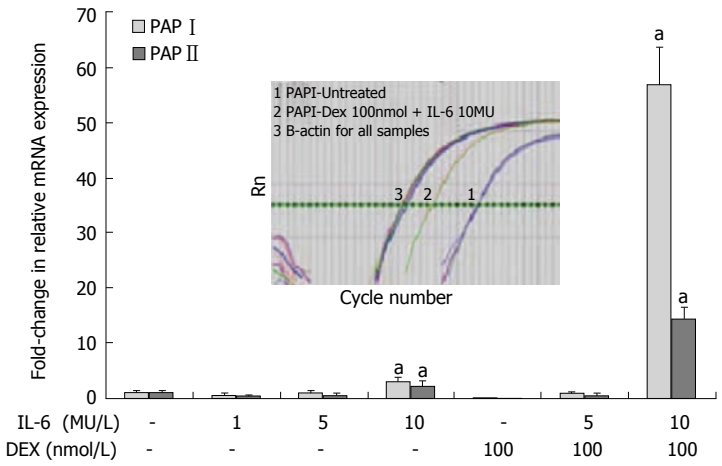

**Figure 1** PAP expression was upregulated by treatment of dexamethasone and IL-6. AR42J cells were treated with indicated dose of dexamethasone (Dex) and IL-6. PAP Ⅰ and Ⅱ mRNA levels were determined by real-time quantitative RT-PCR analysis, using PAP Ⅰ, or Ⅱ-specific TaqMan primers and probe. Amount of mRNA in each group was normalized to β-actin. Results are presented as fold change in PAP Ⅰ or Ⅱ mRNA in treated cells relative to the levels observed in untreated/control cells and similar results were obtained with PAPⅢ (data not shown). Bars represent mean ± SD from 3 independent experiments ($^aP < 0.05$ *vs* untreated/control cells, ANOVA, Tukey). Insert shows representative amplification plots.

and 40 cycles of 15 s at 95℃ and 1 min at 60℃. Assays were performed in triplicate. Data were analyzed with the relative standard curve method[27]. Standard curves of the genes of interest and β-actin were prepared with three 1:2 dilutions (four points, eightfold range) of total RNA from one of the samples that was expected to have the highest amount of mRNA for the gene of interest. For each reaction tube, the amount of target or internal reference was determined from the standard curves. The mean amount of each sample was calculated from the triplicate data and was normalized by division by the mean quantity of β-actin RNA for the same sample. The mean and SD of each treated group were calculated from the normalized value for each rat in that group.

### *Statistical analysis*

Values for results were expressed as means ± SD obtained from multiple determinations in 3 or more separate experiments. *P* values computed were two-tailed, and $P < 0.05$ was considered statistically significant (Student's *t*-test, ANOVA with Tukey post hoc correction).

## RESULTS

When AR42J cells which were cultured in the presence of IL-6 were exposed to increasing amounts of dexamethasone, increased gene expression of PAP Ⅰ, Ⅱ, and Ⅲ was observed at 24 h ($P < 0.05$ when compared with controls) (Figures 1 and 2).

Rats which were treated with dexamethasone prior to pancreatitis induction demonstrated upregulation of pancreas mRNA levels of PAP Ⅰ, Ⅱ or Ⅲ when compared with saline treated controls (PAP Ⅰ: 2.6-fold, PAP Ⅱ: 1.9-fold and PAP Ⅲ: 1.3-fold respectively) ($P < 0.05$ for PAP Ⅰ and PAP Ⅱ) (Figure 3).

Furthermore, serum amylase levels and edema were significantly lower in the dexamethasone group compared with the saline group (Figure 4A and B) and histopathologic evaluation revealed less inflammation and necrosis in pancreata obtained from dexamethasone treated rats when compared with controls (Figure 4C) ($P < 0.05$).

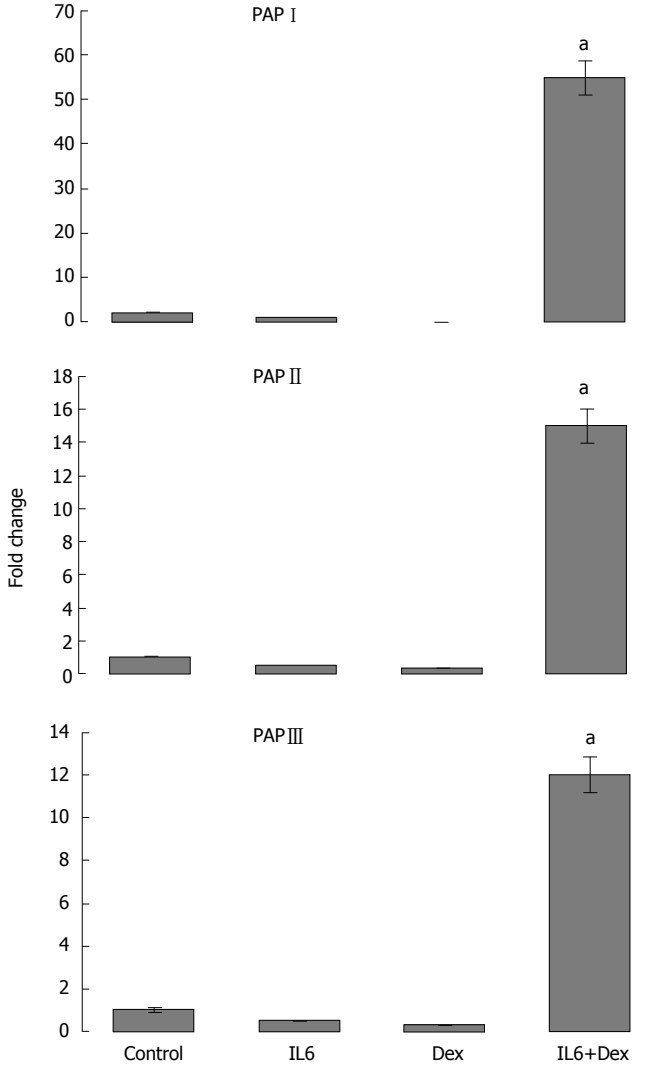

**Figure 2** PAP expression was upregulated by treatment of dexamethasone and IL-6: *In vitro*, dexamethasone (Dex) and IL-6 induced a marked transcription of PAP Ⅰ, Ⅱ and Ⅲ genes in AR42J cells at 24 h when compared with untreated (control) cells. Data represent fold change of untreated/unstimulated cells as determined by real-time PCR analysis (see materials and methods). Bars represent mean ± SD from 3 independent experiments ($^aP < 0.05$ *vs* controls, ANOVA, Tukey).

## DISCUSSION

In the current study, the influence of dexamethasone on PAP gene expression using both *in vitro* cellular analysis and an *in vivo* model of acute pancreatitis was investigated. Our results suggest that dexamethasone has an anti-

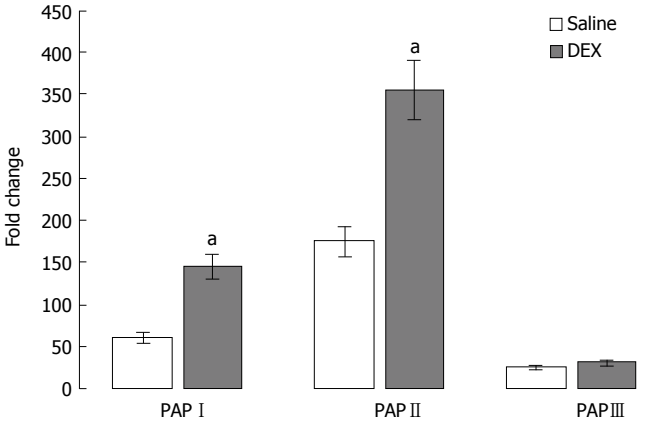

**Figure 3** PAP expression is upregulated by dexamethasone: Rats (8/group) were treated with daily saline (white bars) or dexamethasone (grey bars) prior to pancreatitis induction. Pancreata were harvested 24 h after pancreatitis induction and PAP levels were determined by real time PCR and presented as fold change (normalized to β-actin) as described in materials and methods, and described in text as a ratio of PAP mRNA from NaT treated/saline treated pancreas mRNA ($^aP < 0.05$ *vs* saline treated controls, Student's *t*-test).

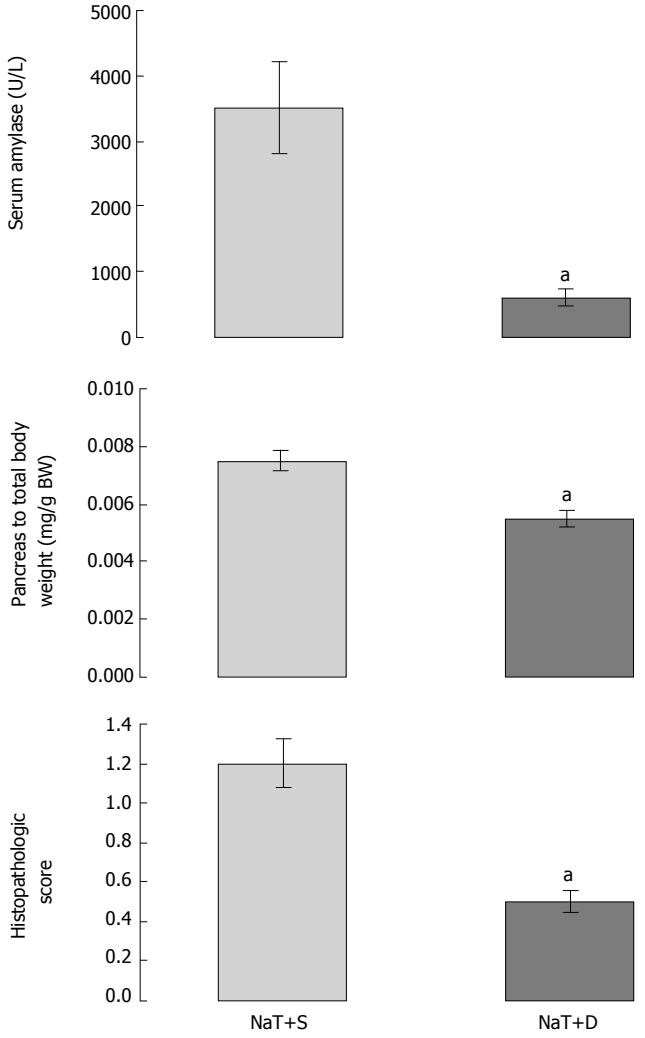

**Figure 4** Dexamethasone treatment decreased pancreatitis severity *in vivo*. Rats were treated with saline (S) or dexamethasone (D) for 4 d prior to pancreatitis induction with sodium taurocholate (NaT). Pancreata were harvested 24 h after pancreatitis induction and severity of pancreatitis was based on serum amylase (U/L), pancreatic wet weight (mg/g BW), and histopathological score. The bars represent the mean ± SD ($n = 8$, $^aP < 0.05$ *vs* the saline-treated control group).

inflammatory effect in acute pancreatitis *via* upregulating PAP gene expression, which is inversely correlated with local pancreatic inflammation such as pancreatic edema and neutrophilic infiltration. Additionally, recent data from our laboratory demonstrates a protective role for PAP at the protein level since administration of anti-PAP antibodies worsened pancreatitis severity *in vivo*[28,29]. PAP is a member of the family of secretory proteins expressed in the gastrointestinal tract and was originally isolated from the pancreatic juice of rats with acute pancreatitis[3]. Currently, three PAP genes have been characterized in human[5] and rat[6,30,31]. mRNA for PAP isoforms (PAP Ⅰ, Ⅱ, and Ⅲ) are expressed in the pancreas and small intestine among other tissues[30,32]. Results of PAP gene regulation studies suggest that PAP is an acute phase stress protein secreted from pancreas. PAP protein, which is not detectable in the healthy pancreas, is significantly expressed six hours after induction and reaches maximal expression after 48 h[21,32]. PAP accounts for about 5% of the secretory proteins during acute pancreatitis and can be detected in blood within 48 h of induction of acute pancreatitis[21]. We have previously reported a direct relationship between the severity of pancreatitis and serum levels of PAP[21]. We have also demonstrated that antisense mediated gene knockdown of PAP expression correlated with worsening pancreatitis *in vivo*[10]. We postulate that PAP proteins serve a protective role in acute pancreatitis and that the protective effect may be *via* the downregulation of acute phase cytokine gene expression in the peripheral immune system[33].

In the present study we showed that AR42J, a rat acinar cell line can be induced and used as a model to express all three PAP isoforms (PAP Ⅰ, Ⅱ and Ⅲ) when treated with combination of IL-6 with dexamethasone. Although previous *in vitro* studies revealed that induction of PAP Ⅰ gene expression could be obtained *via* dexamethasone treatment[34], here we demonstrate that all PAP isoforms are upregulated when cultured with increasing amount of dexamethasone and this effect is potentiated with addition of IL-6. Although many cytokines, including IL-6 are upregulated in many inflammatory states including pancreatitis[35-37], it is possible that IL-6, in conjunction with other mediators, contributes to PAP upregulation and disease resolution *in vivo*. This is likely since PAP/Reg genes possess IL-6 and glucocorticoid response elements[20,34]. We have previously demonstrated that antisense knockdown of PAP correlates with disease progression *in vivo*[10] and that more recently, plasmid and linear based siRNA gene knockdown of one PAP isoform impacts the expression of other PAP isoforms[38], suggesting that expression of PAP isoforms is contingent on one another rather than being redundant genes of common ancestry. Sequence comparisons of PAP isoforms demonstrate that they are closely related[39,40], although differing in their expression pattern and contain a concensus sequence coding for a bioactive protein component common to all three PAP isoforms (GGWEWSN)[41], which is able to knockdown gene expression of PAP Ⅰ, PAP Ⅱ, and PAP Ⅲ. It is our

hypothesis that this highly homologous sequence common to all three isoforms may harbor important genetic information and may encode a bioactive fragment common to all PAP isoforms. To this end, Bodeker and colleagues have shown that PAP Ⅰ interacts with PAP Ⅱ, PAP Ⅲ and lithostatin (RegIα) as well as itself to form homo/heterodimers[42], suggesting that PAP proteins may provide overlapping function for other members of the Reg protein family.

To evaluate the role of dexamethasone-induced upregulation of PAP expression in limiting the severity of pancreatitis, dexamethasone was administered before pancreatitis induction with NaT, an experimental model of necrotizing acute pancreatitis[43]. It is well known that corticosteroids are immunological moderators and influence a number of factors involved in the process of tissue inflammation and edema[11,44]. There is evidence that endogenous glucocorticoids may protect acinar cells in acute pancreatitis by decreasing their sensitivity to the induction of cell death[20]. The adrenocortical function is stimulated during acute pancreatitis and it has been suggested that the secretion of endogenous glucocorticoids may play an important role in mitigating the progress of this disease, probably by inhibiting cytokine production[45-48]. Additionally, hydrocortisone therapy was shown to be effective and beneficial at a dose of 4-25 mg/kg given 30 min before inducing acute pancreatitis, depending on the experimental system[14,44]. Furthermore, amelioration of acute pancreatitis by glucocorticoid treatment is related to the dose and time factor to achieve optimal therapeutic results[44]. The present study indicated that dexamethasone significantly improved both the local pancreatic inflammatory response as well as systemic inflammatory parameters and correlated with upregulation of PAP gene expression. Similarly, studies by Paszt *et al*[49], have also demonstrated a reduction in serum amylase and pancreatic weight/body weight ratios in pancreatitic rats after treatment with dexamethasone. The beneficial effects of dexamethasone treatment may be directly related to PAP upregulation, possibly through utilization of a glucocorticoid response element found in the PAP/Reg gene family[20]. PAP Ⅲ gene expression did not differ between dexamethasone and control groups at 24 h. It could be that PAP Ⅲ responds to corticosteroid treatment at earlier or later time points and may interact with other PAP isoforms and affect their expression, as has been observed with PAP Ⅰ[42].

In conclusion, the present study demonstrates a protective function of dexamethasone in acute pancreatitis which may be *via* upregulation of PAP gene expression during injury. In clinical practice, it is well known that the development of severe acute pancreatitis leads to multiple organ failure. Based on the present results, dexamethasone therapy may have the potential to help prevent the progression of acute pancreatitis. Dexamethasone treatment reduces edema, leukocyte infiltration and fat necrosis in the pancreas which is likely due to the upregulation of PAP. Future studies need to generate recombinant PAP and bioactive PAP peptides and explore their protective role against pancreatitis.

## Abstract

**AIM:** To evaluate the protective effects of preconditioning by α-lipoic acid (LA) in patients undergoing hepatic resection under inflow occlusion of the liver.

**METHODS:** Twenty-four patients undergoing liver resection for various reasons either received 600 mg LA or NaCl 15 min before transection performed under inflow occlusion of the liver. Blood samples and liver wedge biopsy samples were obtained after opening of the abdomen immediately after inflow occlusion of the liver, and 30 min after the end of inflow occlusion of the liver.

**RESULTS:** Serum levels of aspartate transferase and alanine transferase were reduced at all time points in patients who received LA in comparison to those who received NaCL. This was accompanied by reduced histomorphological features of oncosis. We observed TUNEL-positive hepatocytes in the livers of the untreated patients, especially after 30 min of ischemia. LA attenuated this increase of TUNEL-positive hepatocytes. Under preconditioning with LA, ATP content was significantly enhanced after 30 min of ischemia and after 30 min of reperfusion.

**CONCLUSION:** This is the first report on the potential for LA reducing ischemia/reperfusion injury (IRI) of the liver in humans who were undergoing liver surgery. Beside its simple and rapid application, side effects did not occur. LA might therefore represent a new strategy against hepatic IRI in humans.

**Key words:** Liver ischemia; Pringle manoeuvre; Pharmacological pre-treatment; Liver preconditioning; Apoptosis; Adenosine triphosphate

## INTRODUCTION

Excessive blood loss during surgery and the need for transfusion have been shown to hinder the post-operative course of patients[1]. In order to minimize blood loss, clamping of the portal triad (inflow occlusion), also called pringle maneuvre, is used during liver surgery[2]. However, the risk of ischemia/reperfusion injury (IRI) of the liver is increased under these conditions[3].

Ischemia reperfusion injury of the liver is still a major cause of morbidity and mortality in patients undergoing liver surgery and transplantation[4]. A period of ischemia followed by a brief period of ischemia (ischemic preconditioning, IP) prior to sustained ischemia is a method to reduce IRI of the liver in animal models as well as in humans[5]. However, the protective effects are lost in older patients and in patients undergoing major tissue loss (> 50% of the liver)[6].

In animal models there are numerous pharmacological agents protecting the liver from IRI[7]. However, there is a lack of clinically proven strategies to pharmacologically reduce IRI of the liver in humans. We have previously described the potential of α-lipoic acid (LA) to protect from IRI of the isolated perfused rat liver, which could be confirmed *in vivo* for livers undergoing 90 min of warm ischemia[8].

α-Lipoic acid is a naturally occurring compound present in the majority of pro- and eukaryotic cells. For many years LA has been used as a pharmacological agent against diabetic polyneuropathy and is known to be without serious side effects[9]. Therefore, oral and intravenous application as well as the bioavailability of LA

is well established[10]. The aim of the present study was to evaluate the influence of LA in ischemia/reperfusion injury of the liver in patients who are undergoing liver resection.

## MATERIALS AND METHODS

### Experimental design

Informed consent was obtained from each patient before surgery. Patients scheduled to undergo liver resection were included. Characteristics of patients are shown in Table 1. Baseline wedge biopsy samples were taken from the part of the liver to be resected. Clamping of the portal triad was performed with the torniquet technique. Samples of liver tissue (wedge biopsy) obtained during surgery were immediately transferred into liquid nitrogen or stored in 4% paraformaldehyde. Separate clamping of aberrant left hepatic arteries was carefully performed when present. Transection of the liver was immediately performed after complete hepatic inflow occlusion; if necessary vessels and bile duct were ligated with 2-0 silk suture. After exactly 30 min, the portal clamping was released and hemostasis was obtained. Each surgery was performed with a low central venous pressure to minimize blood loss and was carried out by using the same anesthetic combinations. Surgery was performed by one surgeon.

Our protocol is based on the data we obtained in rodents, where an amount of 500 μmol (120 μg) LA strongly protected the liver against IRI after a prolonged period of ischemia[8]. Previous studies have shown that ischemic injury in humans becomes detectable after 30 min of ischemia[11]. Twenty-four patients were subjected either to preconditioning with 600 mg LA (in 50 mL NaCl) intravenously 15 min before inflow occlusion of the liver or to receive 50 mL NaCl intravenously 15 min before inflow occlusion of the liver. We performed ischemia 15 min after ending the LA injection because its bioavailability is sufficient 15 min after intravenous application[10].

In order to minimize bias, LA preconditioning was performed in an alternate fashion. Patients with cirrhosis, elevated liver enzymes as well as high operation risk were excluded. Blood samples and wedge biopsies were taken after opening the abdomen (LAP), after 30 min of ischemia (pP0´), and after 30 min of reperfusion (pP30`). Blood samples were taken every day until discharge. All blood samples were analyzed using a serum analyzer (Olympus AU Connector 640, Hamburg, Germany). Wedge biopsy samples were immediately stored in liquid nitrogen or fixed for histological examination. Liver tissue was weighed prior to homogenization and diluted 1:5 with 0.01 mmol/L PBS (phosphate buffered saline). Homogenization was then carried out with a Potter liver homogenizer at 800 revolutions/mine. The mixture was centrifuged at 1000 × *g* for 10 min, the supernatant was transferred into an Eppendorf cup and centrifuged at 10000 × *g* for 20 min. The clear supernatant was pipetted into a fresh Eppendorf cup, and stored until further measurement.

### ATP content in liver tissue

Measurement of adenosine triphosphate (ATP) in liver tissue was carried out using a standardized method[12]. The liver slices were weighed and diluted in 4 % $HClO_4$ (1:10) prior to homogenization with a Potter liver homogenizer at 850 revolutions/min. The mixture was centrifuged at 10000 × *g* for 5 min at 4℃. The supernatant was pipetted into an Eppendorf cup and neutralized with 150 μL 2 mol/L Tris, 150 μL KOH, and phenol-red. 5 mol/L KOH was then added until a blew-lilac complex was observed. The mixture was again centrifuged at 10000 U/min for 5 min at 4℃. The supernatant was measured immediately as described by Trautschold et al. with a hexokinase/glucose-6-phosphat dehydrogenase reaction by UV photometry[13].

**Table 1 Patients characteristics [mean (range)]**

| characteristics | Vehicle | LA |
|---|---|---|
| Age (yr) | 61 (34-79) | 63 (46-79) |
| Sex (M/F) | 5/7 | 6/6 |
| Resected liver tissue (g) | 434 (40-1100) | 588 (112-1365) |
| Blood loss (mL) | 1175 (400-2000) | 825 (200-2200) |
| RC-transfusion intraoperative (mL) | 300 (0-1000) | 265 (0-1000) |
| Intensive care unit (d) | 1 (0-7) | 2 (0-4) |
| Hospital stay (d) | 13 (6-21) | 14 (11-25) |
| Post-OP complications | 1/12 | 1/12 |
| Mortality | 1/12 | 0/12 |
| Indications, malignant | 11/12 | 11/12 |

### Histology and Immunhistochemistry

Formalin-fixed tissue samples were embedded in paraffin, and 5 μm sections were cut. Replicate sections were stained with hematoxylin and eosin (H&E) for the evaluation of oncosis. Morphological criteria of oncosis, such as increased swelling, vacuolization and blebbing were assessed. The terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling (TUNEL) assay was employed for the evaluation of apoptotic related cell injury. For TUNEL staining, livers were fixed with freshly prepared 4% paraformaldehyde in neutral buffered saline (PBS). Frozen sections (5 μm) of the fixed tissue were prepared and stained with the TUNEL method using a commercially available kit (Chemicon International, ApopTag peroxidase apoptosis detection kit, Hampshire, UK). The number of TUNEL-positve hepatocytes was counted in 10 high power fields (400 fold magnification). All histological evaluations were done in a blinded fashion.

### Statistical analysis

All data are expressed as means ± standard deviation. Statistical differences between experimental groups were calculated by Graph Pad Prism version 4.00 for Windows, GraphPad Software, San Diego California USA 1994-1999, and $P < 0.05$ was considered significant. One-way analysis of variance (ANOVA) with subsequent post hoc Tukey-test was used.

## RESULTS

### Clinical characteristics

There was no statistical difference between the two groups indicating that they were homogeneous and comparable (Table 1, data were expressed with median values with ranges [minimum-maximum]). One patient in the untreated

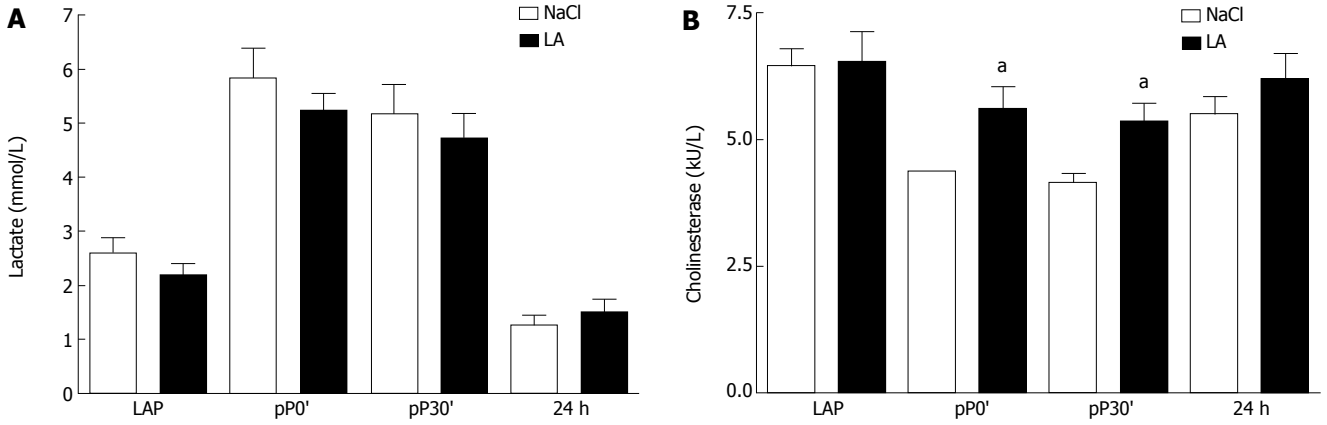

**Figure 1** Lactate (**A**) and cholinesterase (**B**) levels after laparotomy (LAP), 30 min of ischemia (pP0´), 30 min of ischemia with 30 min of reperfusion (pP30´) and 24 h after operation with and without 600 mg LA 15 min prior to ischemia, values as means ± SD, $n = 12$ each group, $^{a}P < 0.05$ *vs* NaCl.

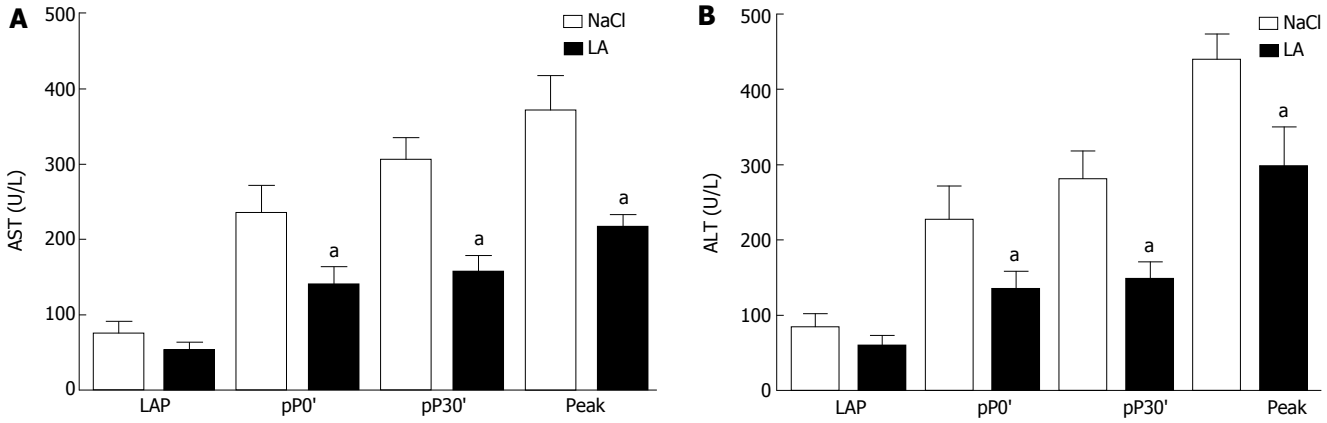

**Figure 2** AST (**A**) and ALT (**B**) levels after laparotomy (LAP), after 30 min of ischemia (pP0´), after 30 min of ischemia with 30 min of reperfusion (pP30´) and after d 1-3 (peak level) with and without 600 mg LA 15 min prior to ischemia, values as means ± SD, $n = 12$ each group, $^{a}P < 0.05$ *vs* NaCl.

group died because he suffered mesenteric ischemia at day 10 after liver resection. During revision of the abdomen we saw great areas of necrotic small intestine whereas the portal vein was not occluded. Operative morbidity was low in both groups. One patient in each group suffered bile leakage; both were cured by local drainage.

### *Lactate in serum*

To evaluate inflow occlusion in both groups we determined lactate levels in serum. We observed no difference of lactate between both groups directly after opening of the abdomen (LAP), after 30 min of ischemia, after 30 min of reperfusion, and 24 h after inflow occlusion (Figure 1A).

### *Cholinesterase in serum*

Cholinesterase (CHE) in serum was decreased in the untreated group at pP0´and pP30` compared to LAP while levels of CHE were significantly increased at both time points in LA-treated patients compared to controls (Figure 1B).

### *AST/ALT in serum*

After opening the abdomen AST levels in serum were low in both groups. After 30 min of ischemia, at 30 min of reperfusion, as well as at days 1-3 after the operation (peak level) the value increased in the untreated patients. In the LA-pretreated group we measured significantly lower levels of AST at each time point (Figure 2A). AST and ALT levels in both groups reached baseline values until discharge (Figure 2B). Total bilirubin (tBIL) and glucose (GC) did not differ from baseline levels neither in controls nor in LA-treated patients (data not shown).

### *ATP content in liver tissue*

After pretreatment by LA we observed significantly increased ATP content in post-ischemic liver tissue compared to the untreated group (Figure 3). During reperfusion ATP content was also increased in the LA group but did not reach statistical significance.

### *Histology/Immunhistochemistry*

Our histological findings strongly support our results regarding the enzyme release of AST and ALT. H&E-stained liver tissue of untreated patients clearly showed histomorphological features of oncocis (Figure 4). In contrast, in livers of the LA-pretreated patients features of oncocis were rare. We observed TUNEL-positive hepatocytes after 30 min of ischemia (pP0´) in the

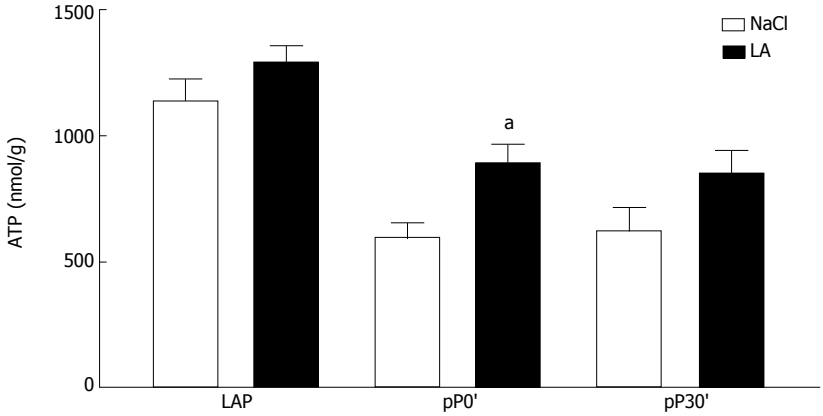

**Figure 3** ATP-content in liver tissue after laparotomy (LAP), after 30 min of ischemia (pP0´) and after 30 min of ischemia with 30 min of reperfusion (pP30´) with and without 600 mg LA 15 min prior to ischemia, values as means ± SD, $n$ = 12 each group, $^{a}P < 0.05$ *vs* NaCl.

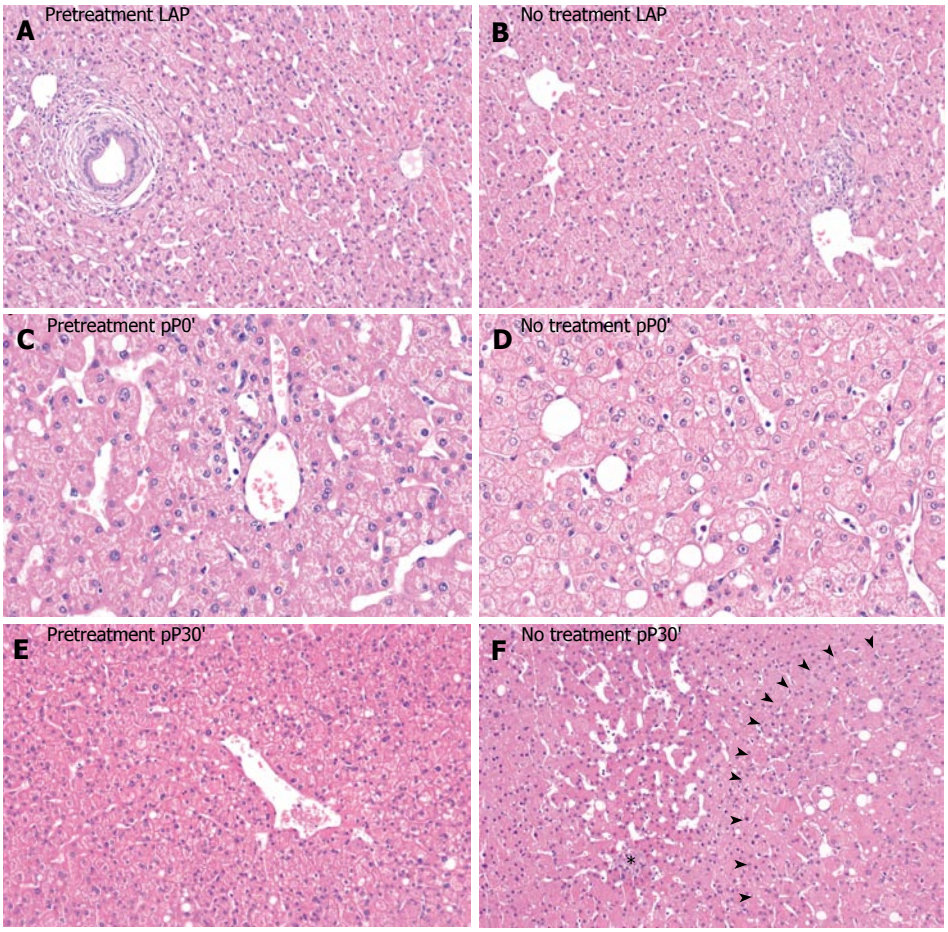

**Figure 4** Representative liver sections after laparotomy (LAP), after 30 min of ischemia (pP0') and after 30 min of ischemia with 30 min of reperfusion (pP30') with and without 600 mg LA 15 min prior to ischemia, (HE× 200-400). **A**, **B**: In both groups no features of cell injury after LAP; **C**, **D**: At pP0' there was a mild oncotic injury in the untreated and pretreated group such as hepatocytes swelling and vacuolization; **E**, **F**: At pP30' oncotic injury was increased especially in the untreated group (**F**): there were areas with focal necrosis (asterisk) and areas with eosinophilia and oncosis (arrows). In the LA pretreated group oncotic cell injury was rare (**E**).

untreated group as well as at pP30`. In the LA-pretreated group TUNEL-positive hepatocytes were significantly reduced (Figure 5).

## DISCUSSION

Our data strongly support the hypothesis that LA reduces hepatic IRI in humans after inflow occlusion and liver resection. The protection is facilitated by preservation of ATP levels in liver tissue and characterized by reduced apoptotic hepatocyte injury upon LA preconditioning.

LA is established in the therapy of diabetic polyneuropathy[14]. It is a safe substance without serious side effects. Although LA is known to increase blood sugar utilization[12] we did not observe any changes in blood sugar during our study after LA administration (data not shown). LA predominantly undergoes β-oxidation and methylation in the liver which is why it is subjected to a high hepatic extraction[15].

Until now there is a lack of clinical trials that describe pharmacological preconditioning of the liver to protect against IRI. Moreover, established strategies, such as IP, lose their potential in patients with age over 60 years or in cases of high volume liver resection[6]. Our current pilot study points to LA as a potential strategy to protect against hepatic IRI of the liver. We observed histomorphological increased features of oncosis in the non-treated group accompanied by significantly increased levels of enzyme

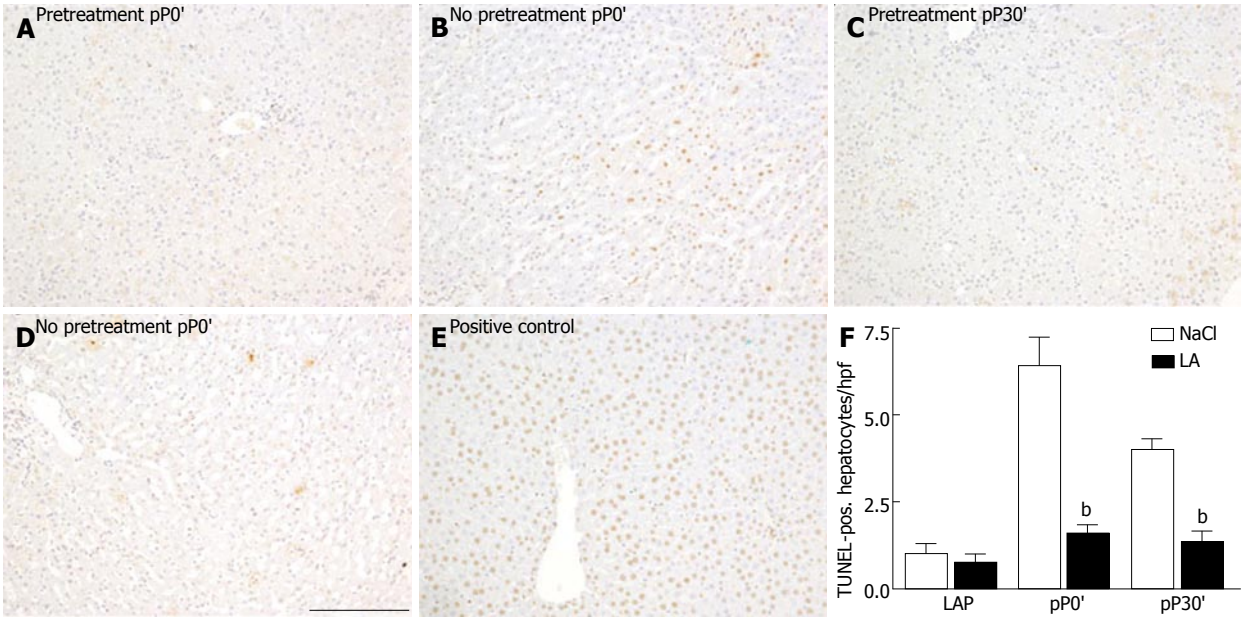

**Figure 5** Representative liver sections stained with TUNEL assay after 30 min of ischemia (pP0') and after 30 min of reperfusion (pP30') with and without 600 mg LA 15 min prior to ischemia. Positive control was prepared from liver-tissue samples by treating with DNase I in accordance with manufactures guidelines (**E**). After LAP TUNEL-positive hepatocytes were rare (data not shown). We observed TUNEL-positive hepatocytes in the untreated group at pP0' and at pP30' (**B**, **D**) while TUNEL staining was decreased in the LA pretreated group at the same time point (**A**, **C**); **F**: TUNEL-positive hepatocytes after laparotomy (LAP), after 30 min of ischemia (pP0') and after 30 min of reperfusion (pP30') with and without 600 mg LA 15 min prior to ischemia, values as means ± SD, $n = 5$ each group, $^{b}P < 0.01$ *vs* vehicle (NaCl) group.

release into plasma. Interestingly, hepatocyte injury clearly occurs in the course of ischemia as it has previously been shown in experimental animal studies[16]. This finding supports the necessity for interventions against IRI to begin *before* the onset of ischemia. Strategies that concentrate on reperfusion of the liver, such as glutathione, may not be sufficient because the initial damage has already started[17].

The clamping period was set exactly at 30 min. This period is the shortest ischemic time associated with elevated transaminase levels after surgery[11]. The lack of significant effects of pretreatment by LA on patient outcome and other parameters of hepatic injury may be related to this short period of ischemia. On the other hand we could demonstrate that LA improves cholinesterase activity in serum. Former studies have shown increased activity of cholinesterase and liver function in patients with compensated liver cirrhosis after LA treatment[18]. We therefore suggest that LA pretreatment also protects against IRI in patients with liver disease, such as cirrhosis or steatosis.

The detailed mechanism of action of LA remains speculative. We observed increased levels of ATP in liver tissue in the LA group accompanied by improved liver histology. One possible explanation for this result may be the known potential of LA to reform vicinal thiol groups in the ATP synthase. Dithiols have been shown to form disulfide bridges during ischemia/reperfusion. ATP synthesis occurs only if the dithiols between the $F_1$ and the $F_0$- part of the enzyme remain functional[19]. Since ATP depletion is known to induce cellular swelling and other features of oncotic and necrotic cell injury[20], LA might decrease hepatic injury by increased levels of ATP.

We observed that LA decreases apoptotic related cell death. The influence of apoptotic cell death on IRI of the liver in humans has been described[4]. The underlying mechanism of LA to reduce apoptotic related cell death was not within the scope of this study. However, results of our studies in rats showed that LA influences pro- and anti-apoptotic proteins towards the anti-apoptotic Bcl-2 (unpublished data). LA might therefore improve expression of anti-apoptotic proteins, such as Bcl-2 but there is a need for respective investigations in the clinical setting.

In summary, we report for the first time the protection of hepatic IRI after liver surgery and hepatic inflow occlusion by a single infusion of LA 15 min prior to ischemia. This strategy might represent a cost effective, safe and efficient strategy to attenuate ischemia reperfusion injury of the liver in the clinical setting.

## Abstract

**AIM:** To explore whether a co-culture of cynomolgus monkey embryonic stem (cES) cells with embryonic liver cells could promote their differentiation into hepatocytes.

**METHODS:** Mouse fetal liver-derived cells (MFLCs) were prepared as adherent cells from mouse embryos on embryonic d (ED) 14, after which undifferentiated cES cells were co-cultured with MFLCs. The induction of cES cells along a hepatic lineage was examined in MFLC-assisted differentiation, spontaneous differentiation, and growth factors (GF) and chemicals-induced differentiations (GF-induced differentiation) using retinoic acid, leukemia inhibitory factor (LIF), FGF2, FGF4, hepatocyte growth factor (HGF), oncostatin M (OSM), and dexamethasone.

**RESULTS:** The mRNA expression of α-fetoprotein, albumin (ALB), α-1-antitrypsin, and hepatocyte nuclear factor 4α was observed earlier in the differentiating cES cells co-cultured with MFLCs, as compared to cES cells undergoing spontaneous differentiation and those subjected to GF-induced differentiation. The expression of cytochrome P450 7a1, a possible marker for embryonic endoderm-derived mature hepatocytes, was only observed in cES cells that had differentiated in a co-culture with MFLCs. Further, the disappearance of Oct3/4, a representative marker of an undifferentiated state, was noted in cells co-cultured with MFLCs, but not in those undergoing spontaneous or GF-induced differentiation. Immunocytochemical analysis revealed an increased ratio of ALB-immunopositive cells among cES cells co-cultured with MFLCs, while glycogen storage and urea synthesis were also demonstrated.

**CONCLUSION:** MFLCs showed an ability to induce cES cells to differentiate toward hepatocytes. The co-culture system with MFLCs is a useful method for induction of hepatocyte-like cells from undifferentiated cES cells.

**Key words:** Primate embryonic stem cells; Fetal liver; Hepatic differentiation; Co-culture

## INTRODUCTION

Embryonic stem (ES) cells are self-renewing, pluripotent cells derived from the inner cell masses of preimplantation blastocysts[1,2]. They can be expanded without limit and retain a potential to differentiate into various somatic cell types of the three germ layers. We previously reported the differentiation of mouse ES (mES) cells into insulin-producing cells[3,4], intestinal tract-related cells[5], dopamine-producing cells[6], photoreceptor-like cells[7], and hepatocytes[8-10].

Several of the characteristics of mES and primate ES cells are different[11-13]. To better understand the differentiation ability and therapeutic potential of human ES (hES) cells, the use of primate ES cells is indispensable. Although the differentiation of hepatocyte-like cells from hES cells has also been reported by some researchers, the use of hES cells for basic and clinical research is regulated in many countries, because of bio-ethical issues. Thus, monkey ES cells might be useful as a substitute model for basic and preclinical research using hES cells.

Herein, we report promoted differentiation of cynomolgus monkey ES (cES) cells into hepatocyte-like cells by use of a co-culture system with mouse

fetal liver-derived cells (MFLCs). The expression of α-fetoprotein (AFP) mRNA expression was not observed until d 21 and 14 in spontaneous and growth factor (GF)-induced differentiations, respectively, and that of cytochrome P450 7a1 (CYP7A1), a possible marker of embryonic endoderm-derived mature hepatocytes[14], was undetectable even on d 28 in both cultures. Further, Oct3/4, a marker of an undifferentiated state, never disappeared throughout the experimental period. In contrast, in the present study of cES cells that were co-cultured with MFLCs on a membrane with 0.4-μm sized pores, the expressions of AFP, albumin (ALB), hepatocyte nuclear factor 4α (HNF4α), and CYP7A1 were detected as early as d 10, while the expression of Oct3/4 was detected only faintly on d 14 and not at all by d 21. Immunocytochemical analysis revealed an increased ratio of ALB-immunopositive cells among cES cells co-cultured with MFLCs, while glycogen storage and urea synthesis were also demonstrated.

These results show that MFLCs provide a conductive environment for the differentiation of cES cells toward hepatocyte-like cells, and suggest that the present co-culture system of cES cells with MFLCs may be useful for preparation of a cell replacement source that is rich with hepatocyte-like cells and does not retain undifferentiated cES cells.

## MATERIALS AND METHODS

### *Cynomolgus monkey ES cells*

A cynomolgus monkey ES (cES) cell line (CMK6) was obtained from Asahi Techno Glass Corp., Chiba, Japan[15]. Undifferentiated cES cells were maintained on a feeder layer of 40 Gy-irradiated mouse embryonic fibroblasts (MEF) in DMEM/F-12 (Asahi Techno Glass Corp.), supplemented with 20% Knockout Serum Replacement (KSR; GIBCO-Invitrogen, Carlsbad, CA, USA), 0.1 mmol/L 2-mercaptoethanol, 1 mmol/L sodium pyruvate, 2 mmol/L L-glutamine, 0.1 mmol/L nonessential amino acids, and a mixture of penicillin (25 U/mL) and streptomycin (25 μg/mL). The medium was changed daily. Cell colonies composed of closely packed cells were split every 3-4 d by incubation in a 0.25% trypsin-EDTA solution for 5 min at 37℃ before transfer by pipetting onto the 40-Gy-irradiated MEF cells.

### *Preparation of mouse fetal liver-derived cells (MFLCs)*

Embryonic liver tissues were collected from C57BL/6CrSlc mice (E14.0) and minced, then dissociated in 0.1% trypsin-EDTA solution for 20 min at 37℃ followed by hemolysis with hypotonic buffer. Dissociated cells were suspended in culture media composed of DMEM supplemented with 10% fetal calf serum (FCS), 2 mmol/L L-glutamine, 1x non-essential amino acid solution, and a mixture of penicillin (25 U/mL) and streptomycin (25 μg/mL), after which $1 \times 10^7$ cells were plated onto a 0.1% gelatin-coated tissue culture dish sized 100 mm in diameter. After 24 h, contaminating hematopoietic cells and cell debris were removed by extensive washing with culture media, and the adherent cells were then cultured for 48 h to reach the confluent growth stage.

### *Spontaneous and GF-induced differentiation of cES cells*

Spontaneous differentiation of undifferentiated cES cells was carried out as follows. Undifferentiated cES colonies were incubated with a 0.25% trypsin-EDTA solution for 5 min at 37℃, which obtained clusters of closely packed cells. Approximately $1 \times 10^6$ of these cells were then cultured in a 60-mm dish in DMEM supplemented with 10% FCS, 2 mmol/L L-glutamine, and 1 × non-essential amino acid solution (DMEM basic medium) for 28 d without any defined chemical factors (Figure 1A). The medium was exchanged with fresh medium every 2-3 d.

For GF-induced differentiation toward hepatocyte-like cells, undifferentiated cES cells were treated stepwise with combinations of defined chemicals and growth factors, according to a method reported previously[16], with some modifications. Approximately $1 \times 10^6$ undifferentiated cES cells, prepared as cellular clusters by enzymatic digestion of undifferentiated cES colonies, were seeded in a 60-mm dish and cultured in DMEM basic medium containing leukemia inhibitory factor (LIF, 100 units/mL; GIBCO BRL, Rockville, MD, USA) and $10^{-8}$ mol/L all-trans retinoic acid (RA; Sigma) for 3 d. The cells were passaged in DMEM basic medium containing fibroblast growth factor 2 (FGF2, 10 mg/L; Genzyme/Techne, Minneapolis, MN, USA), FGF4 (20 mg/L, Genzyme/Techne), hepatocyte growth factor (HGF, 25 mg/L; Genzyme/Techne), and Oncostatin M (OSM, 10 mg/L; Genzyme/Techne). After 5 d, the cells were further cultured in DMEM basic medium containing $10^{-7}$ mol/L dexamethasone (Dex; Sigma), 0.2 mmol/L L-ascorbic-2-phosphate (AP; Wako, Osaka, Japan), and 10 mmol/L nicotinamide (NA; Sigma) until d 28 (Figure 1B).

### *Co-culture of cES cells with MFLCs*

MFLCs showing confluent growth were digested with a 0.25% trypsin-EDTA solution for 5 min at 37℃. One million undifferentiated cES cells, prepared as cell clusters by enzymatic digestion of undifferentiated cES colonies, were co-cultured in a 60-mm dish with the same number ($1 \times 10^6$) of MFLCs in a 35-mm culture insert across a 0.4-μm Millicell CM membrane (Millipore Corp., Bedford, MA USA) for 28 d (Figure 1C). A half volume of medium in the 60-mm dish was discarded with floating cells and replaced with fresh medium every 2 d.

### *RT-PCR*

For RNA extraction and RT-PCR analysis, total RNA was purified using Trizol (Invitrogen) following the protocol of the manufacturer. One microgram of DNase-treated total RNA was used for the first-strand cDNA reaction, which was performed using a random primer (Invitrogen) and M-MLV reverse transcriptase (Promega, Madison, WI, USA). cDNA samples were subjected to PCR amplification with specific primers. The cycling parameters were as follows; denaturation at 94℃ for 1 min, annealing at 55℃-60℃ for 1 min (depending on the primer), and elongation at 72℃ for 1 min (40 cycles). The PCR primers and length of the amplified products are shown in Table 1.

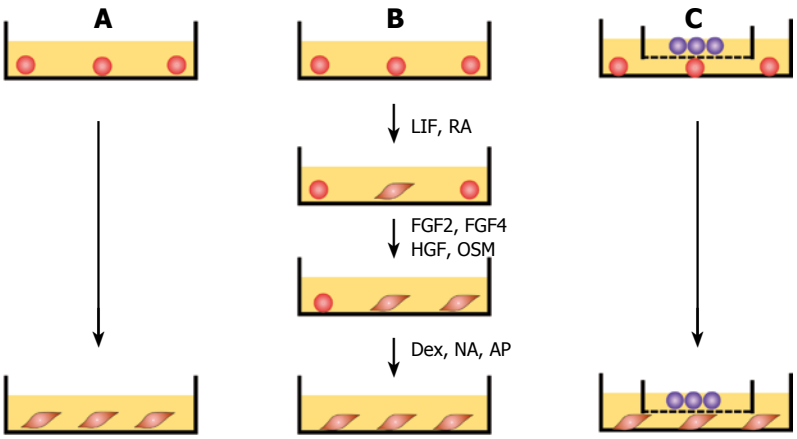

**Figure 1** Protocol for differentiation of cES cells. **A:** Spontaneous differentiation. Undifferentiated cES cells were cultured in gelatin-coated dishes in DMEM basic medium for 28 d without additional feeders or growth factors; **B:** GF-induced differentiation. Undifferentiated cES cells were cultured in DMEM basic medium containing LIF (100 units/mL) and RA ($10^{-8}$ mol/L) for 3 d, followed by a 5-d culture in DMEM basic medium containing FGF2 (10 mg/L), FGF4 (20 mg/L), HGF (25 mg/L), and OSM (10 mg/L). Thereafter, the cells were cultured for 20 d in DMEM basic medium containing $10^{-7}$ mol/L dexamethasone (Dex), 0.2 mmol/L, L-ascorbic-2-phosphate (AP), and 10 mmol/L nicotinamide (NA); **C:** Promoted differentiation by co-culture with MFLCs. Undifferentiated cES cells were plated onto 60-mm dishes and co-cultured with MFLCs in a 35-mm culture insert across a 0.4-μm Millicell CM membrane for 28 d.

### *In vitro immunofluorescence analysis*

Immunofluorescence analysis was carried out using standard protocols. Briefly, the cells were fixed in 4% paraformaldehyde and incubated with cell specific marker antibodies in blocking serum at 4℃ overnight. After incubation in species-specific IgG conjugated with Alexa Fluor 488 (donkey anti-sheep IgG; Invitrogen) or RITC (goat anti-mouse IgG; Biomeda Foster City, CA, USA), the cells were washed with PBS and examined under a microscope. All nuclei were stained with DAPI (Dojindo, Kumamoto, Japan). The primary antibodies and dilutions used were as follows: sheep polyclonal anti-human ALB (Biomeda), 1:100; mouse monoclonal anti-human AFP (Biomeda), 1:100; rabbit polyclonal anti-human HNF4α (Santa Cruz Biotechnology, Santa Cruz, CA, USA), 1:100; and mouse monoclonal anti-human alpha-1 antitrypsin (Biomeda), 1:100.

To examine the immunological similarities between

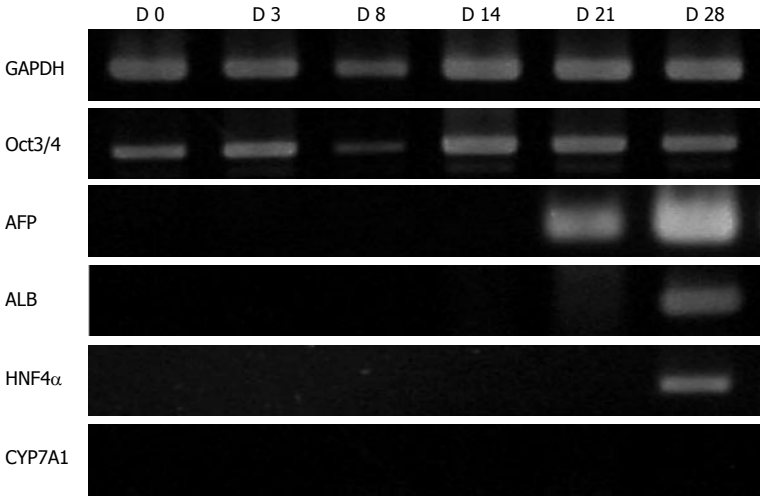

**Figure 2** RT-PCR analysis of spontaneous differentiation of cES cells. AFP mRNA expression was not observed prior to d 14, while ALB was detected on d 21. On d 28, ALB and HNF4α expression became detectable. CYP7A1 was not detected throughout the experimental period, while Oct3/4 was distinctly detected at all time points.

cES-derived hepatocyte-like cells and human hepatocytes, a monoclonal antibody mouse anti-human hepatocyte clone OCH1E5 (HepPar1; DAKO) was used[17,18]. HepPar1 reacts with both normal and neoplastic hepatocytes, but not with cholangiocytes.

In some experiments, cultured cES cells were trypsinized into single cells in suspension. After reattachment to the culture dish by an overnight culture, the cells were subjected to immunofluorescence analysis to determine the ratio of ALB-immunopositive cells. The numbers of total cells and ALB-immunopositive cells in 3 different microscopic fields were then counted.

### *Periodic acid Schiff (PAS) staining*

Staining of glycogen was performed using a PAS reaction. For negative controls, fixed cells in 4% paraformaldehyde were treated with 1 mg/mL of α-amylase (3000 U/mg protein, Sigma) in 0.1 mol/L sodium phosphate buffer (pH 6.2) at 37℃ for 30 min before PAS staining.

### *Measurement of urea*

To examine urea synthesis, cES cells were subjected to spontaneous, GF-induced, or MFLC-co-cultured differentiation for 14 and 28 d. Then they were incubated in serum-free α-MEM medium in the presence of ammonium chloride (20 mmol/L) for 60 min. The level of urea nitrogen in the incubation medium was determined using a colorimetric assay (Determiner LUN kit, Kyowa Medix, Tokyo), after removal of endogenous ammonium by treatment with glutamate dehydrogenase.

### *Analysis*

For qualitative analysis, all cES differentiation experiments were performed in duplicate and repeated. $P < 0.05$ was taken as significant.

## RESULTS

### *Spontaneous differentiation of cES cells*

Undifferentiated cES cell clusters were cultured in basic DMEM for 28 d and differentiation toward hepatocyte-like cells was analyzed by RT-PCR (Figure 2). AFP mRNA expression was not observed until d 14, while ALB remained undetectable on d 21. On d 28, ALB and HNF4α were both detected, whereas CYP7A1 was never detected throughout the experimental period. Further, immunocytochemical results demonstrated that ALB-immunopositive cells on d 28 comprised fewer than 1% of the total cultured cells. The expression of Oct3/4, a marker of an undifferentiated state, was distinctly detected throughout the experimental period.

### *GF-induced differentiation toward hepatocyte-like cells*

Efficient induction of mouse ES cells into hepatocyte-like cells by sequential treatments with defined chemicals and without the use of embryoid bodies (EBs) has been reported[16]. Therefore, we applied that method to the present cES cells with some modifications. Undifferentiated cES cells were first treated with RA and LIF for 3 d, followed by 5 d of treatment with FGF2, FGF4, and HGF, and finally subjected to culture medium containing OSM and Dex.

AFP mRNA expression was not detected following the 3-d treatment with RA and LIF (Figure 3, lane D3), and was faintly detected on d 8 at the end of the 5-d treatment with FGF2, FGF4, and HGF (Figure 3, lane D8). Further, the expression of ALB and HNF4α became detectable after the differentiating cES cells were exposed to OSM and Dex (Figure 3, lanes D14, D21 and D28). Although ALB and HNF4α were clearly detected on d 21 and 28, no expression of CYP7A1 was observed. The immunocytochemical results demonstrated that about 7.2% ± 0.7% of the cultured cells were ALB-immunopositive on d 28. As for the presence of undifferentiated cES cells, Oct3/4 mRNA was still detected in the differentiating cES cells on d 28 of the induction culture oriented for hepatocyte-like cells.

### *Characterization of mouse fetal liver-derived cells (MFLCs)*

Although the cES cells that underwent GF-induced differentiation into hepatocyte-like cells showed an accelerated gene expression pattern as compared to those that underwent spontaneous differentiation, the prolonged detection of Oct3/4 mRNA and lack of CYP7A1 expression in both spontaneous and GF-induced differentiations suggested the presence of undifferentiated

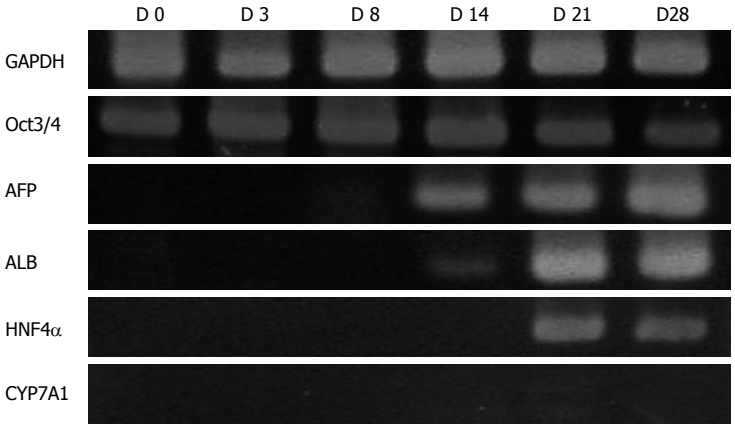

**Figure 3** RT-PCR analysis of GF-induced differentiation of cES cells. AFP mRNA expression was not detected following a 3-d treatment with RA and LIF, though it was detected on d 8, and at the end of 5 d of treatment with FGF2, FGF4, and HGF. ALB and HNF4α were detected after the differentiating cES cells were exposed to OSM and Dex. Although ALB and HNF4α were strongly detected on d 21 and 28, no expression of CYP7A1 was observed. Oct3/4 mRNA expression remained up to d 28.

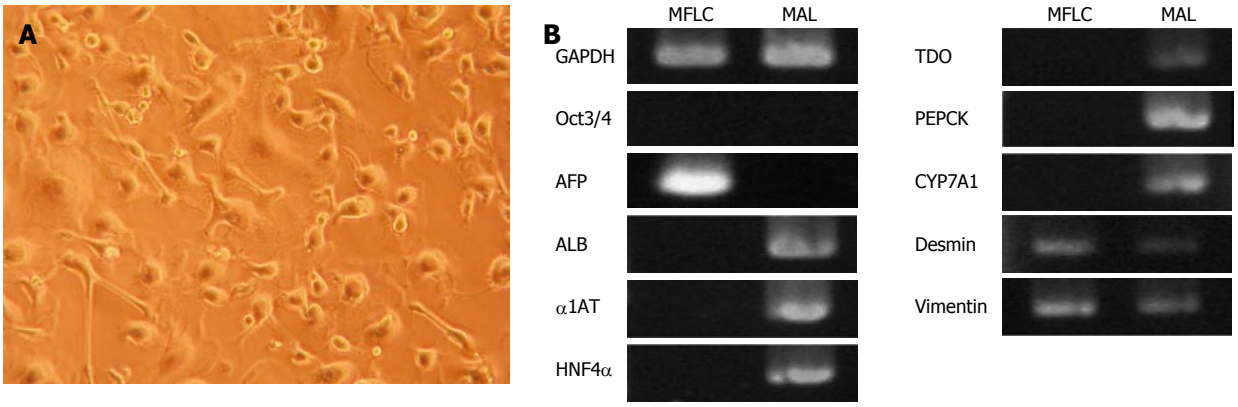

**Figure 4** Characterization of MFLCs. **A:** Optical microscope image of MFLCs (× 100). MFLCs were prepared from E14.0 mouse livers and cultured for 48 h. After the floating cell fraction was discarded from the culture, resting adherent cells were further cultured until semi-confluent. MFLCs showed various morphologies, including cuboidal and stellate-shaped cells; **B:** RT-PCR analysis of MFLCs. AFP, desmin, and vimentin were expressed, whereas ALB was not. MAL: Mouse adult liver cells.

cES cells and insufficient differentiation into mature hepatocyte-like cells, respectively. We performed a co-culture of cES cells with MFLCs to search for epigenetic cues for the *in vitro* differentiation of cES cells toward hepatocyte-like cells. However, before performing that co-culture experiment, we examined the characteristics of MFLCs.

MFLCs were derived from E14.0 mouse livers and prepared as adherent cells by removal of the floating cell fraction from the culture of dissociated liver cells. They showed various morphologies, including cuboidal and stellate-shaped cells (Figure 4A). RT-PCR analysis demonstrated a distinctly different expression pattern as compared to that of adult liver tissues (Figure 4B). The MFLCs expressed AFP mRNA, but not ALB or other markers for differentiated hepatocytes, suggesting the presence of fetal hepatocytes. Further, the expressions of desmin and vimentin suggested the co-existence of cell types different from fetal hepatocytes, such as stellate cell-like cells, in accordance with the presence of cells with various shapes.

### *Promoted differentiation by co-culture with MFLCs*

Undifferentiated cES cells were co-cultured with MFLCs across a membrane with 0.4-μm sized pores for 28 d and the gene expression of the differentiating cES cells were analyzed (Figure 5). There was no expression of AFP, ALB, or HNF4α detected in the differentiating cES cells on d 7, however, each was detectable within the next few days and all by d 10, which remained throughout the experimental period. Further, CYP7A1 mRNA expression, which was undetectable in the spontaneous and GF-induced differentiated cES cells, was observed on d 10. Immunocytochemical results demonstrated a high ratio of ALB-immunopositive cells (28.6% ± 4.2% as early as d 14), though the ratio did not greatly increase throughout the culture period (32.8% ± 5.6% on d 28). Despite the prompt induction of ALB mRNA, AFP mRNA was detected throughout the experimental period, suggesting an incapability of full maturation by the entire fraction of cES-derived hepatocyte-like cells by MFLCs alone. The expression pattern of Oct3/4 in cES cells co-cultured with MFLCs was quite different from that of cES cells subjected to spontaneous or GF-induced differentiation, as Oct3/4 mRNA, which never disappeared in the spontaneous and GF-induced differentiation experiments, was detected only faintly on d 14 and became undetectable by d 21. Without MFLCs on the Millicell CM membrane, no promoted differentiation of cES cells was observed.

### *Immunocytochemical analysis*

cES cells differentiated in the co-culture with MFLCs were examined immunocytochemically on d 28 (Figure 6). Immunopositive reactions to AFP, ALB, and α1-AT

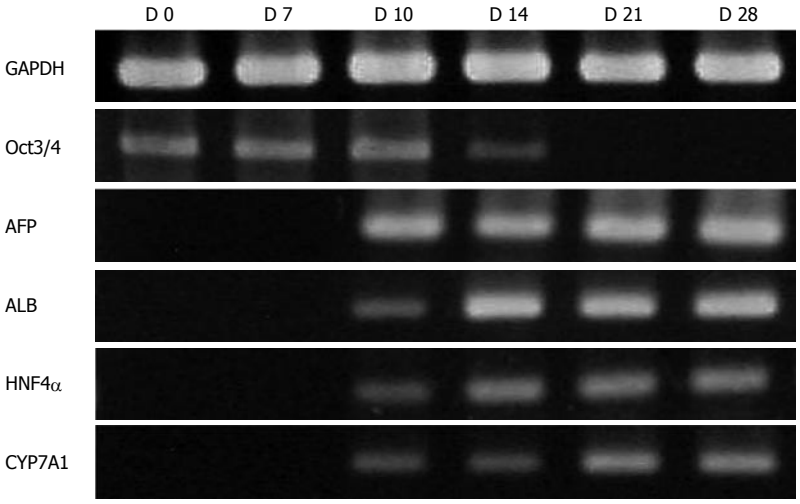

**Figure 5** RT-PCR analysis of cES cells co-cultured with MFLCs. cES cells co-cultured with MFLCs across a membrane with 0.4-μm sized pores for 28 d were analyzed. AFP, ALB, HNF4α, and CYP7A1 mRNA expression was detected on d 10. Oct3/4 expression was faint on d 14 and disappeared by d 21.

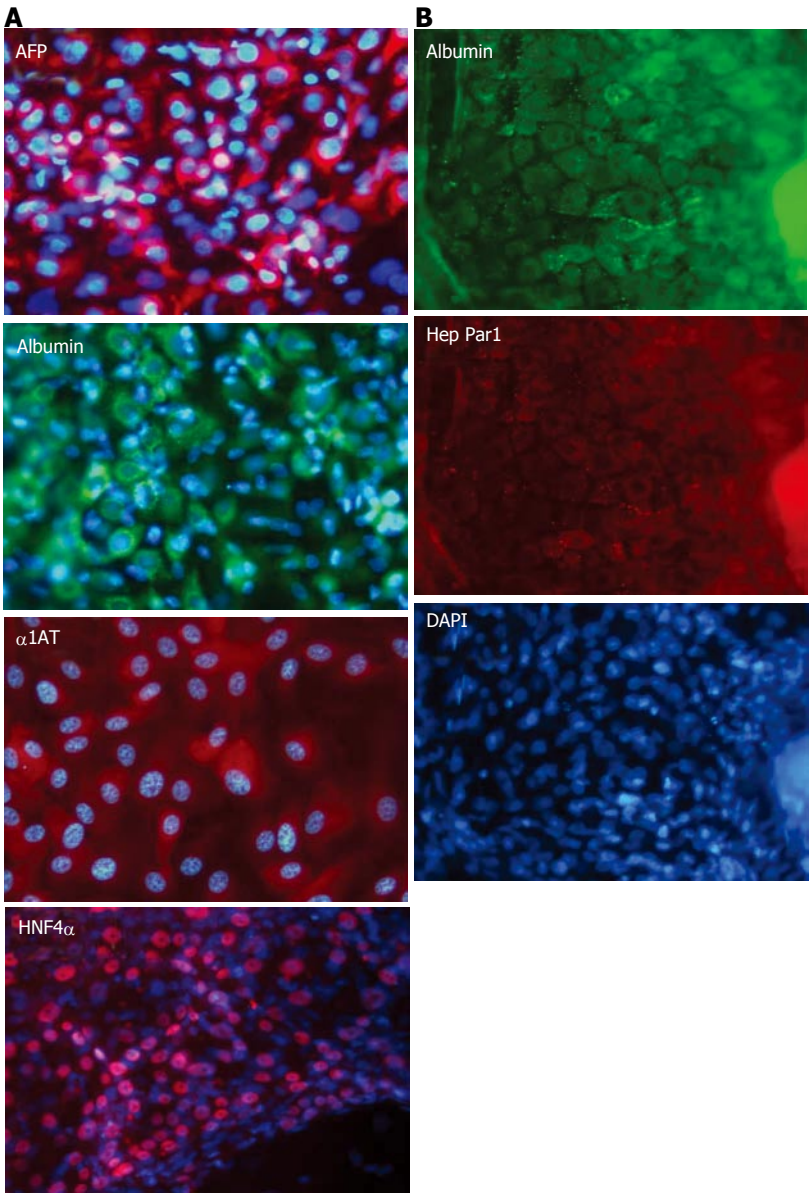

**Figure 6** Immunocytochemical analysis of cES cells co-cultured with MFLCs. **A:** After being co-cultured with MFLCs for 28 d, cES cells were immunostained with anti-AFP, anti-ALB, anti-alpha-1-antitrypsin, and anti-HNF4α antibodies; **B:** Immunoreactivity to the anti-human hepatocyte antibody Hep Par1 was shown by the albumin-positive cells. Original magnification × 100.

were demonstrated as scattered colonized foci among the adherent cells. Representative areas of immunopositive distribution are shown in Figure 6A. In addition, HNF4α, an important transcription factor for mature hepatocytes, was also clearly detected in the cES cells co-cultured with MFLCs. We also examined immunoreactivity to the anti-human hepatocyte antibody Hep Par1. Cells immunopositive for human-albumin were also

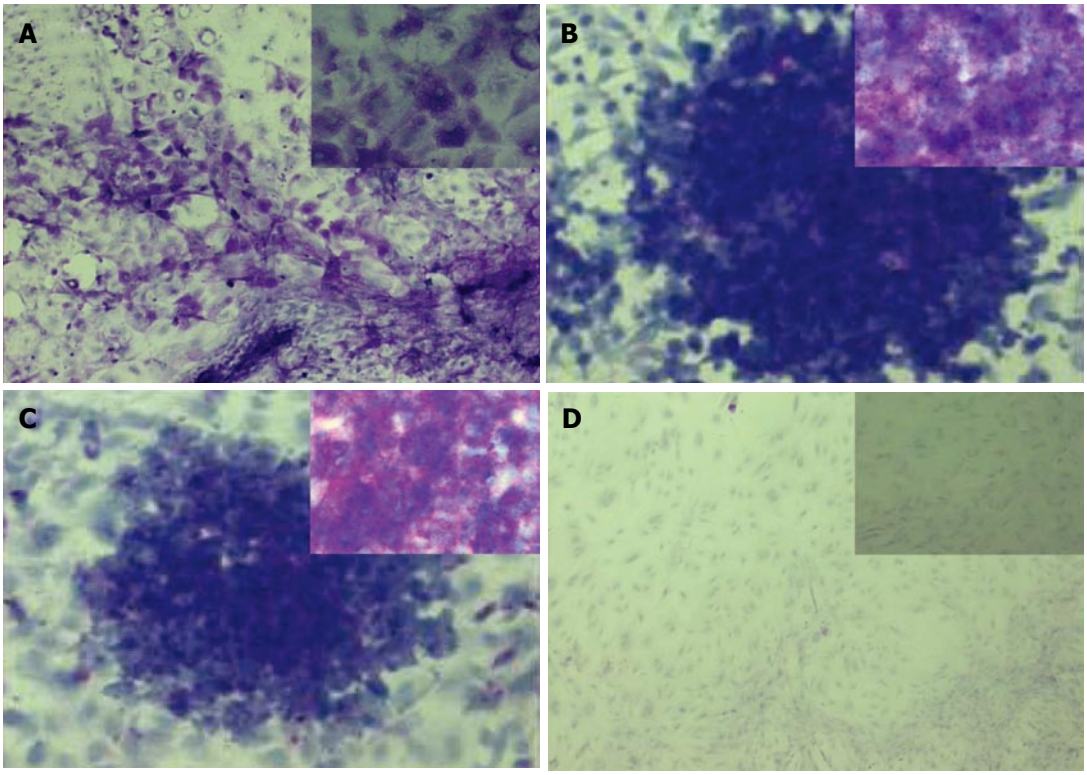

**Figure 7** Histochemical staining of glycogen. Periodic acid Schiff (PAS) staining was performed on cES cells co-cultured with MFLCs for 28 d (**A**) and undifferentiated cES cells (**B**), as well as those following treatment with α-amylase (**C** and **D**, respectively). Both the undifferentiated cES cells and those co-cultured with MFLCs showed violet staining (**A, B**). Violet staining was apparent in the undifferentiated cES cells (**C**), while such staining did not appear in the differentiated cES cells pretreated with α-amylase(**D**). Original magnification ×100 (**A-D**), × 400 (insets in **A-D**).

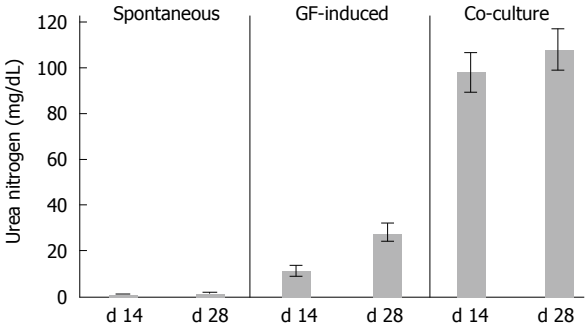

**Figure 8** Urea synthesis by differentiated cES cells. The level of urea nitrogen in the culture medium of cES cells cultured with MFLCs was greater than that in the medium of cES cells subjected to GF-induction, though amounts of urea synthesized by cES cells co-cultured with MFLCs scarcely increased from d 14 to 28. Spontaneously differentiated cES cells showed nearly no ability to synthesize urea.

immunopositive for Hep Par1 (Figure 6B).

### *Presence of glycogen in differentiated cES cells co-cultured with MFLCs*

We performed PAS staining of undifferentiated cES cells and cES cells co-cultured with MFLCs to examine whether glycogen was stored, and both showed violet colored stains (Figure 7A and 7B). Similar staining results were obtained with undifferentiated cES cells pretreated with α-amylase (Figure 7C), while such staining did not appear following pretreatment with α-amylase in the differentiated cES cells co-cultured with MFLCs (Figure 7D). These results suggest that undifferentiated cES cells have an α-amylase-insensitive carbohydrate, while cES cells differentiated by MFLCs have an α-amylase-sensitive carbohydrate, which is probably glycogen.

### *Urea synthesis in differentiated cES cells co-cultured with MFLCs*

We also examined ammonia metabolization in cES cells subjected to spontaneous, GF-induced, and MFLC-assisted differentiation after 14 and 28 d (Figure 8). The urea nitrogen level in the medium from cES cells co-cultured with MFLCs showed a high level as compared to that from cES cells under GF-induction. In a comparison between the levels on d 14 and 28, the amount of synthesized urea in cES cells co-cultured with MFLCs did not increase significantly. Further, spontaneously differentiated cES cells showed nearly no synthesized urea.

## DISCUSSION

A number of studies have investigated the differentiation of mouse and human ES cells into hepatocyte-like cells[8-10,14,16,19-32]. In general, the methods used in those studies can be divided into spontaneous and directed differentiation. For spontaneous differentiation, the formation of EBs has been mostly utilized[8,14,19-23]. As for directed differentiation, a process of enrichment of a specific differentiated cell type that uses elements to promote the differentiation of ES cells into an endodermal lineage, such as the addition of growth factors (GFs) and hormones[16,24-31], and the constitutive expression of hepatic transcription factors[9,10,32], has been utilized.

In the present study, we used MFLCs to promote the differentiation of cES cells into hepatocyte-like cells. We co-cultured undifferentiated cES cells with MFLCs across a membrane with 0.4-μm sized pores and found early expression of AFP, ALB, and HNF4α mRNA, as compared to cES cells subjected to non-EB-mediated spontaneous or GF-induced differentiation. Further, the

expression of CYP7A1 was detected in MFLC-assisted differentiated cES cells, but not in those undergoing non-EB-mediated spontaneous or GF-induced differentiation. In mice, CYP7A1 has been reported to be expressed in the liver, but not in yolk sac tissues[14], and suggested to be a definitive marker for endoderm-derived mature hepatocytes. The detection of CYP7A1 in the present cES cells co-cultured with MFLCs seems to indicate the usefulness of MFLCs in induction toward hepatocytes, though it has not been concluded whether CYP7A1 is a suitable marker for hepatocytes in primate cells.

We confirmed the promoted differentiation of cES cells along a hepatic lineage by immunocytochemistry. The ratio of ALB-immunopositive cells on d 28 was significantly higher with MFLC-assisted differentiation (32.8%) than non-EB-mediated spontaneous (less than 1%) or GF-induced (7.2%) differentiation. Similarly, cells immunopositive for alpha 1 antitrypsin and HNF4α were more abundant among those subjected to MFLC-assisted differentiation (data not shown). We further examined an immunoreactivity of differentiated cES cells to HepPar1. Although the target antigen recognized by HepPar1 has not been identified, HepPar1 is known to react in a restricted manner to adult and fetal human hepatocytes[17,18]. We found that the cES cells immunopositive to human-albumin were also immunopositive to Hep Par1, suggesting that cES-derived hepatocyte-like cells are immunologically very similar to human hepatocytes.

Both glycogen storage and ammonia metabolization are representative functions of hepatocytes. Periodic acid-Shiff (PAS) staining detected glycogen as α-amylase-sensitive carbohydrate in the cES cells differentiated by MFLCs. Although the undifferentiated cES cells were stained violet by PAS staining, they seemed to produce α-amylase-insensitive carbohydrate, not glycogen, which was in accordance with our previous observation of PAS staining of mES cells and mES-derived hepatocyte-like cells[10]. As for the ability to metabolize ammonia, the cES cells co-cultured with MFLCs produced urea more abundantly than those subjected to GF-induced differentiation.

We also evaluated the presence of undifferentiated cES cells among the differentiating cES cells by examining the mRNA expression of Oct3/4. In contrast to the continuous and stable detection of Oct3/4 mRNA throughout the entire 28-d experimental periods in the spontaneous and GF-induced differentiation experiments, the expression of Oct3/4 became faint on d 14 and was undetectable by d 21 in MFLC-assisted differentiation, indicating the absence of undifferentiated cES cells in cES cells co-cultured with MFLCs for more than 21 d. Since contamination by undifferentiated cES cells in transplants is critical for the development of tumors, cES cells co-cultured with MFLCs may be useful as a source rich in hepatocyte-like cells that is less risky for the development of cES-derived tumors.

The precise mechanisms by which MFLCs promote the differentiation of undifferentiated cES cells along a hepatic lineage were not investigated in the present study. However, it is known that non-parenchymal cells are required for differentiation of primitive hepatic endodermal cells and hepatoblasts into mature hepatocytes[33-38]. The MFLCs used in the present study were composed of heterogeneous cells, based on their various morphologies that showed cuboidal and stellate shapes, and on the results of PCR analysis demonstrating the expression of AFP, a hepatocyte-related marker, and desmin and vimentin, which are stellate cell-related markers. It is conceivable that the non-parenchymal cells among the MFLCs were involved in the differentiation of cES cells toward a hepatic lineage.

In the present study, MFLCs were prepared as adherent cells from E14.0 mouse fetal livers. The fetal liver is the major organ of hematopoiesis, and stromal cells there, like those in adult bone marrow, create a hematopoietic microenvironment and promote embryonic hematopoiesis[39]. Fetal liver-derived cells may also induce hematopoietic differentiation of ES cells, as in the case of stromal cells from bone marrow[40-45]. Indeed, a previous report documented the efficient induction of human ES cells into hematopoietic cells by fetal liver-derived cells[46]. In our experiments, MFLC-assisted differentiation of cES cells might have generated a number of hematopoietic cells in the culture as non-adherent floating cells, though they were removed from the culture by repeated media exchanges.

As the process of gestation proceeds from mid-gestation to birth, the fetal liver increases dramatically in size and switches to a metabolic organ from a hematopoietic organ at around the time of birth. Therefore, we anticipated that MFLCs might provide a conductive environment for cES cells to differentiate along a hepatic lineage. However, prior to starting the present experiments, we speculated that any promotion effect by MFLCs toward the hepatic differentiation of cES cells may be not distinguished or exerted only minimally. First, the species from which the cES cells and MFLCs originated were different. Further, the cES cells that were subjected to a co-culture with MFLCs were used in an undifferentiated state and they had not been previously induced toward an endoderm or hepatic lineage. Also, the undifferentiated cES cells were cultured separately from MFLCs by use of a 0.4-μm Millicell CM membrane, which did not allow direct cellular contact between the cES cells and MFLCs, and only permitted the transfer of diffusible factors. However, in contrast to our expectation, the co-culture of undifferentiated cES cells with MFLCs led to the promoted differentiation of cES cells toward a hepatic lineage. These results suggest that diffusible factors from MFLCs worked effectively in a cross-species manner on undifferentiated cES cells and seemed to be sufficient to stimulate the induction of hepatic differentiation of cES cells, though complete maturation of all cES-derived hepatocytes was not achieved, as shown by the prolonged detection of AFP mRNA throughout the experimental period.

In conclusion, the present results demonstrate that cynomolgus monkey ES cells can be induced into hepatocyte-like cells using a co-culture method with mouse fetal liver-derived cells. This co-culture system has been found to be an efficient method to obtain hepatocyte-like cells and may be useful for preparation of cellular grafts

that do not contain undifferentiated ES cells, which would provide a limited risk for the development of tumors.

## Abstract

**AIM:** To verify the impairment of the hepatic lipid metabolism in prehepatic portal hypertension.

**METHODS:** The concentrations of free fatty acids, diacylglycerol, triglycerides, and phospholipids were assayed by using D-[U-$^{14}$C] glucose incorporation in the different lipid fractions and thin-layer chromatography and cholesterol was measured by spectrophotometry, in liver samples of Wistar rats with partial portal vein ligation at short- (1 mo) and long-term (1 year) (i.e. portal hypertensive rats) and the control rats.

**RESULTS:** In the portal hypertensive rats, liver phospholipid synthesis significantly decreased (7.42 ± 0.50 *vs* 4.70 ± 0.44 nCi/g protein; $P < 0.01$) and was associated with an increased synthesis of free fatty acids (2.08 ± 0.14 *vs* 3.36 ± 0.33 nCi/g protein; $P < 0.05$), diacylglycerol (1.93 ± 0.2 *vs* 2.26 ± 0.28 nCi/g protein), triglycerides (2.40 ± 0.30 *vs* 4.49 ± 0.15 nCi/g protein) and cholesterol (24.28 ± 2.12 *vs* 57.66 ± 3.26 mg/g protein; $P < 0.01$).

**CONCLUSION:** Prehepatic portal hypertension in rats impairs the liver lipid metabolism. This impairment consists in an increase in lipid deposits (triglycerides, diacylglycerol and cholesterol) in the liver, accompanied by a decrease in phospholipid synthesis.

**Key words**: Portal hypertension; Free fatty acids; Diacylglycerides; Triglycerides; Phospholipids; Cholesterol

## INTRODUCTION

The most used experimental model to study prehepatic portal hypertension is that obtained by calibrated stenosis of the portal vein in the rat[1,2]. It has been suggested that this experimental model has a homogeneous evolution, with a narrow range of portal hypertension, degree of porto-systemic shunts and hepatic atrophy[2-4]. However, prehepatic portal hypertensive rats have a far from uniform evolution, since they can present wide variability in both the type and degree of portosystemic collateral circulation which is developed[5] as well as in the degree of liver atrophy[5,6].

The different evolution of hepatic weight in rats with prehepatic portal hypertension is an interesting finding, since it demonstrates the existence of a heterogeneous hepatic response in this experimental model. A previous histological study of the liver was performed in order to verify whether the existence of a liver disease could justify this wide spectrum of liver weight. This study demonstrated that prehepatic portal hypertension in the rat produces fatty infiltration of the liver. Moreover, this fat accumulation in hepatocytes progresses from a short-term (1 mo) to a long-term (1 year) evolutive stage of portal hypertension[7].

In order to study hepatic lipid metabolism in these evolutive stages of experimental prehepatic portal hypertension, we determined the concentrations of free fatty acids (FFA), diacylglycerides (DG), triglycerides (TG),

phospholipids (PL) and cholesterol (Ch) in the liver of the rats with calibrated stenosis of the portal vein, both after short-term (1 mo) and long-term (1 year) evolution.

## MATERIALS AND METHODS

Male Wistar rats, weighing 250-300 g, were obtained from the *Vivarium* of the Complutense University of Madrid. The animals were anesthetized by im injection of ketamine (100 mg/kg) and xylacine (12 mg/kg). The animals were fed standard laboratory rodents' diet (rat/mouse AO4 maintenance diet: 17.6% proteins, 43.3% starch 2.5% lipids, Panlab, Spain) and water *ad libitum*. They were housed in a temperature- (22 ± 2℃), humidity- (65%-70%) and light-controlled room (light, 7:30 am-7:30 pm) in groups of three to four animals.

The experimental procedures employed in this study were in accordance with the principles and practices of the 1986 European Guide for the Care and Use of Laboratory Animals, published in Spain in Royal Decree 1201/2005.

### Experimental design

The animals were randomly divided into four groups: group I ($n$ = 5) consisted of control rats at 1 mo of evolution; group II ($n$ = 11) consisted of triple calibrated portal vein stenosis (TPVS) rats at 1 mo of postoperative evolution; group III ($n$ = 4) consisted of control rats at 1 year of evolution; and group IV ($n$ = 6) consisted of TPVS rats at 1 year of postoperative evolution. The control rats (group I and III) did not undergo any operative intervention. All the animals were sacrificed by exsanguination and body (BW), liver (LW) and spleen (SW) weights were determined.

### Establishment of the rat model of portal hypertension

The surgical procedure used to establish portal hypertension by triple partial ligation of the portal vein (TPVS) has been described previously[8]. In brief, the portal vein was isolated and three partial ligatures were performed in its superior, medial and inferior portions. The stenoses were calibrated by a simultaneous ligature (4-0 silk) around the portal vein with a 20-gauge needle. The midline abdominal incision was closed in two layers with catgut and 3-0 silk.

### Portosystemic collateral circulation study method

Portosystemic collateral circulation was studied as follows: first, a midline abdominal incision with a large bilateral subcostal extension was performed and then the areas in which the collateral venous circulation was developed (i.e. the splenorenal, gastroesophageal, colorectal and hepatic hilum) were carefully studied for the presence of increased collateral veins[9].

### Portal vein pressure measurement

Splenic pulp pressure, an indirect measurement of portal pressure (PP), was measured by inserting a fluid-filled 20-gauge needle into the splenic parenchyma[10]. The needle was joined to a PE-50 tube and then connected to a pressure recorder (PowerLab 200 ML 201) and to a transducer (Sensonor SN-844) with a Chart V 4.0 computer program (ADI Instruments) and was calibrated before each experiment. The pressure reading was considered satisfactory when a stable recording was produced and respiratory variations were observed. Previous studies have demonstrated the excellent correlation between splenic pulp pressure and PP[11].

### Lipid synthesis

**Chemicals:** D-[U-$^{14}$C] glucose was purchased from the Radiochemical Centre (Amersham, Buckinghamshire, UK). Standard lipids and 2', 7'-dichlorofluorescein were purchased from Sigma Chemical Co. (Saint Louis, MO).

**Lipid synthesis:** "*De novo*" lipid synthesis was measured by the incorporation of either D-[U-$^{14}$C] glucose (12.5 Ci/mol) into TG, PL, DG and FFA. Labeled glucose was injected after dissolving in saline (5 mL/kg). All the rats were sacrificed 24 h after treatment, and the livers were excised and washed. After specific extraction, lipids were determined. Briefly, 50 mg of tissue was rapidly frozen in acetone chilled with dry ice. After addition of 0.7 mL of acid methanol (methanol/HCl, 100:1) to the tubes, the content was homogenized, centrifuged and sonicated in an MSE ultrasonic disintegrator (Branson, Danburry, CT). The lipids were then extracted with 1.3 mL of chloroform and 0.4 mL of salt solution[12] for 1 h at room temperature. The organic phase was then washed three times with 1.0 mL of the aqueous phase of a system composed of chloroform/methanol/salt solution/concentrated HCL (266:133:100:1). The organic phase was dried under $N_2$ and re-dissolved in 40 μL of chloroform/methanol (2:1). A sample (30 μL) was then applied to precoated plates of silica gel 60 (20 cm × 20 cm; Merck) previously activated for 1 h at 110℃. Lipid separation was performed by unidimensional chromatography. Then, the plates were sprayed with 2' 7'-dichlorofluorescein, and the following spots were detected under UV light and identified with suitable markers: PL, TG, DG and FFA. Each spot was scraped off into a scintillation vial, and its radioactivity was measured.

### Cholesterol determination

Cholesterol determination was performed with a specific commercial kit (Spinreact, Richmond, 1972)[13] based on the action of the cholesterol enzyme stearase which hydrolyzed the esters present in the sample, giving free cholesterol and fatty acids. A subsequent enzymatic oxidation using the cholesterol enzyme oxidase formed hydrogen peroxide and cholesterine. The peroxide was evaluated by the Trinder reaction by a chromogene, in the presence of peroxidase, forming a quinonimine with a red coloring. The intensity of this color was proportional to the cholesterol concentration in the sample. Finally, colorimetric determination was performed in a spectrophotometer (Eppendorf, model Biophotometer) at a wavelength of 500 nm.

### Determination of liver protein concentrations

This was done by the colorimetric method described by Bradford[14]. This method is based on the binding

of Coomassie Blue to proteins. This binding causes a displacement of the peak absorption of the dye from 465 to 595 nm. Absorbance is measured in the samples at the latter wavelength against a known reference curve. The protein complex dye has a high coefficient of extinction, which gives it a high sensitivity at measuring the protein.

Protein determination was carried out because the concentration of lipids and cholesterol is expressed in relation to the concentration of liver proteins.

### Statistical analysis

Results were expressed as means ± SD. ANOVA and Duncan tests were used for the statistical comparison of the variables between the four groups. The results were considered statistically significant when $P < 0.05$.

## RESULTS

### Body and organ weights

The animals with portal hypertension (groups II and IV) showed a markedly less body weight increase than that found in the control animals (groups I and III): 82.49 ± 29.08 g *vs* 64.72 ± 29.32 g and 268.02 ± 78.03 g *vs* 361.02 ± 58.32 g, $P < 0.05$). The animals with TPVS showed a decrease in liver weight (9.98 ± 1.55 g in group II *vs* 12.01 ± 2.64 g in group I , $P < 0.05$; 15.84 ± 2.02 g in group IV *vs* 16.77 ± 2.87 g in group III).

All animals with TPVS showed splenomegaly: 1.00 ± 0.16 g in group II *vs* 0.49 ± 0.06 g in group I ($P < 0.05$) and 1.43 ± 0.84 in group IV *vs* 0.91 ± 0.10 g in group III ($P < 0.05$) (Table 1).

### Portal venous pressure

All the TPVS rats showed characteristic features of splanchnic venous congestion with dilation of mesenteric venous circulation. The portal pressure in groups II and IV was obviously higher compared to groups I and III (14.63 ± 2.84 mmHg *vs* 7.32 ± 1.15 mmHg; and 9.05 ± 2.84 mmHg *vs* 6.72 ± 1.52 mmHg, respectively; $P < 0.05$) (Table 1).

### Portosystemic collateral circulation

In the rats with TPVS (groups II and IV), splenorenal portosystemic collateral circulation was the commonest type (group II: $n = 11$, 100%; group IV: $n = 4$, 66%).

### Hepatic lipid metabolism

The hepatic concentration of phospholipids underwent a significant increase ($P < 0.005$) in the TPVS animals after one year (group IV) compared to the control group (group III) (Figure 1).

The increase in diacylglyceride in the both groups II (TPVS 1 evolutive month) and IV (TPVS 1 evolutive year) was not statistically significant compared to their corresponding controls. Moreover, although the hepatic concentrations of FFA increased in the animal series with portal hypertension (groups II and IV), this increase was not significant compared to their corresponding controls (Figure 2).

A statistically significant increase in hepatic concentrations of TG (Figure 2) and Ch (Figure 1) in the animals with portal hypertension (groups II and IV) compared to their corresponding control groups (group I and III, respectively) was observed.

**Table 1 Body weight increase (BWI), liver weight (LW), spleen weight (SW) and portal pressure (PP) in the control (C) groups of 1 mo and 1 year of evolution and in the rats with triple portal vein stenoses (TPVS) at 1 mo and 1 year of evolution (mean ± SD)**

| Group | BWI (g) | LW (g) | SW (g) | PP (mmHg) |

## DISCUSSION

Our study demonstrated that prehepatic portal hypertension in the rats, for both in the short-term (1 mo) and long-term (1 year) period, produced hepatic accumulation of triglycerides and cholesterol. Our results provided further evidence to support a long-term evolution (1 year) in the production of a severe drop in hepatic phospholipids (Figures 1 and 2).

Liver steatosis could be the cause of the hepatomegaly described in the evolution of prehepatic hypertension in the rat[5,6]. If so, portal stenosis ligation could be used to make a model of steatosis as well as to obtain an experimental model of portal hypertension[7].

Hepatic steatosis alone is thought to be the most common form of non-alcoholic fatty liver disease (NAFLD) and is considered to be "benign", but not quiescent[15]. The NAFLD spectrum is wide and ranges from simple fat accumulation in hepatocytes (fatty liver), without biochemical or histological evidence of inflammation or fibrosis, to fat accumulation plus necro-inflammatory activity with or without fibrosis (non-alcoholic steatohepatitis, NASH) and the development of advanced liver fibrosis or cirrhosis (cirrhotic stage)[15-19].

However, although a progressive hepatocytic fatty infiltration occurs during chronic evolution in TPVS rats, this is not associated with histological signs of inflammation or fibrosis. Therefore, hepatic steatosis could be considered as a "benign" type of the broad spectrum of NAFLD occurring in these rats with prehepatic portal hypertension[7].

The lipid content of hepatocytes is regulated by the integrated activities of cellular enzymes that catalyze lipid uptake, synthesis, oxidation and export. Fat accumulates within the hepatocytes when the "input" (either uptake or synthesis) of fatty acids to hepatocytes exceeds their "output" (oxidation and export)[20].

Different factors, extrahepatic and intrahepatic, can

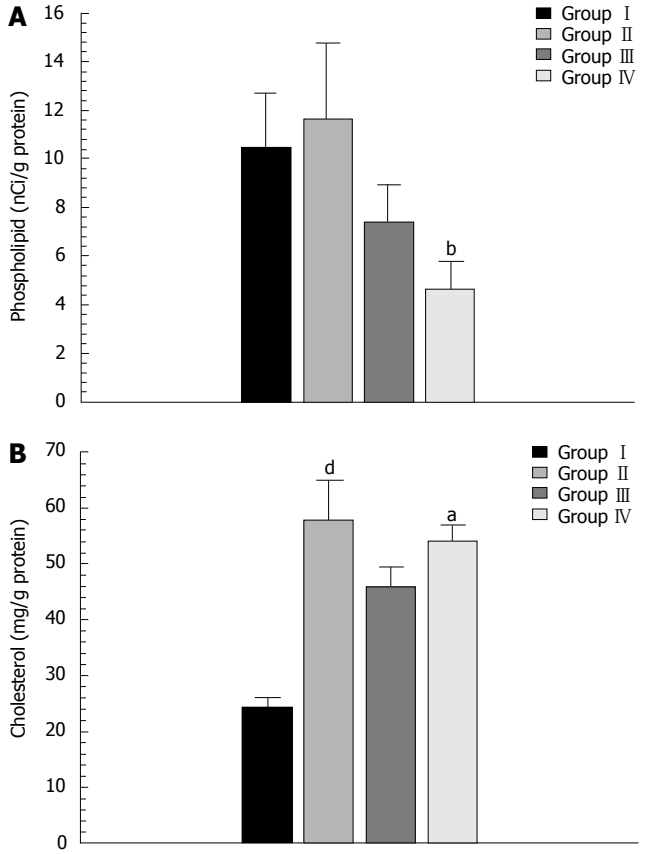

**Figure 1** Liver synthesis of phospholipids and cholesterol liver content in group Ⅰ (control rats) and group Ⅱ (portal hypertensive rats) at 1 mo of postoperative evolution and in group Ⅲ (control rats) and group Ⅳ (portal hypertensive rats) at 1 year of postoperative evolution. [a]*P* < 0.05, [b]*P* < 0.01 *vs* group Ⅲ; [d]*P* < 0.01 *vs* group Ⅰ.

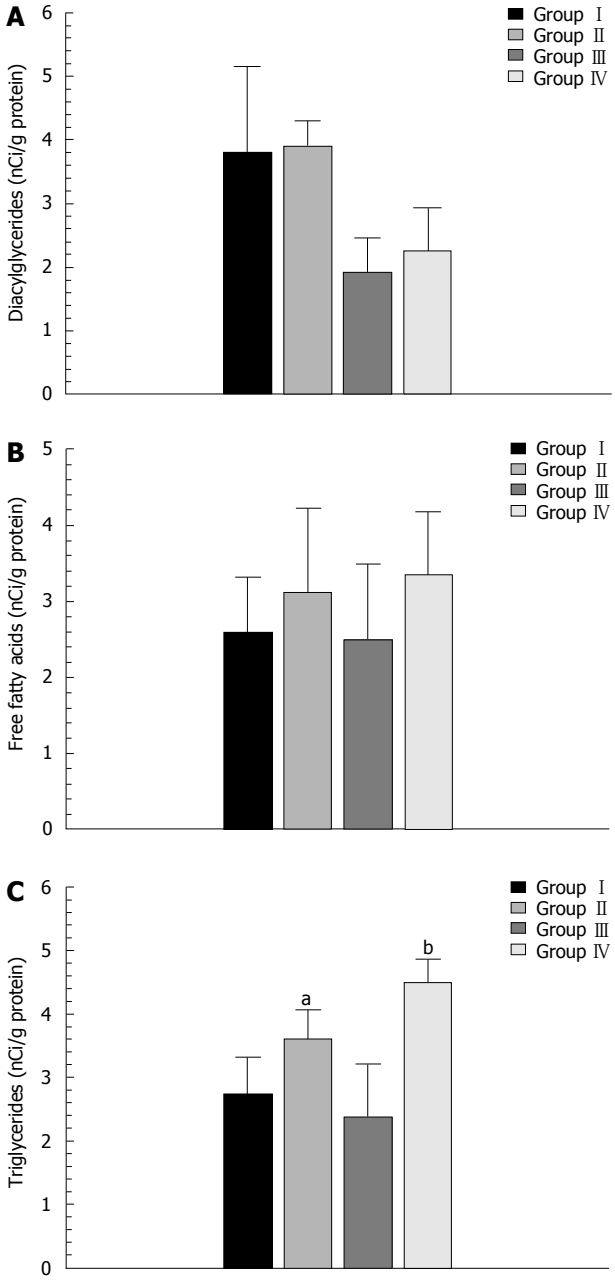

**Figure 2** Liver synthesis of diacylglycerides, free fatty acids and triglycerides in group Ⅰ (control rats) and group Ⅱ (portal hypertensive rats) at 1 mo of postoperative evolution and in group Ⅲ (control rats) and group Ⅳ (portal hypertensive rats) at 1 year of postoperative evolution. [a]*P* < 0.05 *vs* group Ⅰ; [b]*P* < 0.01 *vs* group Ⅲ.

impair both regulator mechanisms and, therefore, promote triglyceride and cholesterol accumulation in the liver of rats with short-term (1 mo) and long-term (1 year) prehepatic portal hypertension. These factors could be divided into neuroendocrine and immunologic for their etiopathogenic study. The possible neuroendocrine factors involved in fat accumulation within the hepatocytes include an increase in the components of the neuroendocrine response to TPVS stress: plasma corticoids[8], catecholamines[21,22] and glucagon[23] levels in portal hypertensive rats. In the neuroendocrine response to stress, a promotion of lipolysis in adipose tissues is also produced with increased plasma free fatty acid concentrations and subsequently, an excess "input" of fatty acids to the liver in short-term prehepatic portal hypertensive rats. In turn, the expanded pool of NAFLD would induce accumulation of triglycerides within the cytoplasm of hepatocytes as fat microvesicles[24-26]. Insulin resistance causes an insufficient suppression of hormone-sensitive lipase activity and reduced glucose uptake in adipose tissue. This results in enhanced lipolysis and increased fatty acid flux into the plasma non-sterified fatty acid pool[26]. It has been demonstrated that approximately 60% of triacylglicerides accumulated in the liver are derived from the plasma non-sterified fatty acids pool. The enhanced adipocyte lipolysis, in turn, is associated with an increased activity of lipogenic enzymes, contributing to hepatic steatosis[26]. Insulin resistance induced by glucocorticoids could also contribute to hepatic steatosis by favouring peripheral lipolysis and hepatic uptake of fatty acids[25,27].

Therefore, in the presence of insulin resistance, increased lipolysis results in the continuous release of long-chain fatty acids (LCFA) from adipose tissue, leading to a characteristic increase in the circulating LCFA concentration[26,28]. When this process occurs in fat-swollen omental and mesenteric fat cells, as it occurs in portal hypertension in the rat, this results in an especially large increase in the mass of LCFAs entering the portal circulation and being delivered directly to the liver[28]. The increase of FFA delivery to the liver, in turn, causes hepatic insulin resistance, as well as tumor necrosis

factor alpha (TNF-α) production[29]. When TNF-α is overproduced relative to adiponectin, adiponectin activity declines. Reduced adiponectin activity also favors hepatic insulin resistance and fat accumulation[29,30]. In addition, low adiponectin activity permits TNF-α activity, which induces insulin resistance[29,30].

The cytokine TNF-α is among the most important immunologic factors potentially involved in the production of hepatic steatosis[17,31,32]. The increase in TNF-α activity, which increases nitric oxide (NO) and carbon monoxide (CO) levels, two potent vasodilators, is at least partially responsible for development of the hyperdynamic systemic and splanchnic state that contributes to maintaining an elevated portal pressure in early evolutive periods of experimental prehepatic portal hypertension[33-37]. However, TNF-α and TNF-regulated cytokines are also considered as effector molecules in liver damage in the animals and patients with non-alcoholic liver diseases, ranging from steatosis to cirrhosis[17,32]. It has been accepted that liver injury requires at least two "hits": One that increases exposure of the hepatocytes to TNF-α and another one that interferes with the normal ability of fat, but renders the liver more vulnerable to a second insult because the hepatocytes became sensitized to the TNF-mediated cell death[32,38].

Although Kupffer cells are a major source of liver-derived pro-inflammatory cytokines, other liver cells can also synthesize cytokines. Particularly, fat accumulation within hepatocytes triggers intracellular signals, activates nuclear factor kappa B (NF-κB) and induces excessive hepatocyte production and insulin resistance[39].

On the other hand, TNF-α has been proposed as causing the hyperlipidemia that occurs in different pathological situations. It has also been shown that TNF-α decreases the level of lipase activity against lipoproteins in adipose tissue[40]. In addition, TNF-α-induced increase in lipid synthesis is accompanied by both an increase in the activity of acetyl coenzyme A carboxylase (a rate-limiting enzyme for fatty acid synthesis) and a rise in its allosteric activator, citrate. This suggests that a relative increase in the activity of this key regulatory enzyme may be one of the mechanisms responsible for. There is also evidence that the rate of triacylglycerol synthesis is controlled by regular coordination of the activities of phosphatidate phosphatase and diacylglycerol acyl transferase[41] .The activities of both enzymes are increased in many conditions of stress, including metabolic stress and exposure to ethanol and glucocorticoids[41].

Accumulated evidence suggests a major role for mitochondrial dysfunction in steatosis[24]. Also, oxidative stress with formation of reactive oxygen species (ROS) increases in fatty livers[42,43]. This abundant ROS formation may oxidize the unsaturated lipids of fat deposits to cause lipid peroxidation[34]. Both lipid peroxidation products and TNF-α may damage mitochondria and directly attack and inactivate respiratory chain components[15,24,25,44,45]. ROS and lipid peroxidation can also lead to ultrastructural mitochondrial alterations and megamitochondria[24,46] and hepatocyte necrosis or apoptosis[44]. The pro-inflammatory cytokines, particularly TNF-α, induce iNOS hyperactivity with an increased NO synthesis. ROS, on binding to NO, form peroxynitrite and this reactive nitrogen radical could bind proteins of the mitochondrial respiratory chain, resulting in its functional impairment with a decrease in oxidative phosphorylation and, consequently, of ATP[47].

ROS, in turn, can cause NF-κB activation, which induces the synthesis of TNF-α, and this cytokine damages mitochondria and increases mitochondrial ROS formation[24]. Mitochondrial dysfunction can, therefore, reduce oxidative phosphorylation and the ATP production that occurs in hepatic steatosis[25,46] and would explain the low resistance of steatotic livers to a second aggressive stimulus or "second hit"[17].

Since the accumulation of triglycerides and cholesterol in the hepatocytes persisted in the long-term (1 year) evolutive stage of prehepatic portal hypertension, possibly, the etiopathogenic mechanisms involved in its production could also persist. Moreover, in this evolutive stage of experimental prehepatic portal hypertension, the increase in lipid deposits associated with a decline in the synthesis of lipid complexes would be associated with the decreased synthesis of lipid complexes, such as phospholipids (PL) (Figure 1), which would worsen the sensitivity to liver injury. Phospholipids are a critical part of the structure of eukaryotic cell membranes. When PL synthesis was examined, we found a significant decrease after one year. Since PC is the main PL in liver membranes, the observed decrease in PL could reflect a decrease in PC synthesis. PC synthesis in the liver mainly occurs through two pathways, the cytidine diphosphate (CDP) choline pathway and the methylation of phosphat-idylethanolamine. In the CDP-choline pathway, the most important pathway, cytidine diphosphate phosphocholine cytidyl transferase catalyses the rate-limiting step. A possible mechanism for the induced PL decrease could be through the release of cytidyl transferase from the membranes, probably mediated by the release of inflammatory mediators, including glucocorticoids and/or cytokines[47].

The excess liver storage of TG and cholesterol results in steatosis and also provides substrates for lipid peroxidation[48]. The accumulation of cholesterol and the PL decrease have been associated with the metabolic syndrome[49]. This classical lipid changes may be envisioned as a highly conserved evolutionary response aimed at tissue repair[50].

An inflammatory hypothesis has been proposed in relation to the etiopathogeny of the portal hypertensive enteropathy. This consists in the involvement of the mast cells[51,52] and the inflammatory mediators released by them, of which histamine would be one of the most important. Histamine, as an effective metabolite, could affect the lipid metabolism in liver cells by facilitating the liver cells' accumulation of lipid droplets (fatty liver)[53]. Therefore, in this experimental model of prehepatic portal hypertension, histamine released by activated mast cells could also be involved in producing a fatty liver.

In summary, prehepatic portal hypertension in rats produces changes in liver lipid metabolism, which are similar to those associated with chronic inflammatory conditions and with sepsis[54].

## Abstract

**AIM:** To investigate whether antioxidants vitamin E and C can retard development of hepatic fibrosis in the biliary-obstructed rats.

**METHODS:** Fifty Wistar albino rats were randomly assigned to 5 groups (10 rats in each). Bile duct was ligated in 40 rats and they were treated as follows: group vitC, vitamin C 10 mg/kg sc daily; group vitE, vitamin E 15 mg/kg sc daily; group vitEC, both of the vitamins; bile duct-ligated (BDL, control) group, physiological saline sc. The fifth group was assigned to sham operation. At the end of fourth week, the rats were decapitated, and hepatic tissue biochemical collagen content and collagen surface area were measured. Hepatic tissue specimens were histopathologically evaluated according to Scheuer system. Serum hyaluronate levels were measured by ELISA method.

**RESULTS:** Despite being higher than sham group, hepatic collagen level was significantly decreased in each of the vitC, vitE and vitEC groups (32.7 ± 1.2, 33.8 ± 2.9, 36.7 ± 0.5 μg collagen/mg protein, respectively) compared to BDL (48.3 ± 0.6 mg collagen/g protein) ($P$ < 0.001 for each vitamin group). Each isolated vitamin C, isolated vitamin E and combined vitamin E/C supplementation prevented the increase in hepatic collagen surface density (7.0% ± 1.1%, 6.2% ± 1.7%, 12.3% ± 2.0%, respectively) compared to BDL (17.4% ± 5.6%) ($P$ < 0.05 for each). The same beneficial effect of vitamin C, vitamin E and combined vitamin E/C treatment was also observed on the decrease of serum hyaluronate levels compared to BDL group ($P$ < 0.001). The relative liver and spleen weights, serum transaminases, cholestatic enzymes, bilirubins and histopathological inflammation scores were not different between the antioxidant treatment groups and the control. However, fibrosis staging scores were obviously reduced only in the vitamin E/C combination group (vit EC: 2.4 ± 0.8 *vs* BDL: 3.1 ± 0.7; $P$ < 0.05).

**CONCLUSION:** Each antioxidant vitamin E, vitamin C and their combination retard hepatic fibrosis in biliary-obstructed rats. Oxidative stress may play a role in the pathogenesis of hepatic fibrosis in secondary biliary cirrhosis.

**Key words:** Hepatic fibrosis; Biliary obstruction; Collagen; Vitamin E; Vitamin C

## INTRODUCTION

Hepatic fibrosis is a highly integrated cellular response to tissue injury[1]. It is essentially characterized by activation of hepatic stellate cells, secretion and accumulation of extracellular matrix proteins[2]. Various causes of cholestasis such as primary biliary cirrhosis, primary sclerosing cholangitis, biliary strictures, atresia, cysts or neoplasia may induce hepatic fibrosis that may potentially culminate in biliary cirrhosis. However, mechanisms underlying the development of hepatic fibrosis in cholestatic liver disease are not thoroughly elucidated.

It is suggested that free radicals might contribute to the development of hepatic fibrosis in biliary obstruction[3-5]. Cholestasis *per se* reduces antioxidative capacities in liver

mitochondria in bile duct-ligated rats[6,7]. Accumulation of hydrophobic bile acids and inflammatory cells in the liver tissue may cause increased production of free radicals in biliary obstruction[8-10]. Bile acids especially, enhance reactive oxygen species released by polymorphonuclear leukocytes[11]. In addition, intraluminal bile salt deficiency in extrahepatic biliary obstruction results in vitamin E malabsorption[12]. Serum and hepatic tissue levels of vitamin E are reduced threefold in biliary-obstructed rats[13]. Accordingly, hepatic tissue levels of lipid peroxides were increased in bile duct-ligated rats[13]. Although the presence of oxidative stress in the course of biliary cirrhosis has been reported, it is still unclear whether it is the cause or consequence of tissue injury or contributes any to hepatic fibrosis. This may partly stem from inadequate number of studies performed to test the efficiency of antioxidants in the prevention of hepatic fibrosis in chronic cholestatic liver diseases.

Type I collagen is the major extracellular matrix protein deposited in the liver during hepatic fibrosis[1,2]. It was reported that lipid peroxides stimulated hepatic deposition of type I collagen in cultured human hepatic stellate cells[14,15]. This suggestion established a possible link between the lipid peroxidation (i.e. oxidative stress) and hepatic fibrosis. Studies demonstrating the beneficial effect of vitamin E supplementation in prevention of both enhancement of lipid peroxidation and synthesis of type I collagen might support this suggestion[16-18]. However, it has been reported that short-term treatment (seven days) of bile duct-ligated rats with vitamin E completely prevented the increase in lipid peroxidation in liver and plasma, but failed to prevent tissue injury histologically[19]. Thus, the current controversies between the few studies performed to evaluate the role of oxidative stress in tissue injury induced by bile duct ligation make newer studies to be performed necessary.

In the liver, vitamin E is the primary fat-soluble chain-breaking antioxidant protecting lipid bilayers whereas hydrophilic vitamin C is the scavenger particularly in plasma, cytosol and other aqueous compartments[20]. In the present study, we aimed to investigate the effect of antioxidants vitamin E and C on hepatic fibrosis in bile duct-ligated rats. Vitamin C was combined to obtain the benefit from synergism of these drugs as the vitamin C reacts with oxidised vitamin E, thereby regenerating vitamin E[21]. Serum hyaluronate levels were used as a marker of liver fibrosis and to predict the response to therapy.

## MATERIALS AND METHODS

Weanling 50 female Wistar albino rats weighing 198 ± 15 g were housed in cages with stainless steel wire tops and with 12-h light-dark cycles under standard animal laboratory conditions at room temperature. The rats had free access to standard rat chow and water. Under aseptic conditions, extrahepatic cholestasis was induced by double ligation with 5/0 polipropilene sutures and transection of the common bile duct in between. In sham-operated rats, the operation was performed in the same way but without bile duct ligation or transection.

The rats were randomly assigned to 5 groups, 10 in each. The 40 bile duct-ligated rats were treated as follows: vitC group, given subcutaneous vitamin C at a daily dose of 10 mg/kg (ascorbic acid; Redoxon®; Roche, Istanbul, Turkey); vitE group, given subcutaneous vitamin E at a daily dose of 15 mg/kg (D-α-tocopherol acetate; Evigen®; Aksu Farma, Istanbul, Turkey) as previously described[22]; vitEC group, given both vitamins by the same route and dose; BDL (bile duct-ligated) (control) group, given subcutaneous physiologic saline. The sham group rats were sham-operated. Administration of vitamin C and E was started immediately after bile duct ligation. At the end of the study period (fourth week), the rats were weighed and decapitated and trunk blood was obtained. Serum samples were collected for liver biochemical tests and serum hyaluronate determinations and then stored at -86℃. The total body weights, liver and spleen weights of each rat were also recorded. Hepatomegaly was defined as liver wet weight of more than 3 g per 100 g rat body weight[23].

This study was approved by the Local Ethical Committee, School of Medicine, Trakya University.

### *Liver tissue sampling*

The left, middle and right lobes of each liver were explored. By cutting six different 5 mm × 5 mm × 5 mm slices, each liver was randomly sampled in 0.75 $cm^3$ tissue. The slices sampled were fixed in 10% buffered formalin, routinely processed and blocked into paraffin for detecting collagen content by biochemical methods and image analysis.

### *Biochemical collagen content determination*

The collagen content of the liver was assayed by the colorimetric method described by Lopez de Leon and Rojkind[24]. The principle is the coloring of collagenous protein by Sirius red (36554-8, 2610-10-8; Aldrich Chemical, Deisenhofen, Germany) and non-collagenous proteins by fast green (14280; MERCK KGaA, Darmstadt, Germany). Fifteen micrometer-thick liver slices taken from each paraffin block were layered on glass slides. Slices were deparaffinized and assayed as originally described. Collagen content was calculated using the formula described by the authors[24] as microgram collagen per milligram protein.

Slices at 5-, 10- and 15- μm thickness were tested beforehand and the optimum depth was determined to be 15 μm, which gave higher absorbency.

### *Histological image analysis of liver fibrosis*

Five-micrometer liver sections of each paraffin block were stained with trichrome for collagen. SAMBA 4000-image analysis system (Unilog, France) was used to determine liver collagen content. Only lobular areas of the liver sections were randomly sampled with × 20 objective magnification. Portal areas were excluded from the analysis by a meticulous area selection. Each representative image frame was 1.278 mm × 0.958 mm (= 1.224 324 $mm^2$). One hundred frames were selected for analysis to reach about 1 $cm^2$ of liver tissue sample. A homemade algorithm generated with SAMBA-IPS software was run. The program automatically outlined and measured the total liver area and the blue-stained collagen area within each frame. Me-

asurements of each frame were added to each other consecutively. The total liver lobular area, total blue spectrum-stained collagen area, and the ratio of the collagen within the liver tissue were summed. Histological image analysis was performed at the Pathology Department of Haydarpasa Hospital.

### Histopathological investigations

Five-micrometer liver sections were stained by HE and trichrome. Necroinflammatory activity grading and fibrosis staging were performed with Scheuer system[25].

### Biochemical assays and serum hyaluronate

Aspartate aminotransferase (AST), alanine aminotransferase (ALT), alkaline phosphatase (ALP), gamma-glutamyl transferase (GGT), bilirubins (total and conjugated) and albumin were assayed in an Olympus AU 800 biochemical automated analyzer.

Hyaluronate quantitative test kit was used to measure serum hyaluronate levels (Corgenix Westminster, CO, USA) by ELISA method.

### Statistical analysis

Data are expressed as mean ± standard error of the mean (SE). The Shapiro-Wilks test was used to assess the normality of continuous data. For all variables, the statistical differences between groups were tested using one-way analysis of variance for normally distributed data. The nonparametric Kruskal-Wallis test was used for nonnormally distributed data. Multiple comparisons were made using the Tukey post hoc multiple comparisons test for normally distributed data, and the non parametric Tukey post hoc multiple comparisons test for nonnormally distributed data. $P < 0.05$ was considered statistically significant. Correlation was calculated using Pearson's test. SPSS/PC+ version 11.0 statistical analysis program (SPSS Inc., Chicago, Illionis) was used for the statistical analysis.

## RESULTS

Forty percent of rats in each vitC, vitE, vitEC and control groups were died, whereas there was no mortality in the sham group. The causes of deaths were biliary peritonitis and various infectious complications. There were no statistically significant differences among the animals in vitamin treated groups and controls in terms of mortality rates and causes of deaths. The numbers of rats that were alive at the end of study period and taken into account were 6, 6, 7, 6 and 10 for vitC, vitE, vitEC, BDL and sham groups, respectively. Body weights of the rats included in the study were not significantly changed at the end of the study period in any of the groups. However, relative liver weights, as expressed in grams per 100 g of body weight, were significantly increased in all BDL groups compared to sham ($P < 0.05$ for both vitC and vitE groups; $P < 0.01$ for vitEC; $P < 0.001$ for control group) (Table 1). No significant difference was observed among the alternative antioxidant regimens or controls. The relative spleen weights were the same among the groups including the sham-operated (Table 1).

### Biochemical collagen content measurement and histological image analysis for fibrosis

The hepatic collagen contents in control group were significantly increased compared with the sham-operated group by biochemical method ($P < 0.001$) (Table 2). However, the antioxidant vitamin groups had significantly less total liver collagen compared to control (physiologic

**Table 4 Correlation of serum hyaluronate with histologic fibrosis staging, collagen surface density and biochemical collagen content**

| | | Fibrosis stage | Collagen density | Collagen content |
|---|---|---|---|---|
| Serum | *r* | + 0.38 | + 0.56 | + 0.71 |
| Hyaluronate | *P* < | 0.025 | 0.005 | 0.0001 |

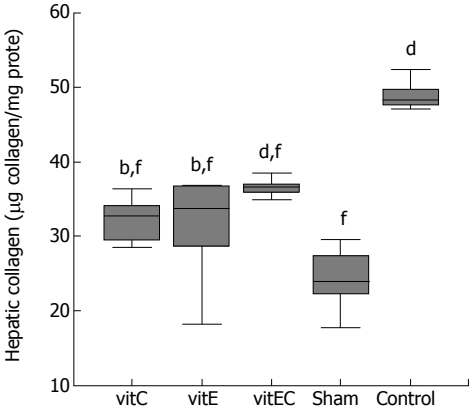

**Figure 1** Effect of treatment on liver collagen content by biochemical method. [b]$P < 0.01$, [d]$P < 0.001$ *vs* sham; [f]$P < 0.001$ *vs* control.

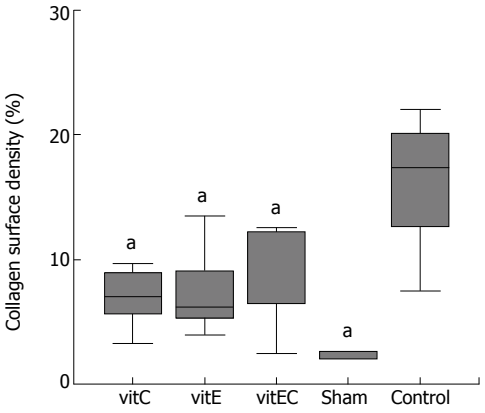

**Figure 2** Effects of vitamin E, C and combination treatment on hepatic fibrosis as determined by computerized image analysis. [a]$P < 0.05$ *vs* control.

saline) group ($P < 0.001$ for all vitamin groups *vs* control group) (Figure 1). The total hepatic collagen contents in antioxidant groups were about 23% less than the BDL (control) group by biochemical method at the end of fourth week. Collagen surface areas were also found to be significantly better in rats treated with antioxidants by computerized image analysis compared to controls ($P < 0.05$) (Table 2, Figure 2). There were no statistically significant differences among the antioxidant treatment groups in regard to the total collagen contents biochemically or collagen surface densities by image analysis (Table 2). Although combination therapy was effective in reducing hepatic fibrosis, it was not statistically more effective than either drugs used alone ($P > 0.05$).

### *Biochemical findings*

The biochemical hepatic profile, including AST, ALT, ALP, GGT, total and conjugated bilirubin measurements, showed no statistically significant difference among the treatment groups and controls ($P > 0.05$) (Table 1). In contrast, serum concentrations of the AST, albumin and bilirubins among the aforementioned biochemical parameters were significantly changed in all of the BDL groups compared to sham-operated group (at least, $P < 0.05$), and without difference in any of the antioxidant regimens that could suggest an improvement in hepatic functions ($P > 0.05$).

### *Histopathological findings and serum hyaluronate levels*

Examination of the liver sections demonstrated inflammation (Figure 3A), bile duct proliferation (Figure 3B) around the portal tracts and fibrosis (Figures 3C and D) in all the BDL groups. Using Scheuer system, the histological necroinflammatory activity observed in the BDL groups were not different compared with any of the treatment regimens (Table 3). However, fibrosis staging was statistically significantly better in the vitamin E and C combination group ($P < 0.05$). The serum hyaluronate levels were significantly elevated in the control group compared to vitamin and sham groups ($P < 0.001$) (Table 2, Figure 4). There was significant correlation between the serum hyaluronate levels and fibrosis staging ($r = 0.38$, $P < 0.05$), biochemical collagen content ($r = 0.71$, $P < 0.0001$) and collagen surface density by image analysis ($r = 0.56$, $P < 0.005$) (Table 4).

## DISCUSSION

Our study showed that antioxidants vitamin E and C retarded the development of hepatic fibrosis without effecting necroinflammation in biliary-obstructed rats. Antioxidants vitamin E and C individually had anti-fibrotic properties. They were equally effective.

In order to demonstrate the efficiency of vitamin E and C in preventing hepatic fibrosis, we started vitamin treatments on the first day of the experiment. As a limitation to our study, we could not measure and compare the serum or hepatic tissue vitamin E levels. However, it has recently been shown that subcutaneous administration of emulsified vitamin E to rats results in substantially elevated serum and liver concentrations of vitamin E comparable with levels achievable by dietary supplementation for conditions in which hepatic oxidative stress is present[26]. Therefore, we preferred to give our

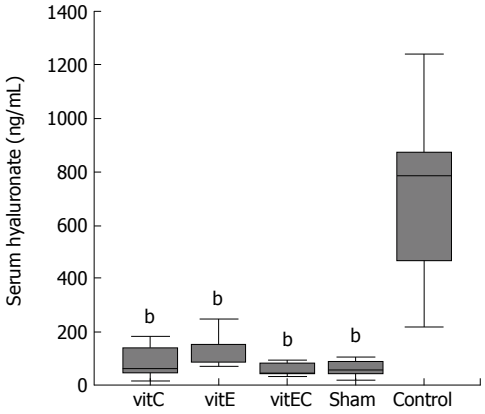

**Figure 4** Effects of vitamin E, C and combination treatment on serum hyaluronate levels. $^{b}P < 0.001$ *vs* control.

rats the vitamins by parenteral route. In contrast, it was reported that oral supplementation with vitamin E and C fails to show any benefit in rats with biliary obstruction[27].

Mild to moderate degrees of hepatic inflammation is usually present especially early in biliary obstruction[28]. Neutrophils infiltrate periductal areas. In our study, we observed this low-grade inflammatory activity in all bile duct-ligated rats. However, antioxidant treatments did not improve the histologic necroinflammation and its surrogate markers serum transaminases and cholestatic enzymes. The reduction in hepatic fibrosis without improvement in necroinflammation needs to be clarified. One possible explanation may be the effect of vitamin E on rat hepatic stellate cell in inducing apoptosis and thus reducing extracellular collagen accumulation[29]. Therefore, in our study, the decrease in hepatic fibrosis in rats taking vitamin E may result from reduced hepatic stellate cell numbers. As another explanation, it is suggested that free radicals may induce apoptosis of hepatocytes in low dose but necrosis in high dose[3]. In biliary obstruction such as in our study, the levels of hepatic tissue free radicals may not be high enough to contribute to the hepatic necroinflammation and disturb liver biochemical enzymes. It would be better if we had preferred to use higher doses of vitamin E or C in order to overcome the necroinflammation and to improve the liver biochemical tests. In our recently published study, the combination of vitamins E and C was associated with decreased ethanol-induced hepatic glutathione peroxidase activity and hepatic fibrosis in protein-deficient rats fed with a high-fat liquid diet[30]. The improvement in hepatic fibrosis was accompanied by reduced necroinflammation and hepatomegaly. However, not all studies indicate that the reduction in fibrosis was due to the reduction in necroinflammation. Similar to the findings of our current study, it has been reported that vitamin E and C combination therapy, although retarded hepatic fibrosis, did not improve hepatic inflammation in patients with nonalcoholic steatohepatitis (NASH) where oxidative stress has a prime role in tissue injury[31]. Antifibrogenic effect of antioxidants vitamin E and C probably interfered with fibrogenesis by mechanisms other than prevention of inflammation or necrosis in both patients with NASH and in our biliary-obstructed rats. In concert with these two studies, the reduction of hepatic collagen by antioxidant sylimarin treatment in biliary-obliterated rats[32] was not accompanied by improvement in clinical findings or biochemical liver enzymes. Meanwhile, antifibrotic effect of sylimarin was mediated by downregulation of type I collagen synthesis[33]. In fact, quiescent stellate cells in tissue culture have the ability to respond to free radicals to express collagen independent of necrosis, inflammation or any other confounding variables[18]. Hepatic stellate cells have been shown to respond to antioxidant vitamin E by downregulating collagen secretion[16-18]. This response was supposed to occur by reduced transforming growth factor-β secretion from hepatic stellate cells in the liver[34].

Bile duct ligation model of rats mimics best the clinical and histopathological aspects of hepatic fibrosis secondary to extrahepatic biliary obstruction in humans[35]. This model allows researchers to study in detail all the developmental stages of hepatic fibrosis, ultimately, terminating in cirrhosis within about 4 wk. In our study the beneficial effect of antioxidants did not reach the levels of improving clinical findings. Neither the liver sizes nor the spleen weights were affected by the antioxidant treatment. Mortality was not improved, either. Maybe, more prolonged study such as 5-6 wk' period would be necessary to observe the expected difference in liver and spleen weights and to judge the effect of treatment on the outcome. The high mortality in our rats was related to postoperative complications. However, these increased complications might also result from the liver damage or from dosage of vitamins which was borderline high for such a long-term treatment. Therefore, by using lower vitamin dosages further studies may also be designed for future experiments. In our study, although the number of rats taken into consideration was not too much, we used four different methods to quantify the extent of hepatic fibrosis. All of the results were in very good correlation and in concordance with each other.

Serum hyaluronate has been suggested to be used in prediction of hepatic fibrosis and the evaluation of treatment response of various antifibrotic drugs in human

studies[36] and in rat[37,38] models of hepatic fibrosis. Several influencing factors such as hepatic inflammatory activity and the indicators of this activity (i.e. liver chemical tests) may reduce diagnostic value of hyaluronic acid and other fibrosis indexes[39]. In our study the presence of low inflammatory activity in the livers of the rats and the absence of difference in serum biochemistry test results between the groups probably attributed to the good correlation between the hyaluronic acid serum levels and the hepatic tissue fibrosis measurements with all methods used. The serum levels of hyaluronic acid in our rats treated with antioxidants were as low as in sham group and correlated well with hepatic collagen quantity. Antioxidant treatment was very effective in preventing the elevation of serum hyaluronic acid levels. However, we could not explain such a significant reduction of the hyaluronic acid level in the treated rats, compared to the negative control with only slight changes in hepatic inflammation and liver biochemistry. It may be appropriate to investigate, if the presumed mechanism, how the vitamins may protect the liver, takes place, or if the hyaluronate serum levels are reduced by another pathway. Nevertheless, our study supported that serum hyaluronic acid levels may be used as an index of liver fibrosis and to evaluate the antifibrotic effects of antioxidant vitamins in biliary-obstructed rats.

In conclusion, oxidative stress might contribute to the pathogenesis of secondary biliary cirrhosis. Antioxidant vitamins E and C or combination of both attenuate the development of hepatic fibrosis without improving necroinflammatory activity in bile duct-ligated rats. Long-term, prospective studies in humans with chronic cholestatic liver diseases may be helpful to evaluate the beneficial effects of these vitamins.

## Abstract

**AIM:** To study the blood coagulation response after partial hepatectomy (PH) at transcriptional level.

**METHODS:** After PH of rats, the associated genes with blood coagulation were obtained through reference to the databases, and the gene expression changes in rat regenerating liver were analyzed by the Rat Genome 230 2.0 array.

**RESULTS:** It was found that 107 genes were associated with liver regeneration. The initially and totally expressing gene numbers occurring in initiation phase of liver regeneration (0.5-4 h after PH), $G_0/G_1$ transition (4-6 h after PH), cell proliferation (6-66 h after PH), cell differentiation and structure-function reconstruction (66-168 h after PH) were 44, 11, 58, 7 and 44, 33, 100, 71 respectively, showing that the associated genes were mainly triggered in the forepart and prophase, and worked at different phases. According to their expression similarity, these genes were classified into 5 groups: only up-, predominantly up-, only down-, predominantly down-, up- and down-regulation, involving 44, 8, 36, 13 and 6 genes, respectively, and the total times of their up- and down-regulation expression were 342 and 253, respectively, demonstrating that the number of the up-regulated genes was more than that of the down-regulated genes. Their time relevance was classified into 15 groups, showing that the cellular physiological and biochemical activities were staggered during liver regeneration. According to gene expression patterns, they were classified into 29 types, suggesting that their protein activities were diverse and complex during liver regeneration.

**CONCLUSION:** The blood coagulation response is enhanced mainly in the forepart, prophase and anaphase of liver regeneration, in which the response in the forepart, prophase of liver regeneration can prevent the bleeding caused by partial hepatectomy, whereas that in the anaphase contributes to the structure-function reorganization of regenerating liver. In the process, 107 genes associated with liver regeneration play an important role.

**Key words:** Partial hepatectomy; Rat Genome 230 2.0 array; Blood coagulation response; Genes associated with liver regeneration

## INTRODUCTION

The liver is the main site where coagulation factors are synthesized[1]. Tissue damage is often companied with angiorrhexis, bleeding and blood coagulation. Blood coagulation is a complex hemostatic process in which zymogens convert into coagulation factors, and promote blood coagulation at the site of wound[2]. This process is classified into extrinsic pathway and intrinsic pathway[3]. A proportion of coagulation factors of the former originate from blood, while that of the latter all from blood. Blood coagulation abnormity can lead to hereditary prothrombin deficiency, vitamin K deficiency, haemophilia and hepatic coagulation defects[4,5].

Partial hepatectomy (PH)[6] causes blood vessel injury and bleeding. Meanwhile, the remnant hepatocytes activated by it enter into cell cycle to compensate for the lost liver tissue, which process is called liver regeneration (LR)[7,8]. Generally, based on the physiological activities of the cells, the regeneration process is classified into 4 phases: the initiation (0.5-4 h after PH), the transition from $G_0$ to $G_1$ (4-6 h after PH), the cell proliferation (6-66 h after PH), the cell differentiation and structure-function reorganization (66-168 h after PH)[9]. According to time course, it is also divided into 4 phases including

forepart (0.5-4 h after PH), prophase (6-12 h after PH), metaphase (16-66 h after PH), and anaphase (72-168 h after PH)[10], which are regulated by many factors including blood coagulation response[11]. To study the relationship between the blood coagulation response after PH and liver regeneration at transcriptional level[10,12], we examined the expression changes of genes in regenerating liver after partial hepatectomy by Rat Genome 230 2.0 array[13] containing 174 blood coagulation-associated genes. One hundred and seven genes were identified which were associated with liver regeneration[14], and we primarily studied the expression changes, patterns and functions of these genes.

## MATERIALS AND METHODS

### Regenerating liver preparation

Healthy SD rats weighing 200-250 g were obtained from the Animal Center of Henan Normal University. The rats were separated into groups at random and each group included 6 rats (male:female = 1:1). PH was performed according to Higgins and Anderson[6]: the left and middle lobes of the liver were removed. Rats were sacrificed by cervical vertebra dislocation at 0.5, 1, 2, 4, 6, 8, 12, 24, 36, 54, 66, 72, 120, 144 and 168 h after PH and the regenerating livers were examined at corresponding time points. The livers were rinsed three times in PBS at 4℃. Then 100-200 mg liver tissues from middle parts of the right lobe, six samples of each group were gathered and mixed together to 1-2 g (0.1-0.2 g × 6) of total liver tissue, then stored at -80℃. The sham-operation (SO) groups were treated the same with partial hepatectomy ones except that the liver lobes were not removed. The guidelines of animal protection of China were followed strictly.

### RNA isolation and purification

Total RNA was isolated from the frozen livers according to the manual of Trizol kit (Invitrogen)[15] and then purified based on the guide of RNeasy mini kit (Qiagen)[16]. In brief, total liver tissues frozen at -80℃ were homogenized liquid nitrogen, and homogenates were split in TRIzol reagent, followed by chloroform extraction and isopentyl alcohol precipitation. The total RNA integrity was confirmed by agarose electrophoresis and checked by the ratio of 28S to 18S. Total RNA concentration and purity were estimated by optical density measurements at 260/280 nm[17].

### cDNA and cRNA synthesis and purification

As template, 0.4 ng total RNA was used for cDNA synthesis. cDNA purification was proceeded based on the methods established by Affymetrix[18]. cRNA labeled with biotin was synthesized using cDNA as the template and then purified[18]. Measurement of cDNA, cRNA concentration and purity were the same as above.

### cRNA fragmentation and microarray detection

Fifteen microliter (1 μg/μL) cRNA incubated with 5 × fragmentation buffer at 94℃ for 35 min was digested into 35-200 bp fragments. The hybridization buffer was added to the prehybridized Rat Genome 230 2.0 microarray produced by Affymetrix, then hybridization was carried out for 16 h at 45℃ on a rotary mixer at 60 rotation/min. The microarray was washed and stained by GeneChip fluidics station 450 (Affymetrix Inc., USA). The chips were scanned by GeneChip Scan 3000 (Affymetrix Inc., USA), and the signal values of gene expression were observed[13].

### Microarray data analysis

Signal values were quantified and normalized with GCOS1.2 software. Quantified signal intensities were obtained by deducting foreground signal values. Signal intensities were replaced by 200 when they were < 200. When experiment/control (Ri) was between 0.1 and 10, Ri was taken as natural logarithms to generate lnRi, and the normalize coefficient factor (ND) was taken by averaged Ri. The modified signal values were generated by ND multiplying control, and were replaced by 200 when it was < 200[13].

### Normalization of microarray data

To minimize error from the microarray analysis, each analysis was performed three times. Results whose total ratio was maximal ($R^m$) and that whose average value of three housekeeping genes (β-actin, hexokinase and glyseraldehyde-3-phosphate dehydrogenase) approached 1.0 ($R^h$) were taken as a reference. The modified data were generated using a correction factor ($R^m/R^h$) multiplying the ratio of every gene in $R^h$ at each time point. To remove spurious gene expression changes resulting from errors in the microarray analysis, the gene expression profiles at 0-4 h, 6-12 h and 12-24 h after PH were reorganized with NAP software (normalization analysis program) according to the cell cycle progression of the regenerating hepatocytes. Data statistics and cluster analysis were done using GeneMath, GeneSpring, and Microsoft Excel software[13,19,20].

### Identification of genes associated with liver regeneration

Firstly, the nomenclature of blood coagulation was adopted from the GENEONTOLOGY database (www.geneontology.org), and input into blood coagulation at NCBI (www.ncbi.nlm.nih.gov) and RGD (rgd.mcw.edu) to identify the rat, mouse and human genes associated with the blood coagulation. According to maps of biological pathways embodied by GENMAPP (www.genmapp.org), KEGG (www. genome.jp/kegg/pathway.html#amino) and BIOCARTA (www.biocarta.com/genes/index.asp), the genes associated with blood coagulation were collated. The results of the analysis were codified, and compared with the results from human and mouse studies in order to identify human and mouse genes which are different from those of rat. In comparison of these genes with the analysis output of the Rat Genome 230 2.0 array, those genes which showed a greater than twofold change in expression level, regarded as meaningful[14] rat homologous genes, were referred to as rat specific genes associated with blood coagulation response under evaluation. Genes, which displayed reproducible results on three independent analyses with the chip and which showed a greater than

twofold change in expression level at least at one time point during liver regeneration with significant difference ($0.01 \leqslant P < 0.05$) or extremely significant difference ($P \leqslant 0.01$) between PH and SO, were referred to as associated with liver regeneration.

## RESULTS

### *Expression changes associated with blood coagulation response during liver regeneration*

According to the databases at NCBI, GENMAPP, KEGG, BIOCARTA and RGD, 357 genes were involved in blood coagulation, in which, 174 genes were contained in the Rat Genome 230 2.0 array. Among them, the expression of 107 genes displayed meaningful changes at least at one time point after PH, showed significant or extremely significant differences in expression between PH and SO, and displayed reproducible results at three detections with Rat Genome 230 2.0 array, suggesting that the genes were associated with LR. Fold changes in up-regulation range were more than 2 to 46 fold compared with control, and down-regulation more than 2 to 10 fold (Table 1). The analysis indicated that 44 genes were up-regulated, 36 genes down-, and 27 genes up/down- during liver regeneration. The total up- and down-regulation times were 342 and 253, respectively (Figure 1A). At the initiation phase (0.5-4 h after PH), 24 genes displayed up-regulation, 14 genes down, and 2 genes up/down; at the transition phase from $G_0$ to $G_1$ (4-6 h after PH), 24 genes up, and 8 genes down; at the cell proliferation phase (6-66 h after PH), 45 genes up, 42 genes down, and 11 genes up/down; at cell differentiation and structure-function reorganization phase (66-168 h after PH), 38 genes up, and 27 genes down, and 5 genes up/down (Figure 1B).

### *Initial expression time points associated with blood coagulation response during liver regeneration*

At each time point of liver regeneration, the numbers of initial up-, down-regulated and total up-, down-regulated genes are as follows in sequence: both 9 and 6 at 0.5 h; 6, 10 and 12, 14 at 1 h; 8, 0 and 16, 3 at 2 h; 4, 1 and 17, 4 at 4 h; 4, 2 and 21, 7 at 6 h; 1, 0 and 13, 5 at 8 h; 0, 5 and 12, 10 at 12 h; 7, 7 and 15, 13 at 16 h; 5, 8 and 17, 24 at 18 h; 3, 0 and 18, 16 at 24 h; 2, 3 and 11, 11 at 30 h; 0, 4 and 23, 18 at 36 h; 1, 1 and 9, 9 at 42 h; 1, 2 and 22, 24 at 48 h; 0, 0 and 12, 13 at 54 h; 0, 0 and 22, 11 at 60 h; 2, 0 and 21, 9 at 66 h; 0, 1 and 15, 11 at 72 h; 0, 0 and 11, 10 at 96 h; 4, 0 and 13, 9 at 120 h; 0, 0 and 15, 9 at 144 h; 0, 0 and 12, 13 at 168 h (Figure 2). Generally, gene expression changes occurred during the whole liver regeneration, with the up- and down-regulation times of 342 and 253, respectively. The initially up-regulated genes were predominantly expressed in the forepart, and the down-regulated genes in the prophase and metaphase, whereas there was little initial expression in the anaphase.

### *Expression similarity and time relevance associated with blood coagulation response during liver regeneration*

Totally 107 genes could be characterized based on their similarity in expression as following: only up-,

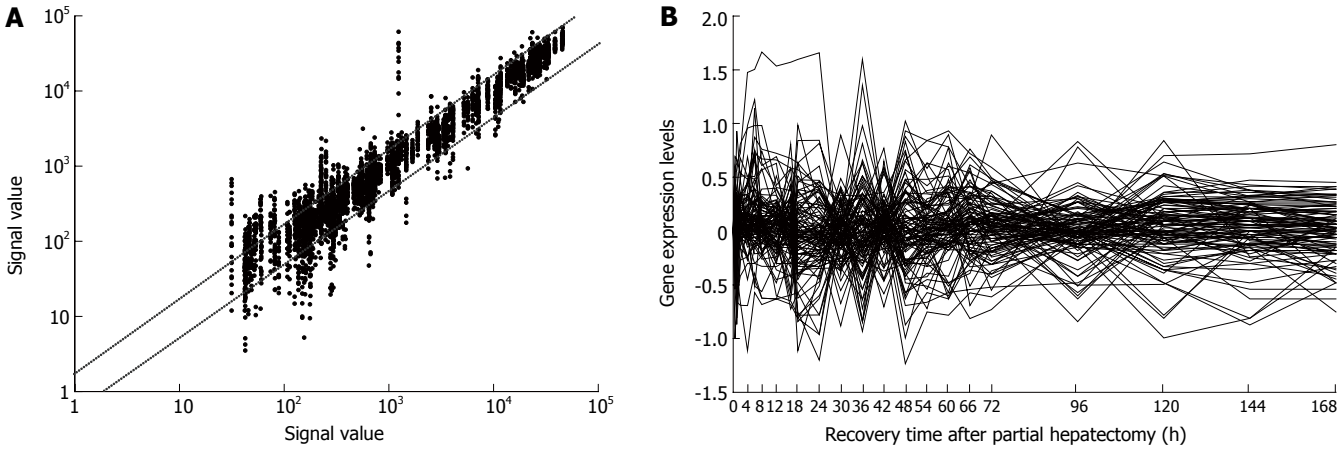

**Figure 1** Expression frequency, abundance and changes of 107 blood coagulation response-associated genes during rat liver regeneration. Detection data of Rat Genome 230 2.0 array were analyzed and graphed with Microsoft Excel. **A**: Gene expression frequency. The dots above bias represent the genes up-regulated more than two fold, and total times of up-regulation were 342; those below bias down-regulated more than two fold, and times of down-regulation were 253; and the ones between biases no-sense alteration; **B**: Gene expression abundance and changes. Seventy-six genes were 2-46 fold up-regulated, and 62 genes 2-10 fold down- regulated.

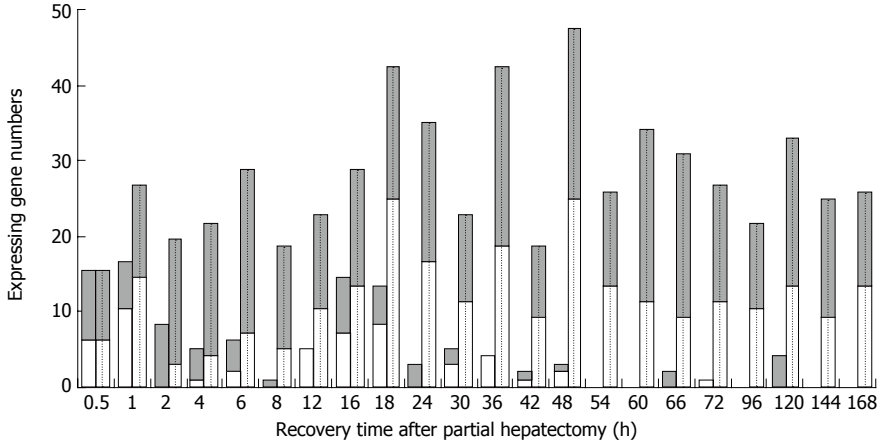

**Figure 2** The initial and total expression profiles of 107 blood coagulation response-associated genes at each time point of liver regeneration. Grey bars: Up-regulated gene; White bars: Down-regulated. Blank bars represent initial expressing genes, in which up-regulated genes were predominant in the forepart, and the down-regulated genes in the prophase and metaphase, whereas there was little initial expression in the anaphase. Dotted bars represent the total expressing genes, in which some genes were up-regulated, and the others down regulated during the whole LR.

predominantly up-, only down-, predominantly down-, up-/down-regulated, involving 44, 8, 36, 13 and 6 genes, respectively (Figure 3). According to time relevance, they were classified into 15 groups, including 0.5 h, 1 h, 2 h, 4 and 6 h, 8 and 12 h, 16 h, 18 and 24 h, 30 and 42 h, 36 h, 48 h, 54 and 60 h, 66 and 72 h, 96 h, 120 h, 144 and 168 h, and the up- and down-regulation times were 9 and 6, 12 and 14, 16 and 3, 38 and 11, 25 and 15, 15 and 13, 35 and 40, 20 and 20, 23 and 18, 22 and 24, 34 and 24, 35 and 20, 11 and 10, 19 and 13, 27 and 22, respectively (Figure 3). The up-regulated expression genes were chiefly associated with promoting blood coagulation, and the down-regulated expression genes mostly associated with inhibiting blood coagulation.

### *Expression patterns of the genes associated with blood coagulation response during liver regeneration*

The 107 genes were categorized into 29 patterns, according to the changes in their expression. (1) up-regulation at one time point, i.e. 6, 16, 30, 66, 120 h after partial hepatectomy (Figure 4A), 8 genes involved; (2) up at two time points, i.e. 6 and 42 h, 30 and 42 h (Figure 4B), 2 genes involved; (3) up at three time points (Figure 4B), 2 genes involved; (4) up at multiple time points (Figure 4C), 5 genes involved; (5) up at one phase, i.e. 1-48, 4-6, 120-168 h (Figure 4D), 3 genes involved; (6) up at one time point/phase, i.e. 0.5 and 4-6 h, 24 and 66-72 h, 42 and 120-168 h, 66 and 120-168 h (Figure 4E), 4 genes involved; (7) up at one time point/two phases (Figure 4F), 2 genes involved; (8) up at one time point/three phases (Figure 4F), 1 gene involved; (9) up at two time points/one phase (Figure 4G), 5 genes involved; (10) up at two time points/phases (Figure 4H), 2 genes involved; (11) up at two time points/three phases (Figure 4H), 3 genes involved; (12) up at three time points/one phase (Figure 4I), 3 genes involved; (13) up at three time points/two phases (Figure 4I), 1 gene involved; (14) up at multiple time points/phases (Figure 4J), 3 genes involved; (15) down at one time point, i.e. 16, 30, 36, 42, 48, 72 h (Figure 4K), 8 genes involved; (16) down at two time points, i.e. 0.5 and 48 h, 1 and 72 h, 16 and 30 h, 16 and 96 h, 18 and 48 h, 18 and 54 h, 30 and 48 h, 30 and 96 h, 36 and 48 h (Figure 4L), 10 genes involved; (17) down at multiple time points (Figure 4M), 4 genes involved; (18) down at one phase, i.e. 6-12 h (Figure 4N), 1 gene involved; (19) down at two phases, i.e. 18-24 and 48-54 h (Figure 4N), 1 gene involved; (20) down at one time point/phase, i.e. 1 and 96-120 h, 18 and 120-144 h, 36 and 12-24 h, 96 and 16-24 h (Figure 4O), 4 genes

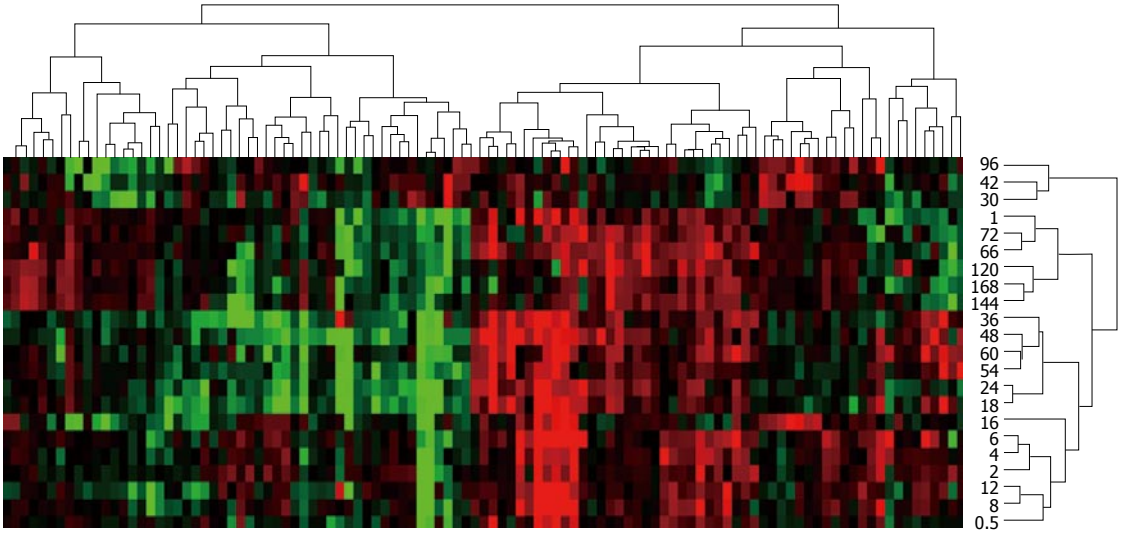

**Figure 3** Expression similarity and time relevance clusters of 107 blood coagulation response-associated genes during liver regeneration. Detection data of Rat Genome 230 2.0 array were analyzed by H-clustering. Red represents up-regulated genes chiefly associated with promoting blood coagulation; Green represents down-regulated ones mainly associated with inhibiting blood coagulation; Black: No-sense in expression change. The upper and right trees respectively show expression similarity and time series clusters, by which the above genes were classified into 5 and 15 groups separately.

involved; (21) down at one time point/two phases (Figure 4O), 1 gene involved; (22) down at one time point/three phases (Figure 4O), 1 gene involved; (23) down at two time points/one phase (Figure 4P), 3 genes involved; (24) down at two time points/phases (Figure 4P), 1 gene involved; (25) down at three time points/two phases (Figure 4Q), 1 gene involved; (26) down at multiple time points/phases (Figure 4Q), 1 gene involved; (27) predominantly up (Figure 4R), 8 genes involved; (28) predominantly down (Figure 4S), 13 genes involved; (29) similarly up/down (Figure 4T), 6 genes involved.

## DISCUSSION

Blood coagulation plays an important physiological role. PH induces blood coagulation, which results from direct or indirect interaction between various proteins. Tissue factor (TF), associated with extrinsic blood coagulation, initiates extrinsic blood coagulation by acting on coagulation factor 7 (F7)[21]. Interleukin 6 (IL6) accelerates the transformation from fibrinogen to fibrin[22]. Twelve proteins including protease serine 2 (PRSS2) inhibit blood coagulation by suppressing the activities of TF and coagulation factors[23-25]. Seven proteins including annexin A 7 (ANXA7) accelerate the transformation from plasminogen to plasmin by inhibiting the activities of factor 10 (F10) and thrombin, repress blood coagulation, and induce migration and tube repair of blood vessel endothelial cells as well[26-28]. The meaningful expression profiles of the proteins encoding the above genes were the same or similar at some points while different at others, indicating that they may co-regulate extrinsic blood coagulation. Among them, *il6* was up-regulated at 2-8, 18, 48, 60 and 96 h, and reached a peak at 96 h, which was 6.1 times higher than the control. This is generally in line with the result reported by Takatori *et al*[29]. *tf* was up-regulated at 16, 30 and 96 h during liver regeneration, and reached a peak at 16 h, which was 2.7 times higher than the control. *prss2* was up-regulated mainly at 18, 36 and 54-60 h, and reached a peak at 36 h, which was 39.4 times higher than the control. *anxa7* was up-regulated at 16, 30, 42 and 96 h, and reached a peak at 96 h, which was 6.8 times higher than the control. It suggests that these genes play a key role in blood coagulation during liver regeneration.

Moreover, six proteins including phospholipid scramblase 1 (PLSCR1), associated with intrinsic blood coagulation, promote blood coagulation by activating coagulation factors[30-33]. Amyloid beta precursor protein (APP) and beta-1,4-galactosyltransferase 1 (B4GALT1) accelerate blood coagulation[34,35]. Nine proteins including alpha-2-macroglobulin (A2M) inhibit blood coagulation by reducing thrombin and collagenase[36-39]. Five proteins including serine peptidase inhibitor clade E member 1 (SERPINE1) depress fibrinolysis by inhibiting the activities of plasma serine protease protein C and plasminogen activator[40,41]. Twelve proteins including plasminogen activator tissue (PLAT) inhibit blood coagulation by converting plasminogen to plasmin through cleaving the Arg-Val bond[42-44]. Thrombomodulin (THBD) restrains blood coagulation[45]. The meaningful expression profiles of the genes encoding the proteins mentioned above were the same -ness or similarity at some points while difference at others, suggesting that they may co-regulate intrinsic blood coagulation. Among them, *thbd* showed up-regulation during almost the whole LR, and had the highest abundance of 9.6 times higher than control at 6 h, which is consistent with the result reported by Takatori *et al*[46]. *a2m* was up-regulated at 0.5-24, 36 and 48-54 h, and reached a peak at 8 h, which was 46.2 times higher than the control. This is generally in conformity with the result reported by Scotte *et al*[47]. *plscr1* was up-regulated at 2-24, 36 and 48-120 h during liver regeneration, and reached a peak at 6 h, which was 2.7 times higher than the control. *app* was up-regulated at multiple phases after PH, and reached a peak at 168 h, which was 3.1 times higher than the control. *serpine1* was up-regulated at 1-48 h, and reached a peak at 6 h, which was 16.7 times

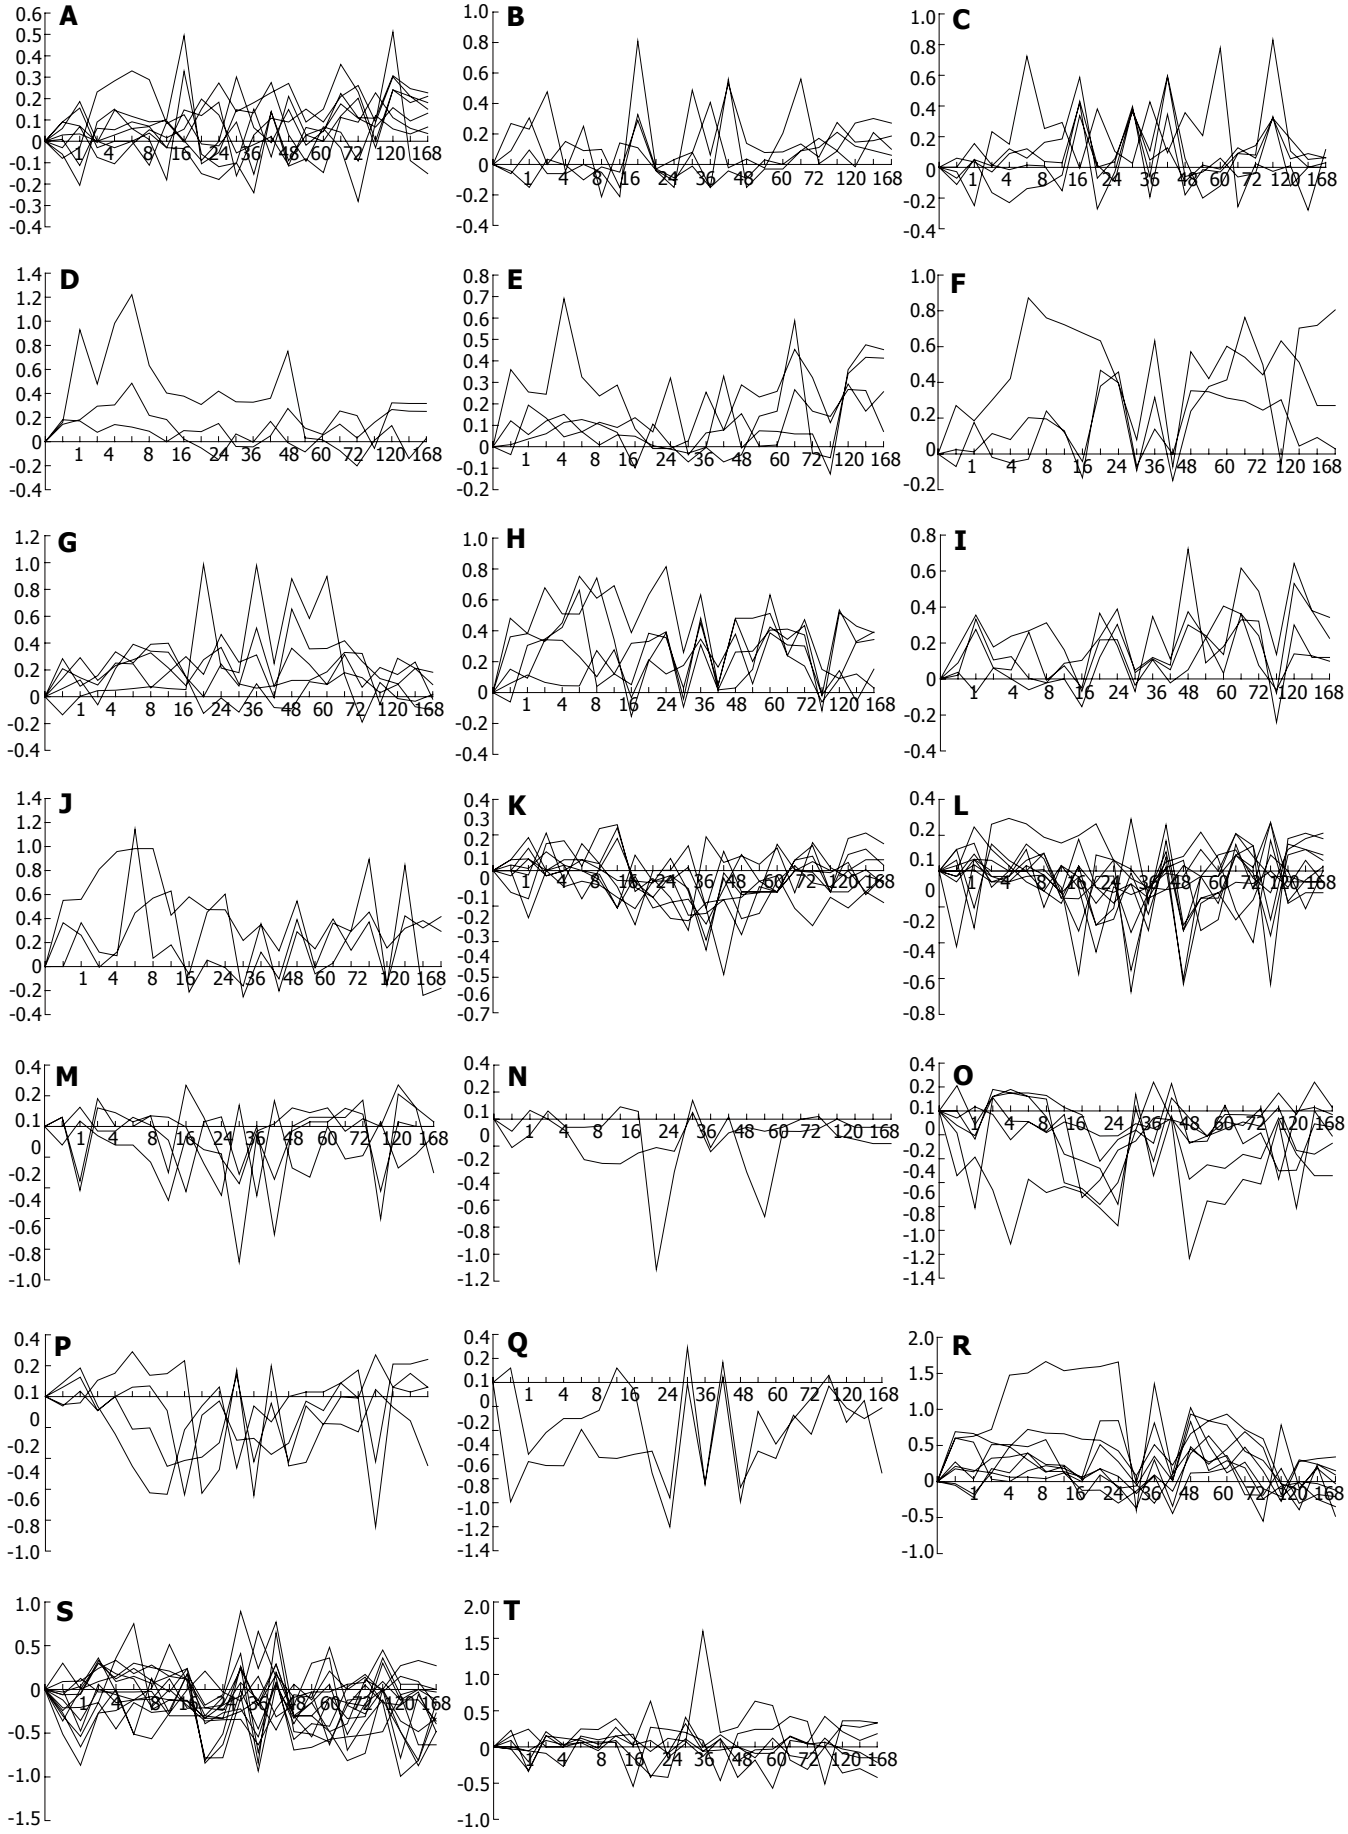

**Figure 4** Twenty-nine gene expression patterns of 107 blood coagulation response-associated genes during liver regeneration. Expression patterns were obtained by the analysis of detection data of Rat Genome 230 2.0 array with Microsoft Excel. **A**-**J**: 44 up-regulated genes; **K**-**Q**: 36 down-regulated genes; **R**-**T**: 27 up/down-regulated genes. X-axis represents recovery time after partial hepatectomy (h); Y-axis shows logarithm ratio of the signal values of genes at each time point to control.

higher than the control. *plat* was up-regulated at multiple phases after PH, and reached a peak at 66 h, which was 4.9 times higher than the control. It implies that these genes play a crucial role in blood coagulation during liver regeneration.

In summary, the expression changes of the genes associated with blood coagulation during liver regeneration have been investigated by high-throughput gene expression analysis and in long time range (0.5 h-7 d after PH) and at multiple time points (totally 23). It is preliminarily proved that PH can cause various physiological responses including blood coagulation, and that Rat Genome 230 2.0 array is a useful tool for analysis of the blood coagulation responses at gene transcriptional level. However, the processes of DNA→mRNA→protein are influenced by many factors including protein interactions. Therefore, our results need to be further analyzed using techniques, such as Northern blotting, protein chip, RNA interference, protein-interaction.

## Abstract

**AIM:** To characterize functional biliary pain and other gastrointestinal (GI) symptoms in postcholecystectomy syndrome (PCS) patients with and without sphincter of Oddi dysfunction (SOD) proved by endoscopic sphincter of Oddi manometry (ESOM), and to assess the post-endoscopic sphincterotomy (EST) outcome.

**METHODS:** We prospectively investigated 85 cholecystectomized patients referred for ERCP because of PCS and suspected SOD. On admission, all patients completed our questionnaire. Physical examination, laboratory tests, abdominal ultrasound, quantitative hepatobiliary scintigraphy (QHBS), and ERCP were performed in all patients. Based on clinical and ERCP findings 15 patients had unexpected bile duct stone disease and 15 patients had SOD biliary type Ⅰ. ESOM demonstrated an elevated basal pressure in 25 patients with SOD biliary-type Ⅲ. In the remaining 30 cholecystectomized patients without SOD, the liver function tests, ERCP, QHBS and ESOM were all normal. As a control group, 30 'asymptomatic' cholecystectomized volunteers (attended to our hospital for general cardiovascular screening) completed our questionnaire, which is consisted of 50 separate questions on GI symptoms and abdominal pain characteristics. Severity of the abdominal pain (frequency and intensity) was assessed with a visual analogue scale (VAS). In 40 of 80 patients having definite SOD (i.e. patients with SOD biliary type Ⅰ and those with elevated SO basal pressure on ESOM), an EST was performed just after ERCP. In these patients repeated questionnaires were filled at each follow-up visit (at 3 and 6 mo) and a second look QHBS was performed 3 mo after the EST to assess the functional response to EST.

**RESULTS:** The analysis of characteristics of the abdominal pain demonstrated that patients with common bile duct stone and definite SOD had a significantly higher score of symptomatic agreement with previously determined biliary-like pain features than patient groups of PCS without SOD and controls. In contrary, no significant differences were found when the pain severity scores were compared in different groups of PCS patients. In patients with definite SOD, EST induced a significant acceleration of the transpapillary bile flow; and based on the comparison of VASs obtained from the pre- and post-EST questionnaires, the severity scores of abdominal pain were significantly improved, however, only 15 of 35 (43%) patients became completely pain free. Post-EST severity of abdominal pain by VASs was significantly higher in patients with predominant dyspepsia at initial presentation as compared to those without dyspeptic symptoms.

**CONCLUSION:** Persistent GI symptoms and general patient dissatisfaction is a rather common finding after EST in patients with SOD, and correlated with the presence of predominant dyspeptic symptoms at the initial presentation, but does not depend on the technical and functional success of EST.

**Key words:** Postcholecystectomy pain; Sphincter of Oddi dysfunction; Functional biliary-pain; Dyspeptic symptoms; Endoscopic sphincterotomy; Follow-up

## INTRODUCTION

Sphincter of Oddi (SO) dysfunction is thought to

responsible for postcholecystectomy abdominal pain in up to 13% of patients[1]. Endoscopic sphincter of Oddi manometry (ESOM) is considered the gold standard for the diagnosis of sphincter of Oddi dysfunction (SOD)[2], and in patients with definite SOD (patients with elevated SO basal pressure and those with SOD biliary type Ⅰ, i.e. clinical signs of biliary obstruction due to SO stenosis), endoscopic sphincterotomy (EST) is regarded as the most definitive treatment. Initially, several controlled landmark studies have supported this therapeutical approach[3-5]; however in the majority of these studies the primary end point was the general symptomatic improvement after EST, and no detailed analysis of the global spectrum of the GI symptoms has been performed. Moreover, as we learned from a recent cohort study, although up to 69% of the postcholecystectomy patients with definite SOD exhibited an overall symptomatic relief after EST as compared with only 31% relief in the sham control group, only 18% of the responder patients became completely asymptomatic after EST[6]. In other words, regardless of optimal diagnostic approach and therapy in patients with postcholecystectomy syndrome (PCS), a significant proportion of these patients will never be completely asymptomatic. One explanation might be that similar to those patients with poor outcome after cholecystectomy, the presence of dyspepsia and other GI symptoms before papillotomy may be continued after EST, and this might influence the overall outcome and patient satisfaction[7]. Another critical point could be that ESOM alone is an insufficient method for optimal patient selection for EST, and this might worsen the effectiveness. Therefore, the aims of the present prospective study were to precisely characterize functional biliary pain and other GI symptoms in patients having PCS with and without SO motility disorders documented by ESOM and/or quantitative hepatobiliary scintigraphy (QHBS), and to assess the post-EST outcome of these symptoms.

## MATERIALS AND METHODS

### *Patients*

During the period of year 2001-2005, we prospectively investigated 85 consecutive cholecystectomized patients referred to our endoscopy unit for ERCP because of suspected SOD (Figure 1). On admission, all patients completed our standardized and validated questionnaire on pain and GI symptoms. Liver function tests (LFTs) [ALAT, ASAT, alkaline phosphatase (AP), γGT, serum bilirubin], abdominal ultrasonography, upper GI endoscopy with antral biopsy to test *H pylori*, quantitative hepatobiliary scintigraphy (QHBS), ERCP and in the presence of clear indication ESOM were performed in each patient with suspected SOD. Based on clinical data and ERCP results our patients were categorised by the Geenen and Hogan classification as follows: SOD biliary group type Ⅰ, Ⅱ and Ⅲ. In order to prevent repeated ERCPs and reduce the post-procedure complication rate, we studied the presence of delayed transpapillary bile flow (longer than 45 min) by QHBS instead of measuring the ERCP contrast drainage time. In 15 of 85 patients an unexpected common bile duct (CBD) stone was detected on the ERCP, and therefore an EST and a stone extraction were completed immediately (CBD stone group). According to the elevated LFTs, abnormal QHBS and dilated bile duct on ERCP, 15 of 85 patients were categorised as SOD biliary type I (SOD I group). In these SOD type Ⅰ patients, an EST was performed just after the ERCP without ESOM. An EST was also performed in a further 25 patients with SOD biliary type Ⅱ or Ⅲ, accompanied with an elevated SO basal pressure (over 40 mm Hg) demonstrated on ESOM (ESOM positive SOD group). Finally, in 30 of 85 patients a PCS without SOD was diagnosed (all of them belonged to SOD biliary type Ⅱ and Ⅲ), based on normal LFTs, normal ERCP and negative QHBS and/or ESOM (SOD negative PCS group) (Figure 1). As a control group, 30 'asymptomatic' cholecystectomized volunteers (attended to our hospital for general cardiovascular screening and none of them had been investigated earlier for postcholecystectomy symptoms) were also included in our study, and they filled our questionnaire repeatedly (cholecystectomized control group). In the control group, no further investigation was performed to diagnose functional biliary diseases for lack of indication.

In 40 of 80 patients having definite SOD (i.e., patients with SOD biliary type Ⅰ and those with elevated SO basal pressure on ESOM) an EST was performed just after ERCP (Figure 1). The frequency of mild post-procedure pancreatitis was 14.8%, but no severe complication or procedure related death occurred. Thirty-five of these 40 patients were followed-up for up to 12 mo after the procedure. In these 35 patients repeated questionnaires were filled at each check-up (every 3-6 mo) and a second look QHBS was performed at the 3rd month after the procedure to assess the beneficial effect of EST. Unfortunately 5 patients were dropped out from this arm of the study, which was always due to poor patient co-operation.

Before entering the study all patients were informed about the study, and all gave written informed consent. The study protocol was approved by the Ethical Committee of University of Szeged and was in accordance with the Helsinki Ⅱ Declaration.

Our questionnaire consisted of 50 separate questions on personal data, symptom characteristics and severity of abdominal pain assessed with a visual analogue scale (VAS). The patients were asked to rate their pain frequency and intensity on two separate 100 mm scale with the margins of "no pain at all" on the left and "continuous pain" on the right, *vs* "no pain at all" on the left and "worst possible pain" on the right, respectively. Patients were requested to mark on the VAS how frequent and intensive of their abdominal pain. Severity scores of abdominal pain were calculated by simple addition of VASs of frequency and intensity. Symptomatic characteristics of abdominal pain were assessed further by six questions (four possible answers each), in which the localization, duration, type, connection with feeding, aggravating and relieving factors were precisely determined. According to the literature, biliary-type pains were initially defined as typically localized in the epigastrium or the right upper quadrant, with episodes of steady pain that lasts more than 15-30 min, maybe aggravated by food or fatty food and relieved

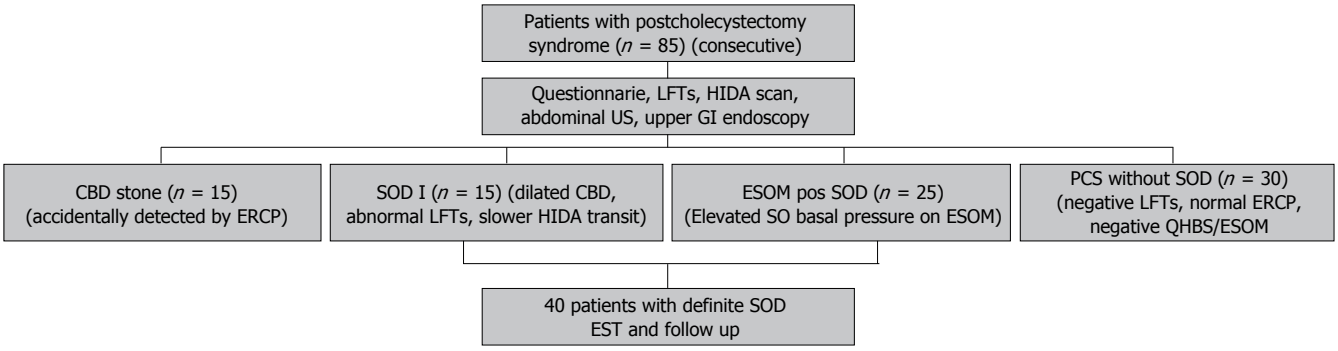

**Figure 1** Flow chart of our patient selection and diagnostic strategy.

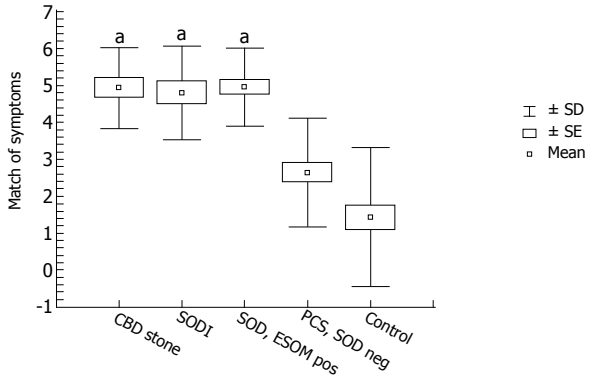

**Figure 2** Abdominal pain characteristics in different postcholecystectomy patient groups based on the results of our questionnaire. Note that significant match of symptom characteristics with the predefined biliary type pain observed predominantly in patients with common bile duct stone and in patients with definite SOD. $^{a}P < 0.05$ *vs* SOD negative PCS and controls.

after spasmolytics or due to low-fat diet. Other possible answers in this part of our questionnaire were focused to characterize possible symptoms of non-biliary diseases such as acid related disorders, dysmotility type dyspepsia, and radiating pain stemming from the thoracic or lumbar zygapophysial joints, i.e. facet syndrome. These abdominal pain characteristics were then scored by counting the cumulative number of the affirmative patient answers that precisely matched with previously described definitions of biliary-type pain.

There were further 28 questions on dyspeptic symptoms, and each of them was assessed by VAS of frequency and intensity in a similar manner as described above. In this part the patients were asked whether they were bothered by heartburn, acid regurgitation, early satiety, bloating and abdominal distension, nausea, vomiting, vomiting of bile, flatulence, borborygmus, diarrhea, constipation, intermittent constipation and diarrhea, anorexia and weight loss. The duration of symptoms and the relation to time of previous cholecystectomy were also determined. The next section aimed to detect psychological vulnerability and neurotic symptoms and consisted of separate questions on psychosomatic and neurotic symptoms, with yes/no category answers. Psychological vulnerability was also scored by counting the cumulative number of affirmative answers. Some previous points of medical history, such as pancreatitis and alcohol consumption were also noted.

### *Statistical analysis*

For statistical evaluation the Kruskal-Wallis followed by the Mann-Whitney *U* tests (quantitative variables) or the chi-square tests (qualitative variables) were applied. Significance was achieved at $P < 0.05$. All results are given as mean, standard error and standard deviation.

QHBS was performed with our standard technique as it was published and validated earlier[8] and was strictly performed in a few days before any invasive procedure. Time-to-peak (Tmax) and half-time-excretion (Thalf) parameters were calculated over the liver parenchyma (L), hepatic hilum (H) and common bile duct (C). The duodenal appearance time (DAT) was also measured. ESOM was performed with the application of the standard station pull through manometric technique[8]. ESOM recording was considered abnormal in cases demonstrating an elevated SO basal pressure (over 40 mm Hg, lasting more than 30 s).

## RESULTS

Analysis of the characteristics of abdominal pain demonstrated, that in patients with CBD stone, SOD I and ESOM positive SOD there was significantly higher score of symptomatic agreement with the previously determined biliary-type pain features than in patient groups with SOD negative PCS and controls (Figure 2). Interestingly, patients with definite SOD (i.e., SOD I and ESOM positive SOD) had exactly similar biliary pain characteristics compared with patients with CBD stone disease. However, most of our patients with SOD negative PCS had atypical pain and symptom presentation.

When the severity scores of abdominal pain at presentation were analysed, all patient groups (CBD stone, SOD I, ESOM positive SOD, and SOD negative PCS) had significantly higher pain severity than the cholecystectomized controls (Figure 3). In fact, the severity level of abdominal pain in SOD negative PCS patients was similar to that in patients having organic disorder such as CBD stone or SOD Ⅰ. Therefore, in contrast to symptomatic characteristics, the severity of abdominal pain had no diagnostic value in differentiating patients with and without SOD.

Based on the analysis of our questionnaire, in 40 patients with definite SOD (SOD Ⅰ patients and ESOM positive patients) a higher prevalence of dyspeptic

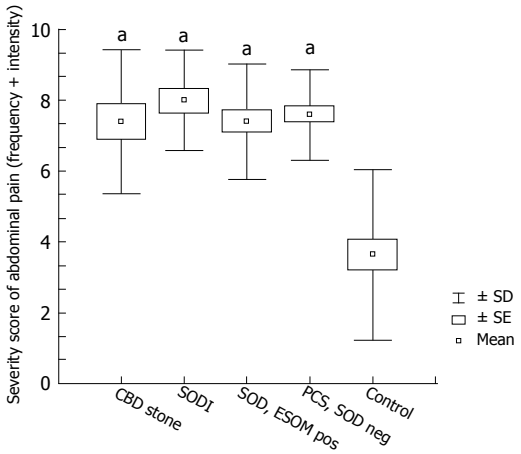

**Figure 3** Severity of abdominal pain (sum of frequency and intensity) determined by VAS in different postcholecystectomy patient groups. Note that patients with postcholecystectomy pain syndrome but without any objective signs of SOD (including negative ESOM/QHBS) have severity scores equivalent to those with common bile duct stone disease. [a]*P* < 0.05 *vs* control.

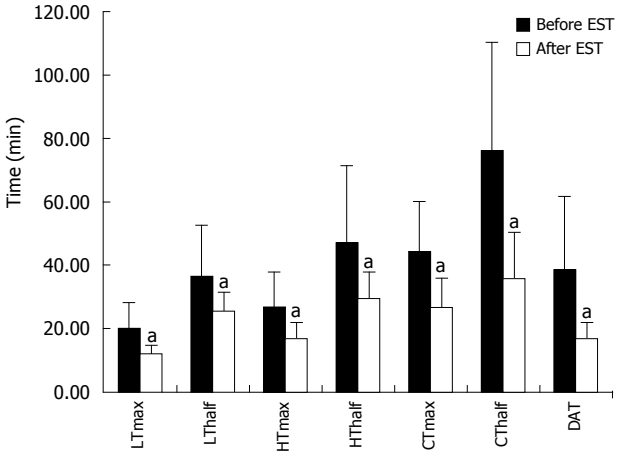

**Figure 5** Effect of endoscopic sphincterotomy on the quantitative parameters of hepatobiliary scintigraphy in patients with definite SOD. Note that all parameters depicts significant improvement of the transpapillary bile flow after papillotomy. [a]*P* < 0.05 *vs* before EST.

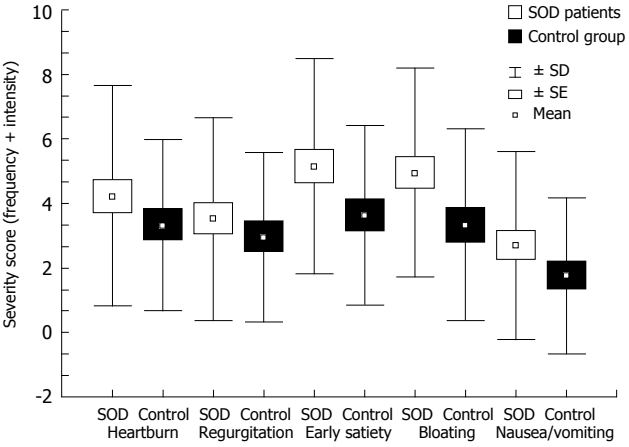

**Figure 4** Comparison of the severity of dyspeptic symptoms (sum of frequency and intensity) determined by VAS in patients with definite SOD and in postcholecystectomy controls. Note that in patients with definite SOD, dyspeptic symptoms were rather frequent coexisting symptoms accompanied with typical biliary pain, although no significant differences detected as compared to "asymptomatic" cholecystectomized controls.

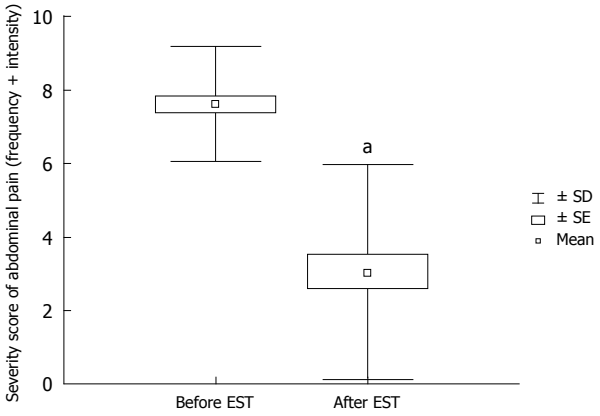

**Figure 6** Dramatic and significant symptomatic improvement of patients with definite SOD determined by the comparison of severity scores (sum of frequency and intensity) of abdominal pain before and after papillotomy documented on the questionnaires (VAS). [a]*P* < 0.05 *vs* before EST.

symptoms associated with biliary-pain was found as compared to controls (Figure 4). The most prevalent dyspeptic symptom was early satiety and bloating, followed by heartburn, regurgitation and nausea or vomiting. Although there was an obvious tendency of higher dyspeptic scores in definite SOD patients, none of the separate symptom scores reached the level of significance as compared to cholecystectomized controls. The prevalence of antral gastritis and *Helicobacter* infection was similar in patients with definite SOD versus in patients with SOD negative PCS: 77% and 27% *vs* 87% and 25%, respectively. No statistical difference was detected between these groups, indicating that dyspeptic symptoms had no relation to antral predominant gastritis or *H pylori* infection in these cholecystectomized patients.

Thirty-five out of 40 patients with definite SOD (SOD I and ESOM positive) were followed up after EST with QHBS and a repeated questionnaire. The median follow up time was 7.5 mo. When the post-EST results of QHBS were compared to the baseline QHBS study (before EST) we detected significant acceleration of all measured quantitative scintigraphic parameters corresponding to both hepatic secretion and transpapillary bile flow (Figure 5). As expected, the EST induced acceleration of the transpapillary bile flow caused a dramatic improvement in the parameters of CBD emptying (Tmax and Thalf), and also the DAT. Based on the comparison of VASs from the pre- and post-EST questionnaires, an impressive and highly significant improvement in the severity scores of abdominal pain was established (Figure 6), which was an obvious demonstration of the therapeutic benefit of EST in these patients with definite SOD. It must be stressed that despite homogenous improvement of biliary pain after endoscopic therapy, only 15 of 35 patients became completely free of pain after EST.

Finally, we categorized our patients based on initial presentation of dyspeptic symptoms into two groups: no or minimal dysmotility in 20 patients (less than 50%

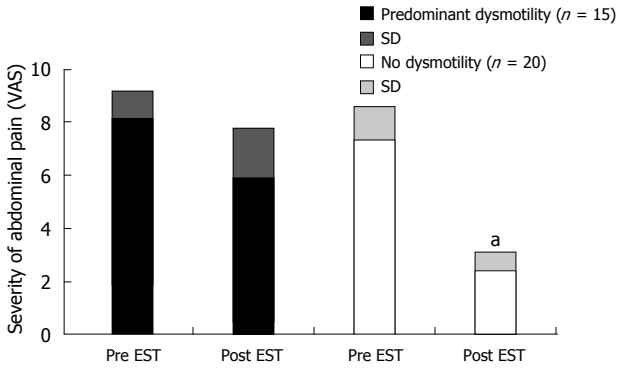

**Figure 7** Effect of the severity of the concomitant dyspeptic symptoms in patients with biliary-type pain and definite SOD on the post-papillotomy outcome. $^{a}P < 0.05$ *vs* those without dyspeptic symptoms.

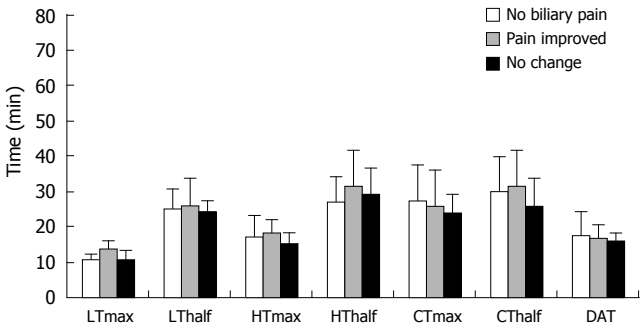

**Figure 8** Comparison of post-papillotomy quantitative hepatobiliary scintigraphic parameters in patient groups with different symptomatic outcome. Lack of statistically significant differences excluded endoscopic technical problems (incomplete papillotomy) in patients with poor symptomatic outcome and persisting biliary pain.

of total dysmotility scores according to the baseline questionnaire), and severe dysmotility in 15 patients (more than 50% of total dysmotility scores on the baseline questionnaire). Interestingly the severity of dyspeptic symptoms before EST was significantly correlated with the symptomatic failure of endoscopic therapy. In fact, we have demonstrated that post-EST severity of abdominal pain based on VASs was significantly higher in those patients with predominant dyspepsia at initial presentation as compared to those without dyspeptic symptoms (Figure 7). This difference in the post-EST outcome was not induced by possible endoscopic technical problems or patient-to-patient variation of the completeness of EST, since the analysis of post-EST QHBS parameters demonstrated no significant differences of these patient groups (Figure 8). No statistical differences were found in the prevalence of gastritis and *H pylori* infection between patients with no or minimal versus predominant dysmotility scores: 80% and 26% *versus* 64% and 27%, respectively. In fact, patients with predominant dysmotility scores had a lower frequency of antral gastritis detected by upper GI endoscopy.

Although there was a tendency for higher psychogenic vulnerability in those patients with definite SOD (SOD Ⅰ and ESOM positive SOD groups), no significant differences were detected when the results of patients were compared to asymptomatic cholecystectomized controls or those with CBD stone. Interestingly, the highest scores of symptom-stress association was detected in those patients belonged to the ESOM positive SOD group, but the patient population was not large enough to reach the level of significance.

## DISCUSSION

Historically, transduodenal biliary sphincteroplasty with transampullary septoplasty has been recommended for the therapy of SOD with a reported symptomatic benefit in 60%-70% of patients during a 1 to 10 years' follow-up[9]. Because of better patient tolerance, lower cost and less long-term re-stenosis endoscopic therapy has widely replaced surgical therapy. According to recent follow-up studies, EST produced a symptomatic relief in 55%-93% of patients with SOD and elevated SO basal pressure documented on ESOM[10-13]. This wide variation in therapeutic response after EST may reflect variations in patient groups treated, but more importantly, differences in criteria used to determine the benefit. Only a few studies evaluated the percentage of improvement after EST in patients with SOD[10,13], but most studies in the literature have applied only qualitative endpoints of symptomatic relief[3-5,11,12]. In the present study, we analysed the effect of EST on the severity scores of abdominal pain assessed by VAS, which demonstrated a homogenous and highly significant improvement in severity scores after EST in patients with definite SOD. In contrary, only 43% of these definite SOD patients became completely pain free after EST. Similar to the findings of Linder *et al*[6], our study clearly demonstrates that although EST does evoke a pain score reduction, complete pain relief is a relatively rare and fortunate outcome in these postcholecystectomy patients. This may be explained by the fact, that similar to patients with irritable bowel syndrome and other chronic functional pain syndromes of GI tract, the pathogenic mechanism of pain in SOD patients is more complex. Dysmotility of the SO is probably only one of the pathogenic components that are frequently accompanied by abnormalities of central nervous system, such as visceral hyperalgesia and hypersensitivity of the sensory receptors.

QHBS is a useful non-invasive method in the diagnosis of SOD by visualizing the consequent partial biliary obstruction, and according to some recent data, there is a highly significant correlation between SO basal pressure and quantitative parameters of transpapillary bile emptying[8,13]. Although the equality of QHBS and ESOM is not generally accepted in the literature[14] due to problems in reproducibility and lack of standardized methodology of QHBS, it is obvious that QHBS is an optimal non-invasive screening method to assess the presence of impaired transpapillary bile flow in SOD patients. Recently, some studies unexpectedly stated that in a certain postcholecystectomy patient population abnormal QHBS is a better predictor for favourable post-EST outcome than abnormal ESOM[13,15]. QHBS has obvious advantages as compared to the traditional ERCP contrast drainage time, as it is cheaper, non-invasive, less time-consuming and prevents unnecessary repeated ERCPs in that patient group, which has an inherent high

risk of post-ERCP complication[16]. Therefore, we suggest a new modified non-invasive SOD classification strategy, where patients must have an adequate biliary pain history, such as our validated questionnaire[17], some relevant LFTs, a QHBS to study bile flow, and an MRCP or endoscopic US to measure bile duct diameter. Based on these data one could be able to classify SOD patients similarly to the original Milwaukee system, but without ERCP and post-ERCP complication.

Although it is rarely mentioned and applied, QHBS is also applicable in the follow-up of SOD patients, to demonstrate the acceleration or normalization of the transpapillary bile flow after EST[13,18-20]. Similar to the study of Corazziari *et al*, in the present study we proved a significant acceleration of all quantitative parameters of QHBS after EST in definite SOD patients as compared to the initial study before ERCP. Interestingly, there was no correlation between the patient general symptomatic improvement or satisfaction and the normalization or improvement in QHBS parameters. Therefore, it seems that there is a patient subpopulation with definite SOD and having biliary pain accompanied with predominant dyspeptic symptoms, which has poor therapeutic response after EST and therefore a general dissatisfaction with endoscopic therapy, despite an effective and complete EST (normalization of transpapillary bile flow on QHBS) performed.

It has been demonstrated by surgical studies, that pain after cholecystectomy was significantly correlated with the concurrent presence of symptoms of dysmotility and dyspepsia[7]. Similarly, our current results demonstrated that post-EST intensity of persistent pain in patients with definite SOD was significantly more severe in the patients with predominant dyspepsia at the initial presentation. Interestingly, there was no correlation between dysmotility and dyspeptic symptoms and the prevalence of antral gastritis or *Helicobacter* co-infection in these patient groups. In comparison to the public data of the general population in Hungary, our patients had a higher prevalence of antral gastritis but a lower prevalence of *H pylori* infection. As a possible explanation, we may consider that duodenogastric bile reflux is a significant cause of gastritis in these postcholecystectomy patients, which might also partially prevent *H pylori* colonization[21]. Whether patients having postcholecystectomy pain are more sensitive to dysmotility and dyspeptic complaints, or they are dyspeptic in origin is unclear. Some studies suggested that the mechanism of dyspeptic symptoms after cholecystectomy might be related to the increased duodenogastric reflux[22]. However, the effect of EST on the volume of duodenogastric reflux is unclear.

In conclusion, EST evokes a significant improvement of pain severity scores in all patients with definite SOD (selected by ERCP or ESOM), but only 43% of these patients became pain free. Persistent gastrointestinal symptoms and general patient dissatisfaction are rather common findings after EST, and correlated with the presence of predominant dyspeptic symptoms at the initial presentation, however, they do not depend on the technical and functional success of EST. Application of a validated questionnaire at the patient selection for EST and the follow up can be extremely useful in all patients having postcholecystectomy syndrome.

## Abstract

**AIM:** To examine the allegations in malpractice litigations related to gastrointestinal endoscopy in Japan.

**METHODS:** A retrospective review of cases tried in the civil court system during the 21-year period from 1985 to 2005, identified in a computerized legal database, was undertaken.

**RESULTS:** Eighteen malpractice litigations and a total of 30 allegations were identified. Of the 18 (44%) malpractice litigations, 8 (44%) were related to esophagogastroduodenoscopy, 4 (22%) to colonoscopy, 4 (22%) to endoscopic sphincterotomy, and 2 (11%) to endoscopic retrograde cholangiopancreatography. Seventeen (94%) cases pertained to complications, and the remaining (6%) case pertained to misdiagnosis. In 10 cases, the patient died of the complications. Allegations were categorized as: (1) performance error during the endoscopic procedure ($n$ = 12, 40%); (2) lack of informed consent ($n$ = 9, 30%); (3) performance error during the treatment after the endoscopic procedure ($n$ = 4, 13%); (4) premedication error ($n$ = 3, 10%); (5) diagnostic error ($n$ = 1, 3%); and (6) indication error for the endoscopic procedure ($n$ = 1, 3%).

**CONCLUSION:** These data may aid in the design of risk prevention strategies to be used by gastrointestinal endoscopists.

**Key words:** Gastrointestinal endoscopy; Malpractice; Litigation; Risk management

## INTRODUCTION

The number of negligence litigations against physicians has been continuously increasing, not only in Western countries but also in Japan[1,2] where a 10-fold increase in malpractice litigations from 102 to 1019 cases per year, has been observed between 1960 and 2003. As the frequency of malpractice claims has risen, physicians have begun to focus on risk management activities. Gastrointestinal endoscopy plays an important role in medical practice. Not only is simple endoscopic examination performed, but also treatment procedures such as endoscopic polypectomy, endoscopic mucosal resection and endoscopic sphincterotomy (EST) are performed. However, various complications associated with these procedures have been reported[3,4]. Thus, gastrointestinal endoscopy is a field in which malpractice actions frequently occur[1,2,5-13].

Furthering the awareness of physicians may be one method of reducing the number of malpractice claims. However, little is known about the allegations underlying medical malpractice litigations in Japan or about those pertaining to gastrointestinal endoscopy in particular. To identify the allegations in malpractice litigations pertaining to gastrointestinal endoscopy, we undertook a review of all Japanese civil court trials from 1985 to 2005 that involved gastrointestinal endoscopy. Our goal was to extract medical information from published court reports to determine the types of gastrointestinal endoscopist errors in these cases.

## MATERIALS AND METHODS

A listing of Japanese civil court trials pertaining to gastrointestinal endoscopy from 1985 to 2005 was retrieved from a computerized legal database (MASTER Library, Shinnippon-hoki Publishing, Tokyo, Japan). Published reports of court decisions in these cases were then obtained from volumes of judicial precedents, and medical information was abstracted from these precedents.

**Table 1 Litigations related to gastrointestinal endoscopy in Japan, 1985-2005**

| | Procedure | Complication/diagnostic error | Allegation 1 | Decision | Allegation 2 | Decision | Allegation 3 | Decision |
|---|---|---|---|---|---|---|---|---|
| 1 | ERCP | Death due to peritonitis induced by duodenal perforation | Performance error during procedure | P | | | | |
| 2 | EGD | Massive hemorrhage | Performance error during procedure | L | | | | |
| 3 | EGD | Death due to premedication shock | Premedication error | P | | | | |
| 4 | Colonoscopic polypectomy | Colonic perforation | Indication error | L | Lack of informed consent | P | | |
| 5 | Colonoscopy | Colonic perforation | Performance error during procedure | P | | | | |
| 6 | EST | Death due to pancreatitis | Performance error during procedure | L | Performance error after procedure | P | | |
| 7 | EGD | Death due to premedication shock | Premedication error | L | Lack of informed consent | L | | |
| 8 | EGD | Massive hemorrhage | Performance error during procedure | P | | | | |
| 9 | EGD removal of foreign body | Unexpected emergent surgery due to fixation of foreign body | Lack of informed consent | P | Performance error during procedure | P | | |
| 10 | EGD | Traffic accident due to the effect of sedative agent | Lack of informed consent | P | | | | |
| 11 | EGD | Death due to premedication shock | Premedication error | L | Lack of informed consent | P | | |
| 12 | Colonoscopy | Colonic perforation | Performance error during procedure | L | Lack of informed consent | P | | |
| 13 | EGD | Misdiagnosis of gastric cancer | Diagnostic error | P | | | | |
| 14 | EST | Death due to pancreatitis | Performance error during procedure | L | Performance error after procedure | L | Lack of informed consent | L |
| 15 | EST | Death due to pancreatitis | Performance error during procedure | L | Performance error after procedure | L | Lack of informed consent | L |
| 16 | ERCP | Death due to pancreatitis | Lack of informed consent | L | Performance error during procedure | P | Performance error after procedure | P |
| 17 | Colonoscopy | Colonic perforation | Performance error during procedure | P | | | | |
| 18 | EST | Death due to peritonitis induced by duodenal perforation | Performance error during procedure | P | | | | |

ERCP: Endoscopic retrograde cholangiopancreatography; EGD: Esophagogastrodudenoscopy; EST: Endoscopic sphincterotomy. P: The claim prevailed; L: The claim was lost.

All allegations of negligence were assigned to 1 of the 6 categories: (1) performance error during the endoscopic procedure, (2) lack of informed consent, (3) performance error during treatment after the endoscopic procedure, (4) premedication error, (5) diagnostic error, and (6) indication error for the endoscopic procedure. Court decisions were also considered.

## RESULTS

Eighteen cases and 30 allegations related to gastrointestinal endoscopy were identified (Table 1). Of the 18 cases, 8 (44%) were related to esophagogastroduodenoscopy (EGD), 4 (22%) to colonoscopy, 4 (22%) to EST, and 2 (11%) to endoscopic retrograde cholangiopancreatography (ERCP). Seventeen (94%) cases pertained to complications, and the remaining (6%) case pertained to misdiagnosis. In 10 cases, the patient died of complications. Perforation was identified in 4 cases, massive hemorrhage in 2 cases, a traffic accident due to the effect of a sedative agent in 1 case, and emergency surgery in 1 case (Table 2). Allegations were as follows: (1) performance error during the endoscopic procedure, $n$ = 12 (40%); (2) lack of informed consent, $n$ = 9 (30%), (3) performance error during treatment after the endoscopic procedure, $n$ = 4 (13%); (4) premedication error, $n$ = 3 (10%); (5) diagnostic error, $n$ = 1 (3%), and (6) indication error for the endoscopic procedure, $n$ = 1 (3%).

In cases related to performance error during the endoscopic procedure, the most frequent procedure was EST (4 cases, 33%) followed by colonoscopy (3 cases, 25%). In all cases related to EST, the patients alleged performance error due to bad technique. Three of the 4 (75%) patients who underwent EST had severe acute pancreatitis after the procedure. The fourth patient died of panperitonitis due to duodenal perforation during the procedure. The 3 cases related to colonoscopy had colonic perforation during the procedure. In these 12 cases, allegations prevailed in 7 (58%) cases.

In cases related to lack of informed consent, 8 of the 9 (89%) allegations involved failure to warn the patient of risks of the procedure, such as possible pancreatitis after ERCP and EST, or the side effects of premedication. In the case related to the side effects of premedication, there were no documented instructions prohibiting driving after endoscopic sedation in the hospital. The remaining case had a foreign body in the patient's stomach, namely an artificial tooth that was 5 cm in length with sharp edges. Because both edges of the tooth were lodged in the esophageal wall during attempted endoscopic removal, the endoscopists abandoned the procedure and performed emergency surgery to remove the tooth. In this case, the

**Table 2 Complications referred to in the litigations ($n$ = 17)**

| Complication | $n$ (%) |
|---|---|
| Death | 9 (53) |
| Shock due to premedication of EGD | 3 (18) |
| Severe acute pancreatitis due to ERCP | 1 (6) |
| Panperitonitis due to duodenal perforation during ERCP | 1 (6) |
| Severe acute pancreatitis due to EST | 3 (18) |
| Panperitonitis due to duodenal perforation during EST | 1 (6) |
| Perforation | 4 (24) |
| Colonoscopy | 3 (18) |
| Colonoscopic polypectomy | 1 (6) |
| Massive hemorrhage after EGD | 2 (12) |
| Traffic accident due to the effect of a sedative used for EGD | 1 (6) |
| Unexpected emergency surgery due to lodging of a foreign body | 1 (6) |

EGD: Esophagogastroduodenoscopy; ERCP: Endoscopic retrograde cholangio-pancreatography; EST: Endoscopic sphincterotomy.

allegation was lack of information about the possible need for emergency surgery. The issue of informed consent never stands alone. In these 9 cases, allegations prevailed in 5 (44%) cases.

Three of the 4 (75%) cases of performance error during treatment after the endoscopic procedure were related to EST, and the remaining case was related to ERCP. All patients in these cases died of severe acute pancreatitis after the procedure. Diagnostic delay and inappropriate treatment to prevent pancreatitis were also alleged. The allegations prevailed in 2 of the 4 (50%) cases.

All of the premedication errors were related to EGD. All patients in these cases suffered shock just after administration of anesthesia or anti-cholinergic agent. Anaphylactic shock was diagnosed in the first 2 cases and acute poisoning due to overadministration of lidocaine was diagnosed in the third case. The allegations prevailed in 1 of the 3 (33%) cases.

The case of diagnostic error was related to misdiagnosis of scirrhous gastric cancer. The patient's stomach was not completely empty during EGD, thus complete gastric examination was not performed. However, the doctor diagnosed gastritis and did not re-examine the patient. She had scirrhous gastric cancer and died 6 mo after the examination. Her family alleged that the doctor overlooked the gastric cancer. The allegation prevailed.

The case of indication error was related to colonic polypectomy. In this case, colonic perforation occurred after colonoscopic polypectomy. The patient alleged that there was no indication for treatment, the allegation was lost.

## DISCUSSION

Medical malpractice has become a predominant concern of physicians in Japan as well as in Western countries. Clinical risk management is the process of collecting, evaluating, and applying data to reduce the frequency of preventable patient injuries[8]. Although general risk management information is abundant in the medical and lay literature, published material specific to gastrointestinal endoscopy is limited to editorials and case presentations[8]. The literature describes various adverse events associated with endoscopy. However, these reports focus on the frequency and nature of procedural complications, avoiding issues of negligence[3,4]. Endoscopists need an understanding of malpractice allegations to develop appropriate risk-reduction strategies for gastrointestinal endoscopy.

In the present study, the most frequent procedure was EGD (39%), followed by EST (22%), colonoscopy (17%), and ERCP (11%). However, according to a Japanese report[2], EGD has been performed 47 times as often as ERCP and 3.5 times as often as colonoscopy. The number of EST procedure is approximately one-tenth that of ERCP. Therefore, the relative frequency of litigation in Japan may be the highest in relation to EST, followed by ERCP and colonoscopy. Additionally, the mortality and complication rates of all endoscopies in Japan have been reported to be 0.00084% and 0.018%, respectively[2]. The mortality rate has been reported to be 0.00045% for EGD and 0.048% and 0.0063% for EST and ERCP, respectively[2]. Given these data showing the remarkable safety of endoscopy, serious complications naturally raise the issue of substandard care. However, an analysis in USA that was derived from an insurance industry database showed that the relative risks of malpractice claims arising from the performance of EGD, ERCP, and colonoscopy are similar[14]. Thus, the relative frequency of litigation may be higher in relation to EST and ERCP in Japan but not in USA. One possible explanation for this discrepancy may be the bias of claims filed against the insurance industry in USA. Another possibility is that strict informed consent may be obtained for EST and ERCP in USA. because of a high frequency of related adverse events. Sufficient information about the adverse events associated with these procedures may decrease litigations.

Performance error during the endoscopic procedure was the most frequent allegation in the malpractice litigations against endoscopists. The potential complications of endoscopy are known to be numerous and well documented. The significant risk of adverse events should be emphasized during the informed consent process[15-17]. Disclosure results in a sharing of risk between the endoscopist and patient may be protective for the endoscopist.

The second most frequent allegation was lack of informed consent. Studies have shown that increased communication reduces malpractice risk, thus the process of informed consent can be a useful tool for reducing this risk[7]. The process of disclosing the inherent risks of a procedure or a medical treatment decision essentially asks the patient to accept those risks as part of the medical plan and procedure. The risk shift does not apply to substandard care, but it would apply to many of the complications that can occur even when procedures are performed properly and medications are administered prudently.

The one diagnostic error in the present study pertained to misdiagnosis of gastric cancer. This case illustrates how an opportunistic diagnosis without complete examination can lead to charges of malpractice[18]. If a complete examination is not performed, doctor should recommend re-examination.

Knowledge of the factors leading to preventable patient injury is needed to develop optimal strategies for reducing malpractice risk related to gastrointestinal endoscopy. On the basis of our study results, we suggest the following risk prevention strategies to decrease the number of malpractice claims related to gastrointestinal endoscopy practice.

First, documenting possible complications during the informed consent process is essential. Complications during endoscopy frequently lead to litigation, especially if the possibility of such complications has not been discussed with the patient in advance.

Second, continued training in safe endoscopic techniques remains the principal method of preventing such complications. For example, participation in morbidity and mortality conferences may help physicians improve their diagnostic and therapeutic skills. Neale[7] examined malpractice claims against gastroenterologists and reported that 44% arose from adverse events related to endoscopy and that there was evidence of serious fault in 50% of the cases, confirming the importance of continued medical education and training in safe endoscopic techniques.

Third, it is important to establish practice guidelines, especially in areas vulnerable to litigation. Such guidelines offer the best method of decreasing endoscopist errors leading to malpractice litigation.

Fourth, endoscopists should recognize that delayed diagnosis of a disease, particularly malignancy, is the most common cause of litigation. Improving the diagnostic ability of endoscopists is essential. In some cases, other modalities such as radiologic and ultrasonographic methods, may aid in prompt and correct diagnosis. Use of other modalities in cases for which a definite diagnosis is not obtained may ensure proper treatment.

In Japan as in USA, most malpractice cases are settled out of court. It has been reported that approximately 90% of malpractice cases in Japan are settled out of court, and the remaining cases lead to litigations[19]. The court decisions are given in only approximately 30% of litigated cases. The compromised and withdrawn cases are not reported or available for review. Therefore, the denominator of the present study might have some bias. However, the aim of this study was to extract medical information from published court reports to determine the sources of endoscopy-related errors in cases requiring litigation. It is hoped that dissemination of the results of the present study among endoscopists can serve as a risk prevention strategy for reducing both complications and malpractice claims pertaining to gastrointestinal endoscopy.

## Abstract

**AIM:** To assess the efficacy of different schedules of consensus interferon (CIFN) plus ribavirin in retreating chronic hepatitis C patients who relapsed after recombinant interferon (rIFN) monotherapy.

**METHODS:** Forty-five patients (34 males and 11 females) with chronic hepatitis due to hepatitis C virus (HCV) genotype 1 who relapsed after a previous course of rIFN monotherapy were randomized to receive 9 μg CIFN three times per week for 52 wk (group A, *n* = 22) or 18 μg CIFN three times per week for 52 wk (group B, *n* = 23) in combination with ribavirin 800 to 1200 mg daily for 52 wk (according to body weight). Virological response was evaluated at week 24 (EVR), at the end of treatment (ETR) and at 76 wk (SVR).

**RESULTS:** By intention-to-treat analysis, subjects in group A had an EVR in 35% of cases, an ETR in 35% and a SVR in 27.3% of cases. Subjects in group B had an EVR in 32% of cases, an ETR in 35% and a SVR in 26.1% of cases. Treatment was stopped because of adverse effects (mostly intolerance) in 15 patients (6 in group A and 9 in group B). IFN dose reduction was needed in 2 patients (1 in group A and 1 in group B). Ribavirin dose was reduced in 2 patients in group A and 1 in group B respectively. Among the 15 subjects who received at least 80% of the intended schedule, the rate of SVR was 80% (6 in group A and 6 in group B).

**CONCLUSION:** CIFN in combination with ribavirin when given to HCV genotype 1 relapsers after rIFN monotherapy obtains an unsatisfactory rate of sustained viral clearance independently of dosage of the drug. This may be due to its scarce tolerability.

**Key words:** Interferon; Ribavirin; Hepatitis C virus; Hepatitis C; Relapser

## INTRODUCTION

Retreatment of hepatitis C patients who relapsed after recombinant interferon (rIFN) monotherapy has a fair rate of success when ribavirin is added to the original protocol. About 30% of patients infected with hepatitis C virus (HCV) genotype 1 can clear their viral infection when retreated with rIFN plus ribavirin[1]. The efficacy of pegylated IFN (PEG-IFN) in this context has not been explored in large phase Ⅲ registration trials, but an increased effectiveness has been shown in investigator-driven smaller trials. Lawitz *et al*[2] have recently obtained a sustained viral response of 38% in HCV genotype 1 relapsers (24 out of 63 patients) upon retreatment with PEG-IFN plus ribavirin.

Consensus interferon (CIFN) is an engineered IFN α molecule containing the most frequently occurring amino acids among the non-allelic IFN α subtypes[3]. It was reported that CIFN can significantly decrease HCV-RNA in naïf patients with chronic hepatitis C as compared with IFN α -2b[4]. It is thus conceivable that this increased antiviral effect can lead to a better rate of HCV clearance in subjects with a former incomplete response to other types of IFN. Heathcote *et al*[5] found that CIFN monotherapy at a dose of 9 mg three times per week, can obtain a SVR in 39% (24 wk) and 52% (48 wk) of relapsers as compared to rIFN that can obtain a SVR in 12% (24 wk) and 17% (48 wk) of relapsers.

In order to further clarify the role of CIFN in retreatment, we explored its efficacy at different doses in combination with ribavirin in subjects with chronic hepatitis infected with HCV genotype 1 who relapsed after a course of rIFN monotherapy.

## MATERIALS AND METHODS

### Patients

Subjects enrolled between January and December 2001, were eligible if they had the following criteria: age 18-65 years, abnormal alanine aminotransferases (ALT), HCV-RNA positive by PCR (Amplicor® HCV, Roche Diagnostic Systems, Basel, Switzerland), genotype 1. All patients received monotherapy with rIFN (alfa-2a or alfa-2b) with an end-of-treatment virological response (HCV-RNA negative by PCR) and subsequent virological and biochemical relapse prior to this study.

Exclusion criteria were: decompensated cirrhosis, hepatocellular carcinoma, autoimmune hepatitis and other autoimmune diseases, metabolic liver diseases (Wilson's disease, haemochromatosis, α-1-antitripsin deficiency), active drug addiction or alcohol abuse, HBV and/or HIV infection, decompensated diabetes mellitus, haemoglobin concentration at baseline less than 120 g/L in women and 130 g/L in men, platelets below 100 000/mm$^3$ and white blood cells (WBC) below 3000/mm$^3$.

The study design was approved by the University's Ethical Committee. Patients provided their written informed consent before entering the study. All subjects after starting treatment were monitored as outpatients. All had a liver biopsy within 12 mo before starting treatment.

### Treatment schedule

All patients were randomized into two groups: group A ($n$ = 22) received 9 μg CIFN plus ribavirin while group B ($n$ = 23) received 18 μg CIFN plus ribavirin three times per week for 52 wk. Dose of ribavirin ranged according to body weight (800 mg < 65 kg, 1000 between 65 and 75 kg, 1200 > 75 kg). Treatment was stopped if HCV-RNA was still positive at 26 wk.

Patients were seen monthly up to the end of 24 wk post-treatment follow-up. At each visit symptoms and adverse event were recorded, physical examination, and biochemical tests were performed, and a serum sample was collected and stored at -80℃ for virology.

All blood tests were performed at our hospital laboratory. HCV-RNA was determined by qualitative and/or quantitative assays (Amplicor® HCV and Monitor® HCV, ver. 2.0, Roche Diagnostic Systems, Basel, Switzerland) with a detection limit of 100 (Amplicor®) and 1000 (Monitor®) genomes/mL.

The effects of treatment were evaluated in patients who obtained an ETR: early virological response (EVR): HCV-RNA negative after 24 wk of treatment; end-of-treatment response (ETR): HCV-RNA negative at the end of 52 wk of treatment; sustained virological response (SR): HCV-RNA negative 24 wk after stopping therapy.

### Statistical analysis

Statistical analysis was performed by using SPSS software version 11.0.1 for Windows. Means and standard deviation were calculated for continuous variables. The differences in mean values for each group were assessed by using the parametric Student's $t$ test for unpaired data. The statistical significance of differences between subgroups of patients was analyzed using the chi square test for categorical data. Statistical significance was set at $P < 0.05$. Positive predictive value (PPV) was defined as the percent of patients who were observed to have SVR out of the patients predicted to have SVR by a certain criterion (HCV-RNA suppression at the end of therapy).

**Table 1 HCV-RNA clearance at different time points in 2 groups after treatment $n$ (%)**

EVR: Early virological response; ETR: End-of-treatment response; SVR: Sustained virological response; NS: Not significant.

## RESULTS

### Features of patients

Forty-five subjects were enrolled between January and December 2001. All patients were infected with HCV genotype 1, and had relapse after an EVR to rIFN monotherapy given 3 to 9 years before. Four subjects had blood transfusions and 4 had a history of i.v. drug abuse, but 37 subjects did not have major risk factors. Twenty-two patients were randomized into group A and twenty-three into group B. The mean age of patients was 41.9 ± 10.9 years. Liver biopsy showed that 3 patients had severe fibrosis (F3 by METAVIR) and 2 had cirrhosis (F4).

### Efficacy of treatment

At 24 wk 9 patients (4 in group A and 5 in group B) discontinued their therapy because they were still HCV-RNA positive. An ETR was observed at 52 wk in 15/45 patients (33.3%) and evolved into a SVR at 76 wk in 12/45 patients (26.6%). At all time points the highest dose of CIFN was not better in obtaining suppression of HCV-RNA replication (ETR: 31.8% in group A *vs* 34.8% in group B, $P$ = NS) and had ultimately a sustained viral clearance (SVR: 27.3% in group A *vs* 26.1% in group B, $P$ = NS, Table 1). The overall PPV value for SVR of negative HCV-RNA in patients with ETR was 80%.

ALT values (Table 2) were comparable between the two groups at different time points. ALT levels became normal under treatment in a number of patients who were still HCV-RNA positive. However, the concordance between ALT and HCV-RNA at 76 wk was 100% in both groups.

### Tolerability and safety

Treatment was stopped in 15 patients (6 in group A and 9 in group B). Five subjects in group A and 7 in group B stopped therapy between wk 1 and 12 (early withdrawal,

**Table 2 ALT normalization at different time points in 2 groups after treatment *n* (%)**

EVR: Early virological response; ETR: End-of-treatment response; SVR: Sustained virological response; NS: Not significant.

EW), 1 in group A and 2 in group B between wk 13 and 52 (late withdrawal LW). Reasons for EW and LW were severe flu-like symptoms and depression.

Reduction of the CIFN dose was needed in two subjects (1 in group A and 1 in group B). Reduction of the ribavirin dose was needed in 2 subjects of group A and 1 subject of group B. Overall, 7 subjects in group A and 8 in group B received at least 80% of the intended cIFN dose and at least 80% of the intended RBV dose. Among these ideally treated patients, the overall rate of SVR was 80% (6 in group A and 6 in group B).

## DISCUSSION

Our results do not support a major usefulness of cIFN in retreatment of patients who had a relapse after IFN monotherapy. ITT analysis was able to obtain a SVR only in 26.7% of all patients, without any clear dose. effect in favor of higher doses. Treatment was not particularly well tolerated, since one third of the patients discontinued their regimen, mostly in its early phase due to adverse reactions. When a reasonable compliance to the intended treatment schedule was obtained, the success rate was markedly higher. The main problem in our study was thus the scarce tolerability of combination therapy even at low CIFN doses.

CIFN was assessed in the patients who did not respond to previous courses of IFN. Lindsay[5], who reviewed the comparative virological efficacy of different interferons, stated that in patients who respond to an initial course of alpha interferon and then have a relapse, retreatment with cIFN for 48 wk obtains a high sustained virological response rate, which is similar to that with interferon alpha-2b combined with ribavirin for 24 wk[6]. An Italian group[7] later reported that cIFN given at a dose of 9 g, 5 times per week for 36 wk could obtain a sustained response in 5 out of 12 subjects (42%) who relapsed after combination therapy with interferon alpha-2b and ribavirin. Recently Moskovitz *et al*[8] found that high dose induction therapy with 15 g cIFN/day in prior non-responders to IFN -2b and ribavirin could lead to loss of detectable HCV-RNA in 50% of patients, but this response is only sustained in 8% of patients (2 out of 24) at the end of therapy. Successful retreatment of IFN/RBV non-responders has been reported by Kaiser *et al*[9], who assessed the efficacy of cIFN daily dosing and induction therapy followed by ribavirin combination treatment in 182 (92% genotype 1) non-responders to former combination therapies. cIFN was given at the dose s of 27, 18 or 9 μg for 4 wk, followed by a reduction to 9 μg for 8 wk in the two higher dosed arms. The sustained SVR was 38%-45% in standard interferon/ribavirin non-responders and 27%-31% in PEG-IFN/ribavirin non-responders. The cIFN dose was reduced in 16%-21% of patients and discontinued in 7%-9% of patients. A randomized controlled trial comparing cIFN plus RBV to standard alfa IFN plus RBV in naïf patients[10] has found a lower rate of treatment withdrawal (less than 10% withdrawals, and treatment within an 80/80/80 schedule achieved in ¾ of all patients). This study also showed that the efficacy of cIFN was higher than that of standard IFN-2b in combination therapy of naïf patients (SVR: 57% *vs* 40%).

The reason for the high rate of treatment interruption in our population is not clear. It was reported that when a formal comparison with IFN-2b was performed in the context or in relapsers after IFN monotherapy[11], the rate of SVR is 58% *vs* 29% in favor of cIFN. However, the overall treatment period was shorter (6 mo for both treatment arms) and 5% of the patients were treated with cIFN and 18% of those on IFN-2b were not infected with HCV genotype 1. Our study could not evaluate whether the low adherence is intrinsic to the drug regimens or attributable to patient-related factors. Since most withdrawals were decided early during therapy at a time when both the patient and the physician were not aware of any virological outcome, and some of these patients had normal or reduced ALT, it is unlikely that any perceived ineffectiveness of therapy may have influenced this choice. An issue that may potentially interfere with the treatment effectiveness is the concurrent diffusion of PEG-IFN based regimens, which are perceived as more tolerable and effective during the period of study. This fact might have oriented the decision of some patients or caregivers to stop therapy in order to receive the newest drug. Since the ultimate results with cIFN are not superior to those with PEG-IFN in the setting of combination therapy, we see no reason to further consider this drug in retreatment of HCV relapsers.

## Abstract

**AIM:** To determine the insulin resistance (IR) and oxidative status in *H pylori* infection and to find out if there is any relationship between these parameters and insulin resistance.

**METHODS:** Fifty-five *H pylori* positive and 48 *H pylori* negative patients were enrolled. The homeostasis model assessment (HOMA) was used to assess insulin resistance. Serum total antioxidant capacity (TAC), total oxidant status (TOS) and oxidative stress index (OSI) were determined in all subjects.

**RESULTS:** The total antioxidant capacity was significantly lower in *H pylori* positive group than in *H pylori* negative group (1.36 ± 0.33 and 1.70 ± 0.50, respectively; $P < 0.001$), while the total oxidant status and oxidative stress index were significantly higher in H pylori positive group than in *H pylori* negative group (6.79 ± 3.40 and 5.08 ± 0.95, and 5.42 ± 3.40 and 3.10 ± 0.92, respectively; $P < 0.001$). Insulin resistance was significantly higher in *H pylori* positive group than in *H pylori* negative group (6.92 ± 3.86 and 3.61 ± 1.67, respectively; $P < 0.001$). Insulin resistance was found to be significantly correlated with total antioxidant capacity ($r = -0.251$, $P < 0.05$), total oxidant status ($r = 0.365$, $P < 0.05$), and oxidative stress index ($r = 0.267$, $P < 0.05$).

**CONCLUSION:** Insulin resistance seems to be associated with increased oxidative stress in *H pylori* infection. Further studies are needed to clarify the mechanisms underlying this association and elucidate the effect of adding antioxidant vitamins to *H pylori* eradication therapy on insulin resistance during *H pylori* infection.

**Key words:** *H pylori*; Insulin resistance; Total antioxidant capacity; Total oxidant status; Oxidative stress index

## INTRODUCTION

*H pylori* is a noninvasive, microaerophile, nonspore-forming, and spiral-shaped microorganism. *H pylori* is associated with severe gastric pathologies, including chronic active gastritis, peptic ulcer, gastric adenocarcinoma and type B low-grade mucosa-associated lymphoid tissue lymphoma[1].

*H pylori* infection causes inflammation, accumulation of reactive oxygen species (ROS), and oxidative DNA damage in gastric mucosa[1]. *H pylori* induces infiltration and activation of neutrophils and macrophages[2]. One characteristic event in inflammation is the infiltration of the affected tissue by neutrophils, which produce large amounts of ROS in host defence reactions. Enhanced ROS levels due to neutrophil infiltration and increased oxidative DNA damage have been reported in *H pylori*-infected patients[3-6]. The increased level of pro-oxidative factors and decreased level of antioxidants in severe oxidative stress can modulate many processes in gastric epithelium[2].

Although *H pylori* seems to be a cause for gastric focal inflammation, it can invade and colonize human stomach, and directly interact with gastric epithelial cells. Moreover, it is associated with non-gastrointestinal tract conditions such as atherosclerosis, insulin resistance, diabetes mellitus and some autoimmune diseases[1,7-9]. The association of *H pylori* infection with insulin resistance has been reported[10-12]. However, to our knowledge, the association between insulin resistance and oxidative status has not been previously investigated in *H pylori* infection.

The present study was, therefore, to determine the insulin resistance, systemic parameters of oxidative stress

and antioxidative system in *H pylori* infection and to find out if there is any relationship between oxidative status and insulin resistance in *H pylori* infection.

## MATERIALS AND METHODS

### Subjects

One hundred and three patients who underwent upper gastrointestinal endoscopy for evaluation of dyspeptic complaints and diagnosed as non ulcer dyspepsia were included in the present study. The patients were divided into two groups according to the presence of *H pylori* infection. Fifty-five patients were *H pylori* positive and 48 patients were *H pylori* negative. The study protocol was carried out in accordance with the Helsinki Declaration revised in 1989. All subjects were informed about the study protocol and written consents were obtained from all participants.

### Diagnosis of H pylori infection

During upper gastrointestinal endoscopy, 2 antral biopsy samples were taken for rapid urease test (CLO test) and histopathologic examination. *H pylori* was considered to be present when the rapid urease test and histological examination were positive. Biopsy samplesl were stained with hematoxylin and eosin for histopathological examination and evaluated according to the updated Sydney System[13]. The patient was considered to be *H pylori* negative if both rapid urease test and histological examination were negative. The diagnosis of *H pylori* infection was confirmed if both the urease test and histological examination were positive.

### Exclusion criteria

Exclusion criteria included recent gastrointestinal by-pass surgery, pregnancy, usage of supplemental vitamins several months prior to the study, *H pylori* eradication therapy, $H_2$ receptor antogonist or proton pump inhibitor within the last 4 wk or nonsteroidal antiinflammatory drugs (NSAIDs) within the last 2 wk prior to study, existence of diabetes mellitus, hyperlipidemia, hypertension, coronary artery disease, cerebrovascular disease, rheumatoid arthritis, renal disease, smoking, cancer, systemic or local infection.

### Samples

Blood samples were obtained following an overnight fasting. Samples were withdrawn from a cubital vein into blood tubes and immediately stored on ice at 4℃. The serum was then separated from the cells by centrifugation at 3000 r/min for 10 min.

### Laboratory methods

Serum glucose concentration was measured using commercial kits (Abbott®) in an autoanalyser (Aeroset®, Germany). Serum insulin levels were measured using an automated chemiluminescence autoanalyzer (Roche®).

### Measurement of serum total antioxidantc capacity

Total antioxidant capacity (TAC) of serum was determined using a novel automated measurement method as previously described[14]. In brief, hydroxyl radical which is the most potentbiological radical was produced. In the assay, ferrous ion solution which is present in the reagent 1 was mixed with hydrogen peroxide which is present in reagent 2. The sequential-produced radicals, such as brown-colored dianisidinyl radical cation produced by the hydroxyl radical, are also potent radicals. Using this method, antioxidative effect of the sample on the potent free radical reactions initiated by the produced hydroxyl radical, was determined. The assay achieved excellent precision values lower than 3%. The results were expressed as mmol Trolox equivalent/L.

### Measurement of total oxidant status

Total oxidant status (TOS) of serum was determined using a novel automated measurement method as previously described[15]. Oxidants present in the sample oxidized the ferrous ion-o-dianisidine complex to ferric ion. The oxidation reaction was enhanced by glycerol molecules abundantly present in the reaction medium. The ferric ion produced a colored complex with xylenol orange in an acidic medium. The color intensity, which could be measured spectrophotometrically, was related to the total amount of oxidant molecules present in the sample. The assay was calibrated with hydrogen peroxide and the results were expressed in terms of micromolar hydrogen peroxide equivalent per liter (μmol $H_2O_2$ equivalent/L).

### Determination of oxidative stress index

The ratio of TOS to TAC was accepted as the oxidative stress index (OSI). For calculation, the resulting unit of TAC was changed to mmol/L, and the OSI value was calculated according to the following formula[16]: OSI (arbitrary unit) = TOS (μmol $H_2O_2$ equivalent/L)/TAC (mmol Trolox equivalent/L).

### Insulin resistance

The insulin resistance index was calculated on the basis of fasting values for glycaemia and insulinemia, according to the homeostasis model assessment (HOMA)[17]: insulin resistance (HOMA-IR) = fasting insulinaemia (μU/mL) × fasting glycaemia (mmol/L)/22.5.

### Statistical analysis

All data were expressed as mean ± SD. Comparisons of parameters were performed with Student's *t* test and correlation analyses were performed using Pearson correlation test. $P < 0.05$ was considered statistically significant. Statistical analyses were performed by SPSS 11 statistical package.

## RESULTS

Demographic charesteristic of the subjects are shown in Table 1. There were no statistically significant differences between the two groups with regard to age, gender, and body mass indexi (BMI) and glucose level ($P > 0.05$) (Table 1).

Insulin and insulin resistance levels were significantly

**Table 1 Demographic and clinical data of *H pylori* positive and negative groups (mean ± SD)**

| Parameters | *H pylori* negative ($n$ = 48) | *H pylori* positive ($n$ = 55) | *P* |
|---|---|---|---|
| Age (yr) | 35 ± 15 | 37 ± 12 | NS |
| Sex (Female/Male) | 28/20 | 29/26 | NS |
| Body mass index (kg/m$^2$) | 22.5 ± 3.1 | 23.5 ± 1.6 | NS |
| Glucose (mg/dL) | 98.15 ± 14.97 | 97.71 ± 14.39 | NS |
| Insulin (μU/mL) | 3.61 ± 1.67 | 6.92 ± 3.86 | < 0.001 |
| HOMA-IR | 0.89 ± 0.47 | 1.67 ± 0.99 | < 0.001 |

IR: Insulin resistance; NS: Not significant.

**Table 2 Oxidative and antioxidative parameters in *H pylori* positive and negative groups (mean ± SD)**

| | *H pylori* negative ($n$ = 48) | *H pylori* positive ($n$ = 55) | *P* |
|---|---|---|---|
| TAC (mmol Trolox eq./L) | 1.70 ± 0.50 | 1.36 ± 0.33 | < 0.001 |
| TOS (μmol $H_2O_2$ equiv./L) | 5.08 ± 0.95 | 6.79 ± 3.40 | < 0.001 |
| OSI (arbitrary unit) | 3.10 ± 0.92 | 5.42 ± 3.40 | < 0.001 |

TAC: Total antioxidant capacity; TOS: Total oxidant status; OSI: Oxidative stress index.

higher in *H pylori* positive group than in *H pylori* negative group ($P < 0.001$) (Table 1).

TAC level was significantly lower in the patients *H pylori* positive group than in *H pylori* negative group ($P < 0.001$), while TOS level and OSI value were significantly higher in *H pylori* positive group than in H pylori negative group ($P < 0.001$) (Table 2).

In Pearson correlation analysis, IR was found to be significantly correlated with TAC ($r$ = -0.251, $P < 0.05$), TOS ($r$ = 0.365, $P < 0.05$), and OSI ($r$ = 0.267, $P < 0.05$).

## DISCUSSION

Information about the association of insulin resistance with *H pylori* infection is scarcely available[10,11]. Aydemir *et al*[10] reported that insulin resistance is significantly related with *H pylori* infection. However, Park *et al*[11] reported that no improvement in the metabolic parameters including insulin resistance could be observed following eradication of *H pylori*. In term of increased insulin resistance during *H pylori* infection, our results are in consistent with those of Aydemir *et al*[10]. As we did not investigate the effect of *H pylori* eradication on insulin resistance, we were not able to compare our results with those of Park *et al*[11].

To our knowledge, the association of oxidative stress with insulin resistance in *H pylori* infection has not been investigated previously. We found a significant association between increased oxidative stress and insulin resistance in *H pylori* infection. It has been reported that *H pylori* infection is associated with increased tissue and systemic oxidative stress[18]. Moreover, oxidative stress has been proposed as the root cause for the development of insulin resistance, B-cell dysfunction, impaired glucose tolerance and type 2 diabetes mellitus[19]. In addition, various antioxidants such as vitamin E, alpha-lipoic acid, and N-acetylcysteine have been shown to have improving impact on insulin resistance[20-22]. Thus, the association of insulin resistance with *H pylori* infection observed in our study seems to be due to oxidative stress induced by *H pylori*.

Many studies indicate that there are evident alterations in gastrointestinal hormone levels in *H pylori* infection[10,23-27]. *H pylori* infection has been found to decrease the expression of antral somatostation and to increase the release of acid-stimulating hormone gastrin[23]. Gastrin can inhibit glucose absorption in the small intestine[24] and amplify glucose-stimulated insulin release[25]. A link beween *H pylori* infection, serum gastrin, insulin and serum glucose concentrations has been demonstrated in dyspeptic patients[26]. During oral glucose ingestion, gastrin probably contributes very little to the insulin release. Gastrin may significantly stimulate the insulin secretion after protein-rich meals. Ordinary meal could stmulate immediate release of endogenous gastrin. The rise in serum gastrin is acute, preceding the increase in insulin concentrations[25]. Somatostatin regulates pancreatic insulin secretion and has an inhibitory effect on insulin release[10,26,27]. Decreased somatostation and increased gastrin hormone levels in patients with *H pylori* infection may play a role in the development of insulin resistance. However, in the present study, since we did not investigate gut hormones except for insulin, we could not provide any information related to this topic.

In conclusion, our findings suggest that insulin resistance seems to be associated with increased oxidative stress in *H pylori* infection. Further studies are needed to clarify the mechanisms underlying this association and elucidate the effect of adding antioxidant vitamins to *H pylori* eradication therapy on insulin resistance during *H pylori* infection.

## Abstract

**AIM:** To investigate the frequency of seropositivity against CagA, VacA proteins and to determine their independent effects on the development of duodenal ulcer (DU) in Turkish patients.

**METHODS:** The study was designed as a prospective one from a tertiary referral hospital. Dyspeptic patients who were referred to our endoscopy unit for upper gastrointestinal endoscopy between June 2003 and March 2004 and diagnosed to have DU or nonulcer dyspepsia (NUD) were included. Biopsies from the antrum and body of the stomach were taken in order to assess the current *H pylori* status by histology, rapid urease test and culture. Fasting sera were obtained from all patients and *H pylori* status of all sera was determined by IgG antibodies using an enzyme-linked immunosorbent assay (ELISA) kit. All seropositive patients were further analysed using Western blot assays detecting IgG antibodies against CagA and VacA proteins. The $\chi^2$ test was used for statistical comparison of the values and age-sex adjusted multiple regression analysis was used to determine the independent effects of CagA and VacA seropositivities on the development of DU.

**RESULTS:** Sixty-three patients with DU and 62 patients with NUD were eligible for the final analysis. Seropositivity for anti-CagA was detected in 51 of 62 (82%), and in 55 of 63 (87%) patients with NUD and DU, respectively ($P$ = no significance), and seropositivity for anti-VacA was found in 25 of 62 (40% ) and in 16 of 63 (25%) patients, with NUD and DU, respectively.

**CONCLUSION:** These findings suggest that none of these virulence factors is associated with the development of DU in the studied Turkish patients with dyspepsia.

**Key words:** *H pylori*; Western blot; CagA; VacA; Duodenal ulcer

## INTRODUCTION

Since the discovery of *H pylori* in 1983, the diagnosis and treatment of upper gastrointestinal disease have changed greatly. A strong association has been established between colonization of the gastric mucosa by *H pylori* and various benign and malignant gastroduodenal diseases including chronic active gastritis, gastric ulceration and duodenal ulcer, gastric adenocarcinoma and gastric lymphoma of mucosa-associated lymphoid tissue type[1]. The World Health Organization and International Agency for Research on Cancer consensus group stated in 1994 that there is sufficient epidemiologic and histologic evidence *H pylori* can be clarified as a definite carcinogen[2].

However, not all infected subjects develop disease complications and such a wide spectrum of diseases associated with *H pylori* infection may depend on the heterogeneity of *H pylori* and/or the host response to the same *H pylori* strain[3]. Besides immunological factors in the host, there are specific virulence determinants in *H pylori* strains that influence the outcome of the infection. It has been suggested that both possession of the *cagA* gene and production of a vacuolating cytotoxin encoded by the *vacA* gene, are linked with the

increased pathogenecity of *H pylori* strains. The *cagA* gene encodes a 120-140 kDa protein CagA, and is a part of a large pathogenecity island[4]. Strains expressing the CagA protein have been found to induce more severe inflammation, a higher degree of gastric atrophy, a higher incidence of duodenal ulcer and gastric adenocarcinoma of intestinal type[5,6]. The *vacA* gene is present in all *H pylori* strains, however it is expressed in only 50%-65% of them, thus inducing vacuolization of cells *in vitro*[7-9]. This *vacA* gene encodes a 81-91 kDa protein VacA, which has been shown to provoke the formation of vacuoles in gastric epithelial cells[4].

Turkey is a developing country with a very high prevalance of *H pylori*. A Turkish study dealing with asymptomatic children, using the UBT as the diagnostic test, found that one child out of two under 11 years of age is infected with *H pylori*[10]. Another serology based Turkish study in asymptomatic subjects indicates that about 70% of adults have antibodies against *H pylori* in our population[11]. These data obviously indicate that infection with *H pylori* is a major health problem in our country. The aim of the current study was to evaluate the frequency of cagA and vacA seropositivity in Turkish patients with deudenal ulcer (DU) and in controls with non ulcer dyspepsia (NUD) and to determine their independent effects on the development of DU.

## MATERIALS AND METHODS

A total of 125 patients (63 with DU and 62 with NUD serving as a control group) who were referred to the Endoscopy Unit of Istanbul University, Cerrahpasa Medical Faculty between June 2003 and March 2004 were included. Inclusion criteria were the indication of endoscopy for the study of dyspeptic symptoms. Exclusion criteria were as follows: age under 18, previous gastric surgery and *H pylori* eradication treatment, consumption of antibiotics a month prior to the study, consumption of antisecretory drugs, bismuth salts or sucralfate two weeks prior to the study. A history of bleeding and coagulation disorders that are contraindications for biopsy sampling was also the reason for exclusion.The study was approved by the Ethics Committee of Istanbul University, Cerrahpasa Medical Faculty and all patients gave their written informed consent to participate in the study.

From each patient four antrum and three corpus biopsies were collected for histology (two antrum and one corpus biopsy specimens), rapid urease test (one antrum and one corpus biopsy specimens) and culture (one antrum and one corpus biopsy specimens). One antrum and one corpus biopsy specimens were placed in a CLOtest (Ballard Medical Products, Draper, Utah, USA), maintained at room temperature and read at 1 h and 24 h after sampling. Biopsy specimens were processed for histological examination according to the standard procedure. Hematoxylin and eosin staining as well as a special staining for *H pylori* (Giemsa) were performed. All biopsy samples were examined by the same pathologist (S.E), who specialises in digestive diseases.

Biopsy specimens used for bacterial culture were placed in 2 mL of phosphat-buffered saline at 4℃ and then smeared on the surface of *H pylori* agar (Biomerieux, Lyon, France) plate. Isolates were identified as *H pylori* by Gram stain morphology and the positivity of urease, catalase and oxidase.

**Table 1 Demographic characteristics of the patients included**

| Endoscopic finding | *n* (%) | Range | Male/Female (%) | % Hp (+) |
|---|---|---|---|---|
| Normal | 62 (49.6) | 36.90 ± 12.36 (18-68) | 20/42 (32/68) | 93 |
| Duodenal ulcer | 63 (50.4 ) | 43.14 ± 16.27 (18-80) | 39/24 (62/38) | 97 |

A patient was classified as *H pylori*-positive if the culture alone or both histology and rapid urease test were positive in the presence of a negative culture and as *H pylori*-negative only if all these tests remained negative.

Fasting serum samples were obtained from all patients and stored at -20℃ until assayed. The *H pylori* status of all sera was determined by enzyme-linked immunosorbent assay (ELISA; Euroimmune, Lübeck, Germany) of anti-IgG as described by the manufacturer. The cut-off value for the ELISA was 20 U/mL, antibody concentrations less than this value were considered seronegative, whereas values more than 20 U/mL were assessed as seropositive. All seropositive patients were further analysed with the Western blot technique. We used commercially available Western blot kits (Euroimmun, Lübeck, Germany) to qualitatively detect IgG antibodies against VacA (95 kDa) and CagA (120 kDa).

Continuous variables, one-way analysis of variance between the groups were calculated using. Categorical variables were analyzed with $\chi^2$ test and age-sex adjusted multiple logistic regression analysis was used to determine the independent effects of different virulence factors on the development of DU. $P < 0.05$ was considered statisticallly significant. All the statistical analyses were performed using SPSS 11 for Windows.

## RESULTS

A total of 158 patients were enrolled in the study. Eleven patients (7%) did not give their serum samples although their written informed consent was obtained, and 22 of the remaining 147 (15%) patients were seronegative by anti- IgG ELISA. These 33 patients were excluded from the final analysis.

A total of 125 patients (62 with NUD, 63 with DU) with a mean age of 40.04 ± 14.74 years (range 18-80 years) were eligible for the final analysis. Demographic characteristics of the patients are summarized in Table 1. The patients were classsified as *H pylori* positive when the culture and/or histology plus rapid urease test gave positive results. When all three tests gave concordant negative results the patient was considered negative for *H pylori*. According to these criteria, 6 of 125 (5%) patients had discordant results and 113 of the remaining 119 (95%) patients were positive for *H pylori*.

**Table 2 Percentage of seroreactivity to CagA and VacA antigens detected by Western blot in different groups of patients *n* (%)**

| | Anti-CagA IgG | Anti-VacA IgG |
|---|---|---|
| NUD (*n* = 62) | 51/62 (82) | 25/62 (40) |
| DU (*n* = 63) | 55/63 (87) | 16/63 (25) |
| *P* | 0.432 | 0.076 |
| Total (*n* = 125) | 106/125 (85) | 41/125 (33) |

NUD : Non-ulcer dyspepsia; DU : Duodenal ulcer.

The percentages of seroreactivity to CagA and VacA antigens detected by Western blot in different groups of patients are summarized in Table 2.

The percentage of seroreactivity to different antigens were as follows: anti-CagA with DU 51 of 62 (82%) patients, with NUD and in 55 of 63 (87%) patients with DU ($\chi^2 = 0.617$; $P = 0.432$), anti-VacA in 25 of 62 (40%) patients with NUD and in 16 of 63 (25%) patients with DU ($\chi^2 = 3.158$; $P = 0.076$).

Age and sex adjusted multiple regression analysis disclosed that none of these factors was an independent risk factor for the development of DU ($P = 0.736$ and $P = 0.214$ for CagA and VacA, respectively).

## DISCUSSION

*H pylori* infection is one of the most common chronic bacterial infections worldwide. Although most infected persons remain asymptomatic, 15% to 20% of *H pylori*-positive individuals develop peptic ulcer, gastric carcinoma, or mucosa-associated lymphoid tissue lymphoma[12]. However, it remains unclear why only a small number of infected patients develop such severe diseases. This phenomenon may be due to the differences in host genetics, environmental factors, and the virulence of bacterial strains.

*H pylori* strains are highly diverse[13,14]. Of the two main *H pylori* strains, type I produces a vacuolating cytotoxin, whereas type Ⅱ usually does not[15]. The genome of almost all type I strains has a gene coding for CagA, a highly immunogenic molecular weight protein, which is not present in most type Ⅱ strains. The *vacA* gene coding for vacuolating cytotoxin is polymorphic and present in all strains and the polymorphism of *vacA* accounts for the phenotypic differences between type I and type Ⅱ strains, both types synthesise a VacA protein which is active as a vacuolating cytotoxin in type I and inactive in type Ⅱ strains[15,16]. Infection with VacA-positive strains has been reported to be associated with particular gastroduodenal diseases[7,17-20] especially peptic ulcers[17, 20].

Approximately 60% of *H pylori* isolates harbor the *cagA* gene which encodes another putative virulence factor, CagA that can be variable in size (128-152 kDa)[21,22]. Serological and microbiological studies indicate that CagA-positive strains are associated with enhanced induction of local inflammatory response[23,24] and the presence of this protein has been linked to the development of peptic ulcer disease and gastric cancer[7,21,22,24-27]. However, there are geographic variations in prevalance of both VacA and CagA. Especially in East Asian countries very high prevalances of VacA and CagA-positive strains have been reported[28-30]. Based on these findings, Maeda *et al*[28] concluded that these virulence factors cannot be used as markers of particular gastroduodenal diseases. However, it was reported that the high prevalance of these factors may contribute to the characterization of *H pylori* infection in Japan.

Besides these, other reports suggest that neither VacA nor CagA positivities are associated with more serious gastroduodenal diseases. Yamaoka *et al*[31,32] examined a large number of strains from both Western and East Asian countries and constructed models to discriminate different clinical outcomes on the basis of the presence of *H pylori* putative virulence factors and concluded that none of these factors is helpful in predicting the clinical presentation.

Such conflicting results in the prevalance and clinical usefullness of these virulence factors have been observed in Turkey too. Regarding the CagA and VacA status, studies in dyspeptic patients from different regions of Turkey showed that the seropositivity is 62%-97% and 70%-76%, respectively[33-36]. However, only two of these studies[33,34] have found a significant correlation between the presence of anti-CagA antibodies and peptic ulcer. A very recent study from Turkey[37] displayed that 78% of dyspepsia patients harbour the *cagA* gene and that the *cagA* gene is significantly associated with peptic ulcer and gastric cancer. All these data indicate that the association between putative virulence factors and the development of particular gastrointestinal diseases in *H pylori*-infected individuals is still a worldwide matter of debate.

In the present study, we did not observe any significant differences in seropositivities of the studied virulence factors CagA and VacA between patients with DU and controls with NUD. The overall prevalence of CagA in seropositive patients was 85%, which is in concordance with other studies from Turkey[33-36], but the seropositivity of VacA was just 33%, a low percentage compared to previous studies[33,36], suggesting that this difference may be due to the use of commercially available different Western blot kits in these studies. We think that using VacA antigens from Turkish *H pylori* strains rather than the commercially available ones could lead to more conclusive results.

*H pylori* has a unique set of virulence factors, actively supporting its survival in the special ecological niche of the human stomach while VacA and CagA are the two major bacterial virulence factors involved in host cell modulation. Although several studies have been performed on this issue, results are still conflicting. It was reported that none of these putative virulence factors has disease specificity and that there is evidence that virulence is a host-dependent factor[38]. The primary factors responsible for the different patterns of gastritis in response to *H pylori* infection are environmental factors (e.g. diet) rather than the *H pylori* strain[38].

In conclusion, the fact that similar frequencies of CagA and VacA-positive *H pylori* strains were observed in all our dyspeptic patients, regardless of ulcer status, suggests that factors other than these may contribute to gastrointestinal pathology in patients with *H pylori* infection. Further studies are needed to eliminate the potential bias like the selection of controls with a large sample size including different diseases and ethnic groups in order to make the results robust.

## ACKNOWLEDGMENTS

The authors thank FAKO AS, Turkey, for kindly supplying the rapid urease tests and Western blot kits.

## Abstract

**AIM:** To detect distribution and relative frequency of endocrine cells in gastrointestinal tract of flower fish (*Pseudophoxinus antalyae*).

**METHODS:** The intestinal tract of flower fish was divided into four portions from proximal to distal; the enlarged area after oesophagus and anterior, middle and posterior intestine. Immunohistochemical method using the peroxidase anti-peroxidase complex was employed. All antisera between four portions of flower fish were compared using ANOVA.

**RESULTS:** Eleven types of gut endocrine cells were determined; they were immunoreactive for calcitonin gene related peptide, substance P, vasoactive intestinal peptide, bombesin, somatostatin-14, secretin, TrkA, TrkB, TrkC, neurotensin, neuropeptide Y, which were found in almost all portions of the gastrointestinal tract.

**CONCLUSION:** The regional distribution and relative frequency of immunoreactive cells in the flower fish, *Pseudophoxinus antalyae*, are essentially similar to those of other fish.

**Key words**: Flower fish; Gastrointestinal tract; Immunoreactive cells; *Pseudophoxinus antalyae*

## INTRODUCTION

Gastrointestinal hormones are secreted by endocrine cells which are distributed throughout the mucosa of the gastrointestinal tract. They play important roles in the overall regulation of digestive processes such as nutrient absorption, gut motility and intestinal blood flow[1]. Fish digestive tract shows remarkable differences in function and morphology. Despite some differences in species basis, some basic histological structures are somewhat common. Differences observed at specific level should be related with food, feeding habits, body weight, shape and sex[2-4] . Furthermore, presence of a relation between feeding behaviour and basic histological structure[2] or improbability of this[3,5] have been argued.

Almost all the activities involved in the physiological control of vertebrate gut function during fasting or feeding are mediated by the neuroendocrine system. In the vertebrate gut, epithelial cells belonging to the diffuse endocrine system (DES) interact with components of the enteric nervous system (ENS) in regulating digestive functions, such as enzyme secretion, nutrient uptake and the progression of food through the alimentary canal. Concerning fish, several peptides are produced by the components of the neuroendocrine system and are involved in the communication between DES and ENS. Some of these peptides are associated with the modulation of fish alimentary behaviour[6].

Although they are one of the most common endemic species, the regional distribution and relative frequency of endocrine cells in the flower fish, *Pseudophoxinus antalyae*, have not been studied. Therefore, in the present study, the regional distribution and relative frequency of endocrine cells in the gastrointestinal tract was investigated by immunohistochemistry using 11 types of specific antisera, calcitonin gene related peptide (CGRP), substance P, vasoactive intestinal peptide (VIP), bombesin, somatostatin-14, secretin, neurotensin, neuropeptide Y (NPY), TrkA, TrkB, TrkC raised against mammalian regulatory peptides.

## MATERIALS AND METHODS

Ten adult (length 15-20 cm, weight 40-50 g) flower fish

*(Pseudophoxinus antalyae)* were used in this study without sexual distinction. After being anaesthetized with ethyl ether, the intestinal tract of flower fish was divided into four portions from proximal to distal; the enlarged area after oesophagus and anterior, middle and posterior intestine. All samples were fixed for 12 h in Bouin's solution and embedded in paraffin. Serial, transverse 6-7 μm sections of these portions were cut. Each representative section was deparaffinized, rehydrated and immunostained using the peroxidase anti-peroxidase (PAP) method[7]. Sections were treated with methanol containing 0.3% $H_2O_2$ for 30 min to block any endogenous peroxidase. Subsequently, the sections were incubated for 1 h at room temperature in normal goat serum (1:100), then stained immunohistochemically to identify specific endocrine cells using PAP. The sections were incubated with specific antisera for individual peptides for 12 h at 4℃. Details of primary antisera used in this study are listed in Table 1. After rinsing with phosphate buffered saline (PBS, 0.01 mol/L, pH 7.4), the sections were incubated in secondary antiserum (ant-rabbit IgG serum raised in goats; 1:200) for 1 h at room temperature. Sections were then washed with PBS buffer and incubated with PAP complex (1:400) for 1 h at room temperature. The peroxidase reaction was carried out in 0.02% 3, 3-diaminobenzidine tetrahydrochloride solution containing 0.01% $H_2O_2$ in Tris-HCl buffer (0.05 mol/L, pH 7.6). After immunostaining, the sections were lightly counterstained with Mayer's haematoxylin and immunoreactive (IR) cells were observed with a light microscope.

### Statistical analysis

The mean number of endocrine cells per intestinal fold that were immunoreactive to CGRP, substance P, VIP, bombesin, somatostatin-14, secretin, neurotensin, NPY, TrkA, TrkB, TrkC antisera between four portions of flower fish were compared using ANOVA. The level of significance was set at 0.001.

## RESULTS

Eleven kinds of immunoreactive cells were detected using the antisera against CGRP, substance P, VIP, bombesin, somatostatin-14, secretin, neurotensin, NPY, TrkA, TrkB, TrkC in the intestinal tract. According to the location of the gut and situation in those regions, different regional distribution and relative frequencies of these immunoreactive cells were observed (Figure 1). These differences are shown in Table 2 and Figure 2.

CGRP-IR cells were found throughout the gastrointestinal tract at various relative frequencies. Numerous CGRP-IR cells were detected in the epithelial mucosa. These cells were moderate in number in the enlarged area after oesophagus and anterior, middle intestine and then decreased slightly in the posterior intestine. Substance P-IR cells were found in all portions of gastrointestinal tract. These cells were moderate in number in the enlarged area after oesophagus and middle intestine. The number of cells was decreased in middle intestine. Cells immunoreactive for VIP were numerous in posterior intestine. VIP-IR cells, which were at highest frequency in the enlarged area after oesophagus, were found in the epithelia throughout the tract at various frequencies. These cells increased in number from the posterior intestine to the enlarged area after oesophagus.

**Table 1 List of primary antisera used in the present study**

| Antiserum | Code | Dilution | Source |
|---|---|---|---|
| CGRP | sc-28920 | 1:200 | Santa Cruz Biotech Inc. |
| Substance P | sc-9758 | 1:200 | Santa Cruz Biotech Inc. |
| VIP | NCL-VIPp | 1:200 | Nova Castra Lab, UK |
| Bombesin | NCL-BOMp | 1:200 | Nova Castra Lab, UK |
| Somatostatin | 14CL-SOMATOp | 1:200 | Nova Castra Lab, UK |
| Secretin | sc-20938 | 1:200 | Santa Cruz Biotech Inc. |
| Neurotensin | sc-20806 | 1:200 | Santa Cruz Biotech Inc. |
| NPY | sc-28943 | 1:200 | Santa Cruz Biotech Inc. |
| TrkA | sc-118 | 1:200 | Santa Cruz Biotech Inc. |
| TrkB | sc-12 | 1:200 | Santa Cruz Biotech Inc. |
| TrkC | sc-117 | 1:200 | Santa Cruz Biotech Inc. |

All antisera were raised in rabbit. CGRP: Calcitonin gene related peptide; VIP: Vasoactive intestinal peptide; NPY: Neuropeptide Y.

Bombesin-IR cells varied in number from moderate to numerous in the tract. They then decreased gradually from moderate numbers in the anterior intestine to only a few in the middle intestine. Cells that were immunoreactive for somatostatin-14 were found throughout the gastrointestinal tract except for the posterior intestine. Somatostatin-14 IR cells were demonstrated in both the enlarged area after oesophagus and middle intestine but were more numerous in the former. No somatostatin-IR cells were observed in the posterior intestine. The secretin-IR cells were restricted to the posterior intestine with a rare frequency. They were most numerous in the other portions.

In the enlarged area after oesophagus the presence of endocrine cells which were TrkA immunoreactive, was of a moderate frequency. No cells were found in other regions. TrkB and TrkC IR cells were found at a very low frequency, with the exception of the enlarged area after oesophagus, where their frequency was very low.

NPY-IR cells were demonstrated in both the enlarged area after oesophagus and middle intestine, but they were very rare. No cells were determined in the anterior and posterior intestine. Neurotensin-immunoreactive cells, which were at highest frequency in the enlarged area after oesophagus, were found in all portions at various frequencies. These cells declined in number from the anterior intestine to the middle intestine. These immunoreactive cells were found in the posterior intestine at very low frequencies.

## DISCUSSION

Endocrine cells of the gastrointestinal tract are different in the relative frequency in regional distribution and cell types, between animal species[8]. In the present study, CGRP, substance P, VIP, bombesin, somatostatin-14, secretin, TrkA, TrkB, TrkC, NPY, neurotensin-IR cells

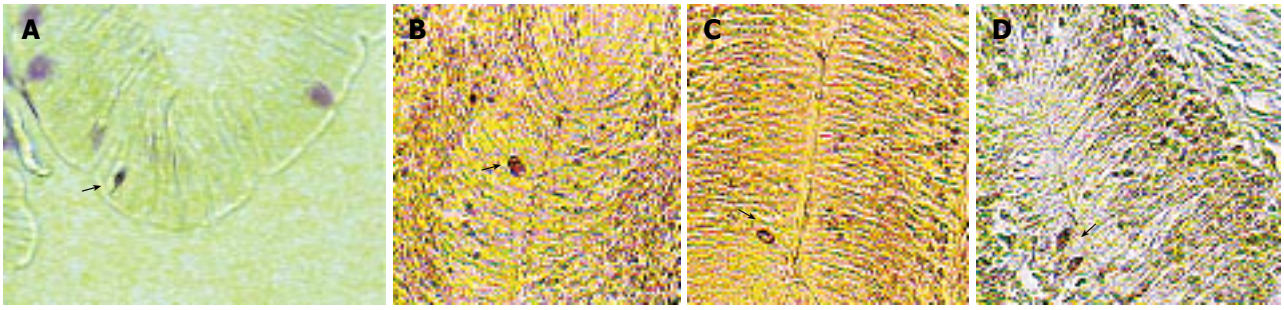

**Figure 1** Photomicrographs of immunoreactive endocrine cells in the gastrointestinal tract of the flower fish. **A**: Bombesin immunoreactive cells in the enlarged area after oesophagus; **B**: Somatostatin immunoreactive cells in the enlarged area after oesophagus; **C**: Substance-P immunoreactive cells in the enlarged area after oesophagus; **D**: Vasoactive intestinal peptide immunoreactive cells in the anterior intestine (× 450).

**Table 2 Mean number of endocrine cells per intestinal fold (mean ± SD) in flower fish (*Pseudophoxinus antalyae*) (200 intestinal folds were examined for each antisera)**

| Region | Calcitonin gene related peptide | Substance-P | Vasoactive intestinal polypeptide | Bombesin | Somato-statin-14 | Secretin | TrkA | TrkB | TrkC | Neuropep-tide Y | Neuro-tensin | Anova (F) | *P* |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| The enlarged area after oesophagus | 5.00 ± 1.550 | 4.75 ± 2.217 | 20.50 ± 9.883 | 3.75 ± 2.500 | 8.50 ± 9.037 | 3.50 ± 1.291 | 4.00 ± 4.359 | 3.00 ± 100 | 5.67 ± 3.215 | 0.67 ± 0.577 | 4.33 ± 3.215 | 4.456 | 0.001 |
| Anterior intestine | 5.25 ± 2.500 | 2.75 ± 0.957 | 12.00 ± 6.481 | 2.25 ± 1.258 | 2.75 ± 1.500 | 4.25 ± 2.062 | 0.00 ± 0.000 | 2.67 ± 2.887 | 1.00 ± 1.000 | 0.00 ± 0.000 | 1.33 ± 0.577 | 6.186 | 0.000 |
| Middle intestine | 5.25 ± 2.217 | 4.25 ± 0.957 | 12.25 ± 6.702 | 1.00 ± 0.816 | 7.75 ± 1.708 | 4.75 ± 1.708 | 0.00 ± 0.000 | 1.67 ± 1.528 | 1.00 ± 1.000 | 0.67 ± 0.577 | 1.00 ± 1.000 | 8.115 | 0.000 |
| Posterior intestine | 4.50 ± 2.380 | 6.75 ± 2.217 | 7.25 ± 2.217 | 3.00 ± 0.816 | 0.00 ± 0.000 | 2.00 ± 1.44 | 0.00 ± 0.000 | 0.67 ± 1.155 | 0.67 ± 1.155 | 0.00 ± 0.000 | 0.33 ± 0.577 | 12.829 | 0.000 |

were identified in the gastrointestinal tract of the flower fish, *Pseudophoxinus antalyae*.

The appearance of CGRP-IR cells was well demonstrated in the gastrointestinal tract of the *Anguilla anguilla*[9] , the *Salmo trutta*[10]. Dezfuli *et al*[10] reported that CGRP-IR cells localized in only nerve cell bodies of the myenteric plexus, but in this study these cells were observed in surface epithelia and crypt.

It is well known substance P exerts immunostimulatory and pro-inflammatory effects[11]. Our present results on the GI tract of flower fish agree with previous reports[6,9,10,12-15].

VIP is a peptide consisting of 28 amino acids. Experiments carried out in fishes demonstrated that this peptide is found in nerves and acts as an exciting or inhibiting agent[1]. In the present study, numerous VIP immunoreactive cells were determined in all regions of the gastrointestinal tract. Similar results were reported by Dezfuli *et al*[10] who also found that VIP IR cells were sparsely distributed in the *Salmo trutta* digestive tract. VIP-immunoreactivity in the intestinal nerve fibres of myenteric plexus and ganglion cells and intestinal muscle layer has also been reported in *Anguilla anguilla*[9], *Scyliorhinus stellaris* and *Brachydanio rerio*[16], *Barbus conchonius*[12].

Bombesin is a tetradecapeptide originally isolated from the skin of the amphibian *Bombina bombin*. The presence of bombesin immunoreactivity has been reported in ECs of the gastrointestinal tract in representatives of all the major vertebrate groups except mammals, and in the enteric nerves of mammals, amphibians and fish[6]. Bombesin-like peptide may play an endocrine role in control of gastric functions such as regulation of acid secretion and gastric motility[17]. These cell types were observed in the gut of *Amia calva*[17], *Oncorhynchus mykiss*[18], *Salmo trutta*[6]. Smilar results were obtained in this study.

Somatostatin, which consists of 14 amino acids, was isolated from the hypothalamus of sheep for the first time and it could be subdivided into straight form and cyclic form[19]. As in the present study, somatostatin-14 immunoreactive cells have been determined in the intestine of many fish species, such as *Oncorhynchus mykiss*[18], species of the *Osteoglossomorpha*[20], *Pelteobagrus fuluidraca*, *Monopterus albus*, *Siniperca chuatsi*[15], *Zacco platypus*[19], *Coreoperca herzi*[9].

Secretin is a 27-amino acid polypeptide and belongs to the structurally-related peptides of the pituitary adenylate cyclase-activating polypeptide (PACAP)/glucagon superfamily[21]. In the present study, secretin-IR cells were found in the gastrointestinal tract. These findings agree well with those of previous reports[6,22] , but differ somewhat from results in the *Zacco platypus*[19] and *Coreoperca herzi*[9] where no secretin immunoreactive cells were observed.

Lucini *et al*[23] showed that Trk-like proteins (TrkA, TrkB, Trkc) IR cells were present throughout the intestine of teleost species. They also stated that this immunoreactivity was present in the myenteric plexus of whole intestinal regions containing nerve fibers in the muscle layer. In addition, Radaelli *et al*[24] reported that these cells were present in the gut of both *Pagrus major* and *Dentex dentex*. In the present study, TrkA immunoreactive cells were found only in the enlarged area after oesophagus. In the other portions of gastrointestinal tract,

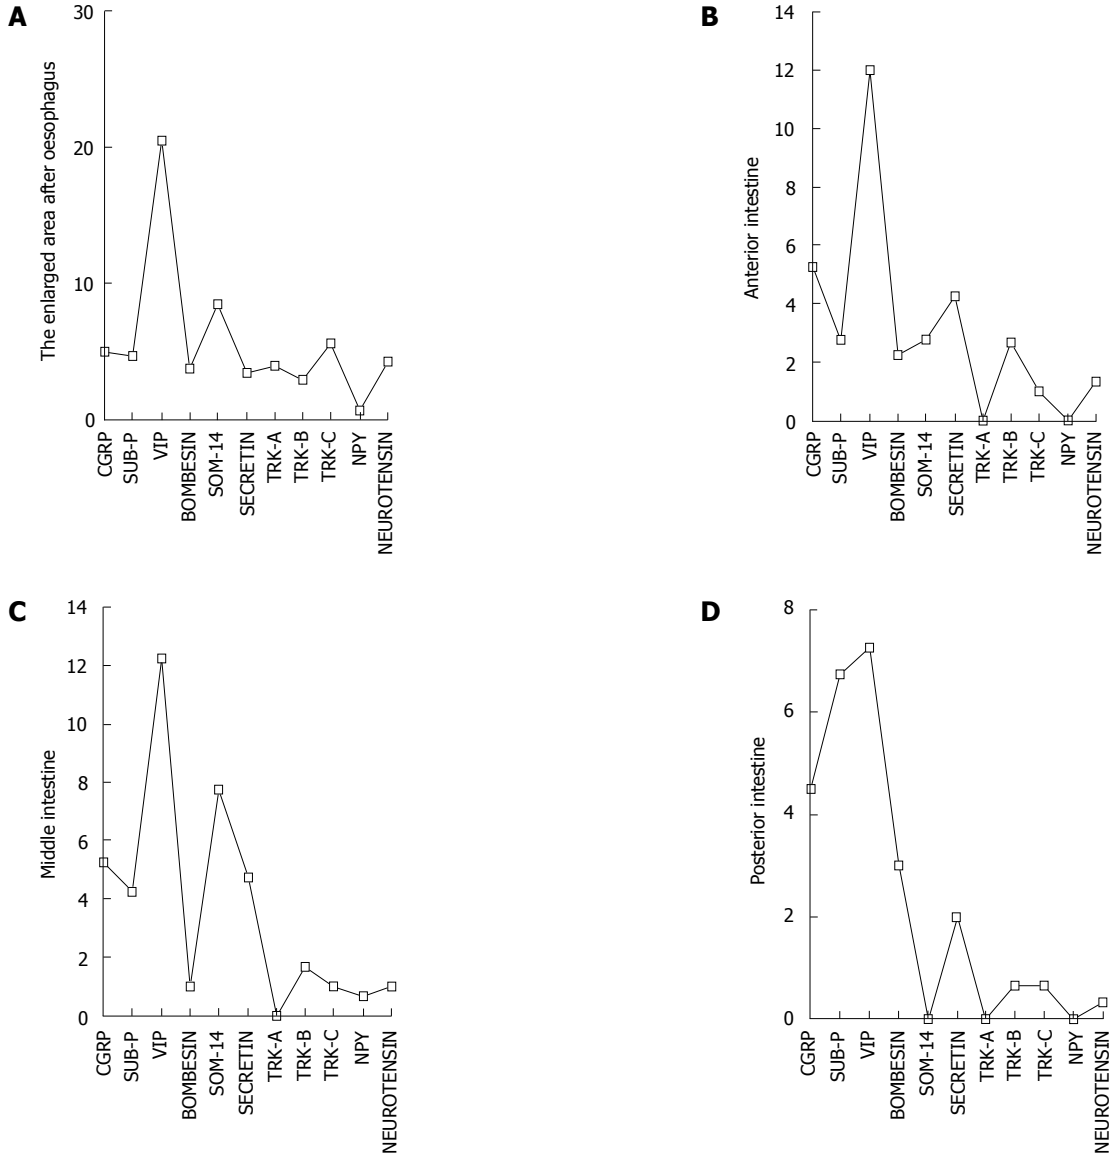

**Figure 2** Density of the immunoreactive endocrine cells in the enlarged area after oesophagus (**A**), the anterior intestine (**B**), the middle intestine (**C**) and the posterior intestine (**D**).

no cells were detected. TrkB and TrkC immunoreactive cells were scattered amongst the epithelial cells throughout the intestine, similar to that reported by Radaelli *et al*[24] and Lucini *et al*[23].

NPY is a 36-amino acid peptide that is widely and abundantly expressed in the central nervous system of all vertebrates investigated[25]. In the present study, NPY-IR cells were found in the enlarged area after oesophagus and middle intestine. These findings are consistent with those of previous reports[9,20]. Rombout and Reinecke[12] showed that neurotensin IR cells were present in the gut of *Barbus conchonius*. They also stated that this immunoreactivity was also present in the myenteric plexus of whole intestinal regions containing nerve fibres in the muscle layer. We found that, a sparse distribution of neurotensin IR cells were observed in all regions of the digestive tract.

In conclusion, the regional distribution and relative frequency of immunoreactive cells in the flower fish, *Pseudophoxinus antalyae*, are essentially similar to those of other fish[9,10,19,20,25]. However, some characteristic differences are observed in this species, which may be due to differences in the antisera tested, the methods used and/or the species investigated in the various studies.

## Abstract

**AIM:** To determine the prevalence of hepatitis B and C virus infections in human immunodeficiency virus (HIV) -positive patients at a tertiary care hospital in New Delhi, India.

**METHODS:** Serum samples from 451 HIV positive patients were analyzed for HBsAg and HCV antibodies during three years (Jan 2003-Dec 2005). The control group comprised of apparently healthy bone-marrow and renal donors.

**RESULTS:** The study population comprised essentially of heterosexually transmitted HIV infection. The prevalence rate of HBsAg in this population was 5.3% as compared to 1.4% in apparently healthy donors ($P < 0.001$). Though prevalence of HCV co-infection (2.43%) was lower than HBV in this group of HIV positive patients, the prevalence was significantly higher ($P < 0.05$) than controls (0.7%). Triple infection of HIV, HBV and HCV was not detected in any patient.

**CONCLUSION:** Our study shows a significantly high prevalence of hepatitis virus infections in HIV infected patients. Hepatitis viruses in HIV may lead to faster progression to liver cirrhosis and a higher risk of antiretroviral therapy induced hepatotoxicity. Therefore, it would be advisable to detect hepatitis virus co-infections in these patients at the earliest.

**Key words:** Human immunodeficiency virus; Hepatitis B; Hepatitis C; Hepatitis B surface antigen; Co-infections

## INTRODUCTION

Diseases of the hepatobiliary system are a major problem in patients with human immunodeficiency virus (HIV) infection. An estimated one-third of deaths in HIV patients are directly or indirectly related to liver disease. Liver diseases in HIV infected persons can occur due to hepatitis B virus (HBV) and hepatitis C virus (HCV) co-infections, chronic alcoholism, hepatic tuberculosis, or due to the effects of anti-retroviral therapy (ART)[1,2]. Since the principal routes for HIV transmission are similar to that followed by the hepatotropic viruses, as a consequence, infections with HBV and HCV are expected in HIV infected patients. Co-infections of HBV and HCV with HIV have been associated with reduced survival, increased risk of progression to liver disease and increased risk of hepatotoxicity associated with anti-retroviral therapy.

Worldwide, HIV is responsible for 38.6 million infections as estimated at the end of 2005[3] while HBV and HCV account for around 370 million and 130 million chronic infections respectively. Moreover, among the HIV-infected patients, 2-4 million are estimated to have chronic HBV co-infection while 4-5 million are co-infected with HCV[4]. The reported co-infection rates of HBV and HCV in HIV patients have been variable worldwide depending on the geographic regions, risk groups and the type of exposure involved[4-8]. In Europe and USA, HIV-HBV co-infection has been seen in 6%-14%[4,5] of all patients while HIV-HCV co-infection has been variably reported ranging from 25% to almost 50%[6,7] of these patients. Evidence of exposure to HBV and HCV has been found in 8.7% and 7.8%, respectively, of HIV patients from Thailand[8] in Southeast Asia.

India, with a whopping 5.2 million cases of HIV infection, has distinction of harboring the second highest number of these patients in the world. Within India also, variable co-infection rates have been reported from region to region. HIV-HBV co-infection (HBsAg positives) is reported in 6% of people from Chennai, South India[9], 7.5% in Chandigarh, Northwest India[10] and 16% in Mumbai, Western India[2]. Similarly, HIV-HCV co-infection rates also vary from 4.8%-21.4% in South India[9,11] and 30% in Western India[2] to as high as 92% in the North-East[12].

While HIV-HBV co-infection has been linked to both sexual and intravenous injection route of transmission, the HIV-HCV co-infection has predominantly been associated with non-sexual parenteral route of transmission. In India, HIV infection is predominantly acquired through heterosexual route, but no work from India has been

carried out to study the differential transmission rate of these two hepatitis viruses in HIV positive persons. With this background we set out to determine the prevalence of hepatitis B and C virus infections in HIV-positive patients coming to a tertiary care hospital located in north India.

## MATERIALS AND METHODS

### Patients and controls

The study was carried out in the Microbiology Division, Department of Laboratory Medicine at the All India Institute of Medical Sciences (AIIMS). Patients attending clinics at AIIMS were screened for HIV based on clinical suspicion after pre-test counseling and informed consent. As a routine, our laboratory follows the World Health Organization (WHO) testing strategies for HIV testing. Only the confirmed HIV positive serum samples were included in this study and were anonymously tested for hepatitis B surface antigen (HBsAg) and anti-HCV antibodies. The study period was from January 2003 to December 2005. Seroprevalence of HBsAg and anti-HCV antibodies in apparently healthy, HIV-negative organ-donors (kidney/bone-marrow) was also analyzed during the same study period and compared with the prevalence of hepatitis markers in HIV positive individuals. These organ donors are screened for viral markers as a routine work-up for their family members requiring organ transplant.

### Viral diagnosis

The serum samples which were found to be HIV positive according to WHO testing strategy Ⅲ were coded and stored at -20 degree Celsius. The coded samples were anonymously tested using enzyme linked immunosorbent assay kits at a later date for the presence of HBsAg (Cat. No.B9 280252, bio Merieux, France) and anti-HCV antibodies (DETECT-HCV™ Third generation, Cat. No. HCA 702B/700B, Adaltis, Italy). All serum samples were tested in duplicate.

### Statistical analysis

Comparison of proportions between HIV-infected and non-infected individuals was done using Chi-square tests. $P < 0.05$ was taken as significant.

## RESULTS

Sera from a total of 451 HIV-positive patients were included in this study. The retrospective demographic data of these subjects showed that out of the 451 patients, 345 (76.4%) were males and 106 (23.6%) females. The mean age of the study group was 32 years (95% CI +/- 3.2 years, range 5-70 years). The predominant mode of acquiring HIV infection was heterosexual contact (80%) followed by transfusion of blood products (6%), intravenous drug use (2.3%) and the rest unknown.

Data was available for 428 prospective organ donors who were also tested during the same period. It was presumed that these donors represent the general population and they are exposed to similar risk factors as the general population. There were 259 (60.5%) males and 169 (39.5%) females. The mean age of the donors was 38.4 years (95% CI +/- 1.1 years, range 16-67 years).

**Table 1 Seroprevalence of HBsAg and anti HCV antibodies in HIV positive patients**

| | HBsAg | HCV |
|---|---|---|
| HIV patients ($n$ = 451) | 24 (5.32)[b] | 11 (2.43)[a] |
| Males ($n$ = 345) | 23 (6.6) | 6 (1.7) |
| Females ($n$ = 106) | 1 (0.94) | 5 (4.7) |
| Controls ($n$ = 428) | 6 (1.4) | 3 (0.7) |
| Males ($n$ = 259) | 4 (1.5) | 2 (0.7) |
| Females ($n$ = 169) | 2 (1.1) | 1 (0.59) |

Values in parenthesis are percentages. Control group includes HIV negative healthy donors. [a]$P < 0.05$, [b]$P < 0.001$ *vs* controls.

### Prevalence of viral co-infections in HIV positives

Overall, the prevalence of co-infection in HIV-positive patients with hepatitis viruses was 7.76% (35 in 451). Among the co-infected patients, there were 29 males and 6 females. Triple infection with both HBsAg and HCV was not seen in any HIV patient.

The rate of HBsAg co-infection was 5.32% (24 in 451) in HIV positive patients as compared to HBsAg prevalence of 1.4% in apparently healthy donors ($P < 0.001$) (Table 1). Among males, HIV/HBV co-infection was seen in 23 of 345 (6.6%) patients while HBsAg was positive in only 4 out of 259 male donors (1.5%). Among the females, HIV/HBV co-infection was seen in only 1 of 106 (0.94%) patients while 2 out of 169 (1.1%) female donors were HBsAg positive. HBsAg co-infection rates were significantly higher in HIV positive men than in women ($P < 0.025$). HBsAg prevalence was also significantly higher in HIV males as compared to control males ($P < 0.01$), but such significance was not seen in females.

The rate of HCV co-infection was 2.43% (11 in 451) in HIV positive patients as compared to 0.70% in controls ($P < 0.05$) (Table 1). Among males, HIV/HCV co-infection was seen in 6 of 345 (1.7%) patients while only 2 out of 259 (0.7%) male donors were HCV positive. Among females, HIV/HCV co-infection was found in 5 of 106 (4.7%) patients while only 1 of 169 (0.59%) female donors was HCV positive. No statistically significant difference was seen in HCV co-infection rates between HIV positive men and women. But, the HCV seroprevalence was significantly higher in HIV positive female patients as compared to female donors ($P < 0.05$).

The majority of the HIV-infected patients comprised the 31-40 years age group (41.5%) followed by the 21-30 year age group (34.7%). Mean age of the HIV positive patients was 32 years (95% CI +/- 3.2 years) while that of the co-infected patients was 37.7 years (95% CI +/- 3.2 years). HBV-HIV co-infection was seen highest in the 31-40 year age group (45.8%) while HCV-HIV co-infection was predominant in the ≥ 51 years of age (45.4%) (Figure 1).

## DISCUSSION

The Joint United Nations Programme on HIV/AIDS (UNAIDS) estimated that 38.6 million people were living

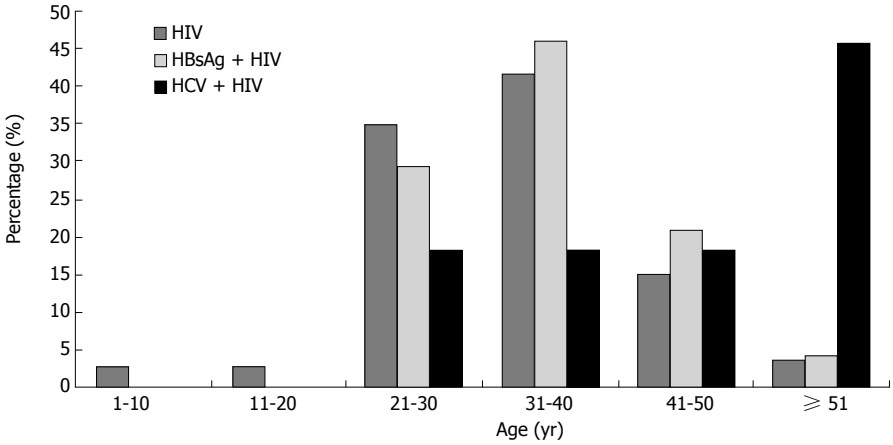

**Figure 1** Age-related distribution of HBsAg and HCV in HIV positive patients.

with HIV globally at the end of 2005[3]. India alone had the second highest number of people living with HIV (5.2 million) by the end of 2005[13]. Globally, around three million people died of the acquired immunodeficiency syndrome (AIDS) related illnesses in 2005[3]. About two-thirds of patients with AIDS develop hepatomegaly and abnormalities in serum biochemical parameters of liver function[14]. Liver damage may be directly related to HIV infection or may result from conditions such as alcoholism, prior viral hepatitis or intravenous drug abuse, which are highly prevalent in patients with HIV infection[2]. In addition, sepsis, malnutrition, or the administration of possibly hepatotoxic antiretroviral medications may also lead to liver damage[15,16].

Due to declining opportunistic infections as a result of highly active antiretroviral therapy (HAART), life expectancy of patients with HIV has increased. As a consequence, focus has shifted to the management of concurrent illnesses such as chronic HBV and HCV infections which have the potential to increase long term morbidity and mortality. As a result of the shared epidemiological factors, patients infected with HIV have a higher risk of both HBV and HCV infection as compared to those uninfected with HIV. It is very likely that the presence of HIV infection makes the transmission of hepatitis viruses more efficient, both through sexual contact as well as perinatal contact[17]. This has also been directly correlated with the degree of immunosuppression and viral load. Though HCV transmission is not widely documented through sexual contact but the presence of HIV may facilitate transmission of HCV in HIV positive individuals who otherwise have no history of blood transfusion or injection drug abuse.

Our study findings indicate that HIV-infected men and women are at a high-risk of viral co-infections, as illustrated by the high prevalence of HBsAg (5.32%) and HCV (2.43%) antibodies (Table 1). This study showed that infection with these viruses in the test group was significantly higher than the comparable group of healthy adult organ donors at the same hospital. The study group predominantly comprised of heterosexually acquired HIV infections. Also, a significant risk for HBV was seen in males. This is similar to previous reports that male gender is associated with a significant higher risk of co-infections with HBV[4]. The carriage of HBsAg in our study matches with that of Kumarasamy *et al*[9] from South India and at the National AIDS Research Institute, and of Pune (4.8%)[18] from Western India.

HCV prevalence in our study group was lower than other studies from Western countries and other parts of India. This can be related to the type of risk-groups in this study. Saha *et al*[11] reported an HCV co-infection rate of 92% in intravenous drug-users from Northeast India, while in the report by Kumarasamy *et al*[9] HCV co-infection was seen at 4.8%, but in those patients 25% had a history of blood transfusion and 50% were injection drug users (IVDU). However, in our study group IVDUs comprised only 2% of the patients while the majority of HIV infections were heterosexually transmitted. The low HCV prevalence in our data could be attributed to the mode of transmission of these viruses. While epidemiological evidence indicates sexual transmission of HCV, this occurs much less efficiently than HBV or HIV. Moreover, we need to address other possible non-sexual sources of HCV acquisition which are often overlooked[19] and several methodological shortcomings that tend to overestimate the proportion of HCV infections attributed to sexual contact. Earlier studies used first-generation antibodies for HCV assays which have a higher false positive rate than presently available third-generation assays. Moreover, only limited studies performed virological analyses to confirm that anti-HCV concordant sexual partners were infected with the same virus. In addition, other independent non-sexual factors need to be looked for such as prior history of injection drug use, tattooing, or sharing of razors and toothbrushes.

HCV-HIV co-infection in our male patients was higher than HCV mono-infection in male donors, though not statistically significant. Among HIV positives, though females showed a higher HCV co-infection rate as compared to males, the patient numbers were not comparable. Among the female group, HIV/HCV co-infection was significantly higher than HCV mono-infection in donors ($P < 0.05$). HIV co-infection appears to increase the rate of HCV transmission by sexual contact. In India, the majority of the women are in a monogamous relationship with their husbands and usually acquire HIV infection from their spouse. Therefore, while the risk for HCV acquisition in steady monogamous relationships is quite low[19], we need to look into other factors like sharing

of toothbrushes and other contaminated personal items with her husband who may be the index for the HCV infection.

At present, limited clinical information is available about the possible effects of HBV and HCV co-infection and the reciprocal interactions between these hepatotropic viruses and HIV. In the post-HAART era, with increased survival of HIV infected patients, HCV-induced liver disease has emerged as a leading cause of significant morbidity and death in this population[6,7]. Clinically, hepatitis C is a more severe disease in HIV-infected individuals rather than HCV mono-infection alone. HIV/HCV co-infected patients have a faster rate of HCV-related liver fibrosis and a more rapid progression to liver failure or hepatocellular carcinoma than HCV mono-infected persons[20-22]. In contrast, most studies have shown that HCV does not influence progression of HIV infection to AIDS or death[20].

There is also evidence that HIV may modify the natural history of HBV infection[23,24]. HIV positive subjects have higher rates of HBV chronic carriage, higher HBV replication and lower rates of seroconversion to anti-HBe and anti-HBs antibodies. The impact of HIV co-infection on the outcome of HBV infection is still controversial; while some studies have shown a rapid progression of liver fibrosis and an accelerated progression towards decompensated cirrhosis in HIV co-infected subjects[24], others have shown decreased liver necro-inflammatory processes[25]. Though some studies from the pre-HAART era described a more rapid progression to AIDS in patients having chronic HBV infection[26], post-HAART, no impact of HBV co-infection on HIV-disease progression has been detected[27].

Presently, ongoing clinical trials with pegylated interferon and ribavirin are reported to show encouraging results in HIV/HCV co-infected patients[7] while lamivudine and other combinations are also encouraging in HIV/HBV co-infections[28]. Therefore, with newer drug formulations it is now becoming evident that early initiation of therapy before marked immunosuppression sets in could be highly beneficial for the HIV infected patient, in order to decrease long term mortality and morbidity associated with these co-infections.

## CONCLUSION

Co-infection of HIV with hepatitis B and hepatitis C viruses is seen in 5.3% and 2.4% patients, respectively. This is significantly higher as compared to the prevalence of these two hepatitis virus infections in control population of the representative region of the country. Therefore, universal screening for hepatitis B and C viral infections in all HIV positive patients should urgently be started in Asia also.

## Abstract

**AIM:** To study the effect of albumin administration on lung injury in trauma/hemorrhagic shock (T/HS).

**METHODS:** Sixty experimental animals were randomly divided into three groups: rats undergoing laparotomy without shock (T/SS); rats with T/HS and resuscitation with blood plus twice the volume of shed blood as Ringer's lactate (RL), and rats with T/HS and resuscitation with blood plus additional 3 mL of 50 g/L human albumin. Expression of polymorphonuclear neutrophil (PMN) CD11b/CD18, intercellular adhesion molecule-1 (ICAM-1) of jugular vein blood and the severity of lung injuries [determined mainly by measuring activity of lung tissue myeloperoxidase (MPO) and lung injury score (LIS)] were measured after a 3-h recovery period.

**RESULTS:** All three groups showed a significant difference in the expressions of CD11b/CD18, ICAM-1, and severity of lung injury. The expressions of CD11b/CD18 in T/SS group, T/HS + RL group, T/HS + albumin group were 17.76% ± 2.11%, 31.25% ± 3.48%, 20.36% ± 3.21%, respectively ($F$ = 6.25, $P$ < 0.05). The expressions of ICAM-1 (U/mL) in T/SS group, T/HS + RL group, T/HS + albumin group were 258.76 ± 98.23, 356.23 ± 65.6, 301.01 ± 63.21, respectively ($F$ = 5.86, $P$ < 0.05). The expressions of MPO (U/g) in T/SS group, T/HS + RL group, T/HS + albumin group were 2.53 ± 0.11, 4.63 ± 1.31, 4.26 ± 1.12, respectively ($F$ = 6.26, $P$ < 0.05). Moreover, LIS in T/HS + RL group, T/HS + albumin group was 2.62 ± 0.23, 1.25 ± 0.24, respectively. The expressions of CD11b/CD18, ICAM-1 and MPO in T/HS + RL group were significantly increased compared to T/SS group ($P$ = 0.025, $P$ = 0.036, $P$ = 0.028, respectively). However, administration of 3 mL of 50 g/L albumin significantly down-regulated the expressions of CD11b/CD18, ICAM-1 and lung injury index (MPO and LIS) when compared with the T/HS + RL rats ($P$ = 0.035, $P$ = 0.046, $P$ = 0.038, $P$ = 0.012, respectively).

**CONCLUSION:** The infusion of albumin during resuscitation period can protect lung from injury and decrease the expressions of CD11b/CD18, ICAM-1 in T/HS rats.

**Key words:** Albumin; CD11b/CD18; Intercellular adhesion molecule-1; Lung injury; Trauma/hemorrhagic shock

## INTRODUCTION

Previous studies have shown that there is obvious pulmonary microvascular injury at the early stage of trauma/hemorrhagic shock (T/HS)[1]. The polymorphonuclear neutrophils (PMNs) accumulated in lung are closely correlated with lung injury[2]. Endothelial cells can control and regulate the adhesion, recruitment and migration of white blood cells (WBC) through expressing adhesion molecules such as intercellular adhesion molecule-1 (ICAM-1), and ICAM-1 plays an important role in the process of conducting WBC firmly adherent to endothelial cells[3,4]. Colloid *versus* crystalloid resuscitation in the acute trauma remains a controversial subject[5]. Although several studies have proved the relative benefits of albumin resuscitation, no consensus has been reached by now[6]. More recently, the immunomodulatory effects of various resuscitation solutions have begun to be revaluated[7].

Trauma/hemorrhagic shock (T/HS) may lead to splanchnic ischemia-reperfusion and to gut barrier failure[8]. This sequence of events gets the gut into an inflammatory cytokine-secreting organ, which contributes to the pathogenesis of shock-induced lung injury[9]. Lung injury generally results when mediators released by systemic

inflammatory processes up-regulate PMN interactions with endothelial cells (ECs). Endothelial cells play an important role in regulating cells of blood vessel walls in response to injury. ICAM-1 is expressed on endothelial cells and is responsive to numerous inflammatory mediators[10]. It mediates both leukocyte adhesion and migration through the endothelium into tissues. Shock and trauma-induced neutrophil activation have been implicated in the pathogenesis of the adult respiratory distress syndrome (ARDS) and, as a contributory factor, in the development of the multiple organ dysfunction syndrome (MODS)[11,12]. In the study of trauma/hemorrgic shock-induced organ failure, lung often serves as an ideal model of dysfunction.

Lung injury following T/HS is a well-accepted phenomenon; the exact mechanisms of injury are not yet defined[13]. Albumin, a broadly binding protein, has been characterized as an scavenger in addition to being an anti-apoptotic agent and an antioxidant[14]. A recent study showed that albumin protected endothelial cells *in vitro* from the injury by hematin[15]. We hypothesize that albumin would protect against lung injury induced by activation of PMN in our T/HS model.

## MATERIALS AND METHODS

### Experiment design

The aim of this experiment was to determine the protective effects of albumin on lung injury in a T/HS model. Rats were randomly divided into three groups: rats undergoing laparotomy without shock (T/SS), rats with T/HS and resuscitation with blood plus twice the volume of shed blood as Ringer's lactate (RL), and rats with T/HS and resuscitation with blood plus 50 g/L human albumin (Aventis Behring GmbH, Gemany). Rats of the albumin group received 3 mL of 50 g/L human albumin (150 mg of albumin) in addition to their shed blood. In a 400-g rat, with a circulating blood volume of about 24 mL, this dose is 6 g/L, approximating the distribution of a 25-g dose of albumin in the approximately 4 L blood volume of a 60-kg man. Polymorphonuclear neutrophil (PMN) CD11b/CD18, ICAM-1 in jugular vein blood and the severity of lung injuries [determined by myeloperoxidase (MPO) and lung injury score (LIS)] were measured after a 3-h recovery period.

### Subjects

Sixty adults Sprague-Dawley (SD) rats, weighing 300-350 g, were used after a minimum acclimatization period of 7 d. These animals were randomly divided into three groups according to aforementioned experimental design. The animals were allowed free access to food and water. The animals and their diet were provided by the Laboratory Animal Center, Collage of Medicine, Zhejiang University. The animals were maintained in accordance with the guideline of the National Guide for the Care and Use of Laboratory Animals, and the experiment was approved by Local Ethical Committee of the College of Medicine, Zhejiang University.

### T/HS model

As described above[16], rats were anesthetized using intraperitoneal sodium pentobarbital (50 mg/kg). A heparinized polyethylene catheter (PE-50) was introduced into the femoral artery for measuring the arterial pressure. A right jugular vein catheter was similarly inserted for blood withdrawal and resuscitation. Laparotomy (trauma) was performed to the animals through a 5-cm midline incision with two-layer closure using 3-0 silk in a running suture. The T/HS rats were subjected to T/HS (90 min at a mean artery pressure of 30 mmHg) by withdrawing blood through the jugular vein catheter in a heparinized syringe until the pressure reached 30 mmHg. The blood pressure was maintained for 90 min by withdrawing or re-infusing the shed blood. At the end of the 90-min shock period, the HS rats were resuscitated by their shed blood (average 18 mL). The RL group received an additional crystalloid (average 18 mL) and the albumin group received an additional 3 mL of 50 g/L albumin. Sham (T/SS) animal underwent vascular cannulation and laparotomy, but had no blood withdrawn and received no resuscitation. The animals' body temperature during the experimental period was maintained at about 37℃ by using a heating pad.

### Assay of blood CD11b/CD18 and ICAM-1

After the 3-h resuscitation period, each 1 mL of blood sample from the jugular vein was taken and treated with anti-coagulant EDTANa2. The 100-μL blood sample was put into a tube with size of 12 mm × 75 mm and then 10 μL of either anti-rat CD11b or CD18 fluorescent-labeled monoclonal antibody (BD Pharmingen) was added into the tube. The samples were gently vortexed for 10 min and then placed into a dark place for 40 min. And then the red blood cells of the sample were lysed and the sample was fixed with Coahem_Q-PREP equipment (Couletr Company, USA) for 15 min on ice. After being treated with centrifugation and washed for 3 times, PMN cells obtained were analyzed for detection of adhesion molecule expression using flow cytometer (ESPLL-XL, BECKMAN, USA) according to the manufacturer's recommendation. The amounts of these neutrophils labeled with monoclonal antibody among each 10000 neutrophils were counted and the percentage was evaluated.

The expression of serum ICAM-1 in the venous blood was detected using a special Regent Box (Jianqing Company, Nanjin, China) with ELISA methods following manufacturer's instructions.

### Assay of MPO and LIS

After the 3-h resuscitation period with aforementioned different methods, rats were killed immediately, and the right lobe lung was taken. One part of lung tissue was frozen, homogenized and processed for detection of MPO with special Regent-Box (Jiancheng Bio-Technolgy Company, Nanjing, China) according to the manufacturer's recommendation. One unit of MPO activity represents the amount of enzyme that will reduce 1 μmol/L peroxide per minute. The other part of lung tissue was fixed by

**Table 1 Comparisons of the expressions of CD11b/CD18, ICAM-1, MPO, and LIS among the three groups (mean ± SD)**

| Group (*n*) | CD11b/ CD18 (%) | ICAM-1 (U/mL) | MPO (U/g) | LIS |
|---|---|---|---|---|
| T/SS (20) | 17.76 ± 2.11 | 258.76 ± 98.23 | 2.53 ± 0.11 | - |
| T/HS + RL (20) | 31.25 ± 3.48[a] | 356.23 ± 65.6[a] | 4.63 ± 1.31[a] | 2.62 ± 0.23 |
| T/HS + albumin (20) | 20.36 ± 3.21[a,c] | 301.01 ± 63.21[a,c] | 4.26 ± 1.12[a,c] | 1.25 ± 0.24[c] |
| *F* | 6.25[e] | 5.86[e] | 6.26[e] | - |

ICAM-1: Intercellular adhesion molecule-1; MPO: Myeloperoxidase; LIS: Lung injury score. [a]$P < 0.05$ *vs* T/SS group; [c]$P < 0.05$ *vs* T/HS + RL group; [e]$P < 0.05$ comparison among the three groups (ANOVA).

100 g/L formaldehyde and then was cut into olefin slice stained with standard H&E. The LIS was evaluated with OLYMPUS (Olympus, Japan) optical microscope. The LIS standard composes of three character: (1) the severity of leukocytes sequestration in the lung tissue: 0 = 0%, 1 = 0%-25%, 2 = 25%-50%, 3 = 50%-5%, 4 = 75%-100%; (2) the severity of leukocytes sequestration in lung alveolus: 0 = none, 1 = few, 2 = a lot of, 3 = almost full, 4 = absolutely full; and (3) the severity of exudation (such as fibrin, transparent membrane, edema liquor) in lung alveolus: 0 = none, 1 = few, 2 = a lot of, 3 = almost full, 4 = absolutely full.

### *Statistical analysis*

Results were expressed as mean ± SD. The data were analyzed with SPSS.11.0 statistical software. The three groups were compared using analysis of variance (ANOVA). The comparison of two groups among multiple groups was dealt with *q* test. A *P* value less than 0.05 was considered statistically significant.

## RESULTS

As shown in Table 1, we observed a significant difference in expression of CD11b/CD18, ICAM-1, and severity of lung injury ($P < 0.05$) among the three groups. The T/HS + RL and T/HS + albumin groups showed a significant increase in the expressions of CD11b/CD18, ICAM-1, and severity of lung injury compared with the T/SS group ($P < 0.05$), thereby indicating that T/HS pathological process could up-regulate the expressions of CD11b/CD18, ICAM-1, and cause lung injury. The administration of 3 mL of 50 g/L albumin significantly down-regulated the expression of CD11b/CD18 and alleviated lung injury compared with the T/HS + RL rats ($P < 0.01$). These results indicated that resuscitation with albumin may have utility in reducing CD11b/CD18, ICAM-1 expression and alleviating lung injury when compared with crystalloid in the T/HS model.

## DISCUSSION

The present study showed that PMNs infiltrated and aggregated in the lung after trauma/hemorrhagic shock (T/HS)[17]. Up-regulation of CD11b/CD18 on PMNs and ICAM-1 in endothelial cells are the molecular basis of PMNs adhering to the endothelium[18]. Trauma/hemorrhagic shock is associated with the generation of reactive oxygen species, which may contribute to delayed multiple organ system failure and death[19]. It has been shown the phenomenon of neutrophil activation is often companied with T/HS. In addition, the activated neutrophil may play an important role in the pathogenesis of lung injury or multiple organ dysfunction (MOD), multiple organ failure (MOF) in T/HS[20]. The activation of neutrophil and lung injury are often chosen as ideal quantifiable indices to assess the severity of trauma in an animal model and patients. In this study, CD11b/CD18 was chosen as the marker of PMN activation; MPO and LIS were chosen as the markers of lung injury[21].

The integrins CD11b/CD18 have been found to be involved in monocyte adhesion to endothelial cells and transendothelial migration[22,23], release of hydrogen peroxide[24,25] and oxidative activity[26]. ICAM-1 is expressed on endothelial cells and is responsive to numerous inflammatory mediators[27]. It mediates both leukocyte adhesion and migration through the endothelium into tissues[28].

The potential advantages and disadvantages of colloids during resuscitation in T/HS have been long debated[29]. Some animal experiments showed that albumin was linked with increased mortality, but which did not accord with some clinical findings that albumin could decrease mortality in the trauma population[30]. However, a more recent study has demonstrated that early albumin infusion during resuscitation period may decrease neutrophil activation in animal model[31]. Some studies indicated that resuscitation with 250 g/L albumin significantly reduced transpulmonary protein flux, bronchoalveolar lavage fluid neutrophil counts, and the degree of histopathological injury compared to resuscitation with Ringer's lactate[32].

The exact mechanism by which albumin does benefit to alleviate lung injury and down-regulate CD11b/CD18 expression is still uncertain. In addition to colloid oncotic effects during resuscitation period, a variety of other properties of albumin have been described[33]. Albumin has been shown to have antioxidant properties and proven to inhibit apoptosis in certain cell lines[10]. As a broad binding protein, albumin may bind and neutralize toxic factors and inflammatory mediators, including cytokines, eicosanods, oxidants, platelet-activating factors, complement fragments, and endotoxin[34,35]. And many of these mediators can prime or activate neutrophils and endothelial cells and cause lung injury directly or indirectly. Although the exact function and identity of the toxic factors in T/HS lymph/plasma remain unknown, it is clearly that albumin has a neutralizing effect[36].

Based on our results, the beneficial effect of albumin infusion occurred during the resuscitation period in T/HS. The results showed that up-regulated expression of PMN CD11b/CD18, ICAM-1 and the lung injury induced by T/HS could be alleviated by the infusion of albumin during resuscitation period. On the other hand, considering the ability of albumin to bind and neutralize the toxic factors,

our study further supports the hypothesis of organ injury induced by some factors released or produced by the post-ischemic intestine through mesenteric lymph pathway in T/HS[37].

## Abstract

**AIM:** To detect the hemodynamic alterations in collateral circulation before and after combined endoscopic variceal ligation (EVL) and splenectomy with pericardial devascularization by ultrasonography, and to evaluate their effect using hemodynamic parameters.

**METHODS:** Forty-three patients with esophageal varices received combined EVL and splenectomy with pericardial devascularization for variceal eradication. The esophageal vein structures and azygos blood flow (AZBF) were detected by endoscopic ultrasonography and color Doppler ultrasound. The recurrence and rebleeding of esophageal varices were followed up.

**RESULTS:** Patients with moderate or severe varices in the esophageal wall and those with severe peri-esophageal collateral vein varices had improvements after treatment, while the percentage of patients with severe para-esophageal collateral vein varices decreased from 54.49% to 2.33%, and the percentage of patients with detectable perforating veins decreased from 79.07% to 4.65% ($P < 0.01$). Color Doppler flowmetry showed a significant decrease both in AZBF (43.00%, $P < 0.05$) and in diameter of the azygos vein (28.85%, $P < 0.05$), while the blood flow rate was unchanged. The recurrence rate of esophageal varices was 2.5% (1/40, mild), while no re-bleeding cases were recorded.

**CONCLUSION:** EVL in combination with splenectomy with pericardial devascularization can block the collateral veins both inside and outside of the esophageal wall, and is more advantagious over splenectomy in combination with pericardial devascularization or EVL in preventing recurrence and re-bleeding of varices.

## INTRODUCTION

In patients with portal hypertension, collaterals should be established to reduce the high portal pressure, and the hemodynamic indicators of such collaterals have been used for the evaluation of therapeutic effects. According to the location of veins, they can be divided into collateral veins inside and outside of the esophageal wall[1]. The collateral veins inside of the esophageal wall may form varices which can be evaluated by routine endoscopy, and are the major source of recurrent bleeding. The collateral veins outside of the esophageal wall, where hypoechic round spaces can be shown by endoscopic ultrasound (EUS), include peri-esophageal collateral veins (peri-ECVs), para-esophageal collateral veins (para-ECVs) and perforating veins. Peri-ECVs are adjacent to the esophageal wall while para-ECVs are distal to the esophageal wall, the perforating veins penetrate the esophageal wall connecting peri- or para-ECVs[2-5].

Irisawa *et al*[2-5] demonstrated that both the prevalences of perforating veins and severe peri-ECVs are positively correlated with the form of varices. The incidence of severe peri-ECVs, para-ECVs, and perforating veins in variceal recurrent cases is significantly higher than that in non- variceal recurrent cases (70%, 50% and 90% *vs* 3.6%, 32.1% and 21.4%, respectively)[6].

On the other hand, endoscopic Doppler ultrasound for measurement of azygos blood flow (AZBF) volume has been used widely in evaluation of the porto-systemic collateral circulation[7], and is a safe and useful method for monitoring portal venous flow in patients with portal hypertension.

It is reported that more than 70% of portal hypertension patients with variceal bleeding history may suffer from recurrent bleeding[8,9]. Splenectomy with pericardial devascularization, sclerotherapy, endoscopic variceal ligation (EVL) or other combined therapies have been recommended for those patients. We have previously reported that splenectomy with EVL is superior to splenectomy with pericardial devascularization in the treatment of portal hypertension[10-12]. However, whether combined EVL and splenectomy with pericardial devascularization is effective and the hemodynamic alterations in this process remain unknown.

In this study, we used EUS and color Doppler ultrasound to detect the hemodynamic alterations in collateral circulation before and after EVL in combination with splenectomy with pericardial devascularization. The hemodynamic parameters were used to evaluate its effect. An ultrasound microprobe (UMP) was adopted for the detection of collateral veins, which could provide better images of vascular structures than conventional EUS due to its higher frequency and resolution[3,13,14].

## MATERIALS AND METHODS

### Patients

From March 2001 to May 2004, consecutive patients with untreated esophageal varices caused by portal hypertension were admitted to the Third Affiliated Hospital of Sun Yat-Sen University. Patients who did not want to participate in the study, those with severe diseases in major organs other than in liver and/or older than 70 years, and those with different Child-Pugh's scores before and after all EVL sessions were excluded to avoid the influence of alterations of Child-Pugh's grade on the portal blood flow rate[5]. Finally, 43 patients who were clinically diagnosed as portal hypertension with endoscopically confirmed esophageal varices were included in this study. The clinical data of the enrolled patients are shown in Table 1.

Written informed consent was obtained from all the patients, and the study was approved by the Ethics Committee of Sun Yat-Sen University.

### Ligation of endoscopic varices

Patients underwent EVL first. After local application of lidocaine, an endoscope (GIF 240 or 260, Olympus Optical, Tokyo) was introduced, and ligation was carried out 6-12 times by placing a single rubber band (Bard Interventional Products, Tewksbury, Mass.) over a varix. The ligation was repeated every 2 wk till the complete disappearance of varices under endoscope.

### Splenectomy with pericardial devascularization

Patients underwent splenectomy with pericardial devascularization (Hassab's operation) 4-10 wk after the first EVL session as previously described by Yang and Qiu[15]. In brief, extended left subcostal incision or L incision of the left upper abdomen was used for extreme splenomegaly. After routine splenectomy, the gastric branch and 5-8 small branches of the gastric coronary veins were disconnected. The esophageal branch was disconnected and suture-ligated. The gastric posterior vein was ligated by suturing, and then the left subphrenic vein was ligated as well[16]. In addition, the arteries accompanying the veins including the left gastric, left gastroepiploic, gastric posterior and left subphrenic arteries, were disconnected.

### Color Doppler ultrasound

Color Doppler ultrasound detection was performed before the treatment and 1 wk prior to discharge. AZBF was measured with EUS duplex Doppler technique with a Pentax FG-32UA echo-endoscope (Tokyo, Japan) and a Hitachi EUB-515A ulterasound scanner (Tokyo, Japan) with a frequency of 7.5 MHz[17]. The diameter of the vessel and the blood velocity were measured, the mean value of 3 repeated measures performed at the same position was used. AZBF was calculated with the following formula: AZBF = $(\text{radius})^2 \times$ blood velocity.

### Detection of the veins inside and outside of the esophageal wall

The structure of vessels inside and outside of the esophageal wall was examined before the treatment and 1 wk prior to discharge with an Olympus UM-3R 20MHz UMP (Tokyo, Japan ) passed through the accessory channel of a GIF 250 Olympus endoscope (Tokyo, Japan). Before examination, the esophagus was filled with deaerated water through a water supply tube attached to the endoscope. The veins around the esophagus were scanned from the esophago-gastric junction (GEJ) to a point 5 cm proximal to the EGJ. Varices inside of the esophageal wall (EV) were evaluated as mild (< 5 mm in diameter), moderate (5-7 mm in diameter), and severe (> 7 mm in diameter).

According to the definition of location[3], esophageal collateral veins outside of the esophageal wall could be divided into peri-ECVs and para-ECVs. There were less than 4 mild peri-ECVs (< 2 mm in diameter) and more than 5 severe peri-ECVs (≥ 2 mm in diameter) adjacent to the muscularis externa of the esophagus, a few mild para-ECVs (< 5 mm in diameter) and severe para-ECV (≥ 5 mm in diameter) distal to the esophageal wall without contact with the muscular externa. The presentations of

EV: Varices inside of the esophageal wall; Peri-ECVs: Periesophageal collateral veins; Para-ECVs: Paraesophageal collateral veins.

perforating veins penetrating the esophageal wall which were connected either to peri-ECV or to para-ECV, were recorded.

### Follow-up of patients

Endoscopic follow-up was performed every 12 wk after discharge of the patients. The degree of varices was evaluated at each follow-up.

### Statistical analysis

Values were expressed as mean ± SD. Statistical analysis was performed using the statistical SPSS version 10.0. Differences in numerical variables between groups were analyzed with paired $t$ test. Mann-Whitney test was used for the analysis of ranked data. Comparison of categorical data was performed by the chi square test. $P < 0.05$ (two-tailed test) was considered statistically significant.

## RESULTS

### Alterations in varices and perforating veins

Compared to pre-treatment, EV, peri- and para-ECV in varices as well as perforating veins were all improved after treatment. Patients with moderate or severe EV or severe peri-ECVs had improvement after treatment, while the percentage of patients with severe para-ECVs decreased from 54.49% to 2.33%, and the percentage of patients with detectable perforating veins decreased from 79.07% to 4.65% ($P < 0.01$, Table 2).

### Alteration in appearance of UMP images

In the UMP images before treatment, enlarged tortuous varices were found inside of the esophageal wall, while many small vessels adjacent to the muscularis externa formed a venous plexus. After treatment, the anechoic areas inside and outside of the esophageal wall disappeared or remained only tiny, while the echo of mucosa and submucosa of the esophagus enhanced. The alteration in appearance of UMP images intuitively implied the improvement in varices after treatment (Figure 1).

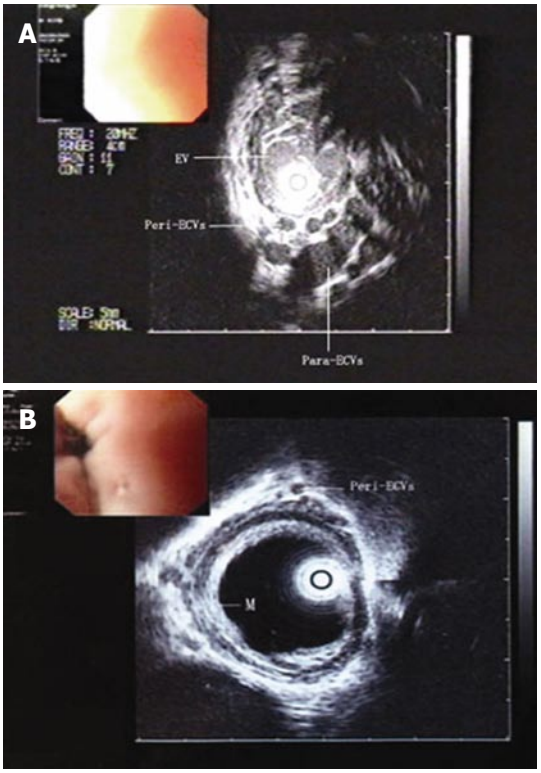

**Figure 1** Alteration in appearance of ultrasound microprobe images. **A**: Before treatment, enlarged tortuous varices were found inside of the esophageal wall, while many small vessels adjacent to the muscularis externa formed a venous plexus. **B**: After treatment, anechoic areas inside and outside of the esophageal wall disappeared or remained only tiny, while the echo of mucosa and submucosa of the esophagus enhanced. EV: Varices inside of the esophageal wall; Peri-ECVs: periesophageal collateral veins; Para-ECVs: Paraesophageal collateral veins; M: Esophageal mucosa.

**Table 3 Alteration in inside diameter, blood flow and blood flow rate of azygous vein (mean ± SD)**

| | Inside diameter (mm) | Blood flow (cm/s) | Blood flow rate (mL/s) |
|---|---|---|---|
| Pre-treatment | 10.12 ± 1.16 | 1.00 ± 0.14 | 22.73 ± 5.46 |
| Post-treatment | 7.20 ± 1.13[b] | 0.57 ± 0.05[b] | 20.15 ± 4.66 |

[b]$P < 0.01$ *vs* pre-treatment group (ANOVA).

### Alteration in azygos blood flow

Color Doppler flowmetry showed a significant decrease both in AZBF (43.00%, $P < 0.05$) and in diameter of the azygos vein (28.85%, $P < 0.05$), while the blood flow rate was uncharged (Table 3).

### Results of follow-up

A total of 40 patients were followed up for 6 mo to 1 year, with a follow-up rate of 93.0%. Three patients were not followed up due to death (1 died of liver cancer, 2 died of other diseases). The recurrence rate of esophageal varices was 2.5% (1/40, mild), while no re-bleeding cases were recorded.

## DISCUSSION

Although splenectomy with pericardial devascularization has been commonly used for portal hypertension and can control bleeding[15], re-bleeding is likely to occur because of the existing portal hyperdynamic pressure[18]. Varices cannot be eliminated by splenectomy with pericardial devascularization, and the unblocked blood flow in reverse direction in esophageal submucosa and muscular layer may increase the venous pressure at the distal part of stomach, which increases the risk of variceal bleeding.

EVL is a more effective method for portal hypertension with less side effects than surgery[19,20]. However, it causes fibrosis in mucous layer where the esophageal varices locate and has no effect on the formation of collateral circulations in the muscular layer or outside of the esophageal wall.

Nagamine *et al*[13] showed that after repeated EVL, almost all varices are undetectable in UMP imaging. However, neither collateral nor the azygous vein significantly changes its size. Similar results have been repeated by Seno *et al*[21].

In our study, not only varices were relieved, but also the sizes of collaterals and azygous vein were reduced after combined EVL and splenectomy with pericardial devascularization, suggesting that this combined therapy can almost completely relieve collateral vein varices both inside and outside of the esophageal wall.

In addition, more obvious improvement in collateral vein varices outside of the esophageal wall was found in peri-ECVs (the percentage of severe cases reduced from 69.77% to 0%) and perforating veins (the percentage of detectable cases reduced from 79.07% to 4.65%), suggesting that peri-ECVs play a more important role in the formation of esophageal varices than para-ECVs[3].

The incidence of varix and its recurrence observed in a short-term follow-up were low. However, the long-term results of the treatment in this study may be influenced by many factors, such as liver function, infection and food consumption. Therefore, the long-term effect of combined EVL and splenectomy with pericardial devascularization should be further studied.

In conclusion, combined EVL and splenectomy with pericardial devascularization can block the collateral veins both inside and outside of the esophageal wall and is more advantagious over splenectomy with pericardial devascularization or EVL in preventing recurrence and rebleeding of varices.

## Abstract

**AIM:** To identify genes differentially expressed in mouse hepatocarcinoma ascites cell line with low potential of lymphogenous metastasis.

**METHODS:** A subtracted cDNA library of mouse hepatocarcinoma cell line with low potential of lymphogenous metastasis Hca-P and its synogenetic cell line Hca-F with high metastatic potential was constructed by suppression subtracted hybridization (SSH) method. The screened clones of the subtracted library were sequenced and GenBank homology search was performed.

**RESULTS:** Fifteen differentially expressed cDNA fragments of Hca-P were obtained which revealed 8 known genes, 4 expressed sequence tags (ESTs) and 3 cDNAs showed no homology.

**CONCLUSION:** Tumor metastasis is an incident involving multiple genes. SSH is a useful technique to detect differentially expressed genes and an effective method to clone novel genes.

**Key words:** Suppression subtracted hybridization; Liver neoplasm; Metastasis suppression genes

## INTRODUCTION

Tumor metastasis is an incident involving multiple genes. However, the number of metastasis related genes available nowadays is very limited to elucidate the puzzling process of metastasis. Therefore, more attentions have been paid to screen candidate genes responsible for metastasis by high throughput technique. Hca-P and Hca-F are a pair of synogenetic mouse hepatocarcinoma ascites cell lines, possessing a specific potential of lymphogenous metastasis when inoculated subcutaneously into 615 mice, Hca-P showing a low metastatic potential (< 30%), while Hca-F showing a high potential (> 80%)[1]. In the current study, we employed suppressive subtracted hybridization (SSH) technique to identify differentially expressed genes specific for Hca-P in an effort to obtain candidate genes related to lymphogenous metastasis of hepatocarcinoma in mice.

## MATERIALS AND METHODS

Hca-F and Hca-P have been established and maintained by our laboratory[1]; inbred 615-mice were provided by the experimental animal center of our university.

### *Determination of lymph node metastatic rates of Hca-P and Hca-F*

Sixty inbred 615-mice were randomly divided into 2 groups. The Hca-P and Hca-F tumor cell lines were inoculated at $2 \times 10^6$ tumor cells of approximately 0.1 mL cell suspension into each mouse subcutaneously in each group. The mice were decapitated on the 28th day post-inoculation. The implanted tumor and the regional lymph nodes were removed and paraffin sections of tissues were HE stained and examined under microscope. The lymph node metastatic rates of Hca-F and Hca-P tumor cells were calculated.

### *Construction of a subtracted cDNA library by SSH*

**Preparation of total RNA and mRNA:** Isolation of total RNA was performed by TRIZOLTM(GIBCOBRL) and that of mRNA was carried out according to the

protocol of oligotex mRNA spin column purification kit (Qiagen). The quantity and integrity of mRNA were detected by ultraviolet spectrometer and by electrophoresis on a denaturing formaldehyde agarose stained by EB. mRNA of Hca-P served as tester and mRNA of Hca-F as driver. SSH was performed between tester and driver by a PCR select$^{TM}$ cDNA subtraction kit and 50 × PCR enzyme kit (Clontech, Heidelberg, Germany) following the instructions of the manufacturer.

**dscDNA synthesis and digestion with *Rsa* I :** Briefly, 2 μg aliquots of each of poly ($A^+$) mRNA from the tester and the pooled driver were subjected to dscDNA synthesis. Thereafter, they were purified by passing through Chroma spin-400 columns (Clontech, USA). Each purified dscDNA was digested with *Rsa* I .

**ligation to adaptor 1 and 2R:** The tester cDNAs were subdivided into 2 equal groups and then ligated to adaptor 1 and 2R in separate ligation reactions. Ligation efficiency analysis was performed by amplifying ligation products with G3PDH 3' primer/PCR primer 1 and G3PDH 3' primer/G3PDH 5' primer, respectively, and their intensity was compared.

**Subtractive hybridization:** Subtractive hybridization was performed by annealing an excess of driver cDNAs with each sample of adaptor-ligated tester cDNAs. The cDNAs were heat-denatured and incubated at 68℃ for 8 h. After the first hybridization, the 2 samples were mixed together and hybridized again with freshly heat-denatured driver cDNAs for 20 h at 68℃. Two rounds of hybridization would generate a normalized population of tester-specific cDNAs with different adaptors at each end. After filling in the ends, 2 rounds of PCR amplification were performed to enrich desired cDNAs containing both adaptors by exponential amplification of these products[2]. The optimized cycles for the first and second PCRs were 27 and 13 respectively to increase representation and reduce redundancy of subtracted cDNA libraries.

**Analysis of subtractive efficiency:** Secondary PCR products were used as templates for PCR amplification of human G3PDH for 18, 23, 28 and 33 cycles respectively to assure subtraction efficiency. PCR products were run on 1.8% agarose gel.

### *Ligation of the subtracted library into a TA vector*

Products of the secondary PCR reactions were cloned into a pT Adv vector (Clontech) and the resultant ligation products were then transformed into DH5α *E. coli* competent cells. The bacteria were subsequently grown in 800 μL of liquid Luria-Bertani medium and allowed to incubate for 45 min at 37℃ with shaking at 150 rpm. Thereafter, the cells were plated onto agar plates containing ampicillin (50 μg/mL), 5-bromo-4-chloro-3-indoly-b-D-galactoside (X-gal; 20 μg/cm$^2$) and iso-ploprl-b-D-thiogalactoside (IPTG; 12.1 μg/cm$^2$) and incubated overnight at 37℃. Individual recombinant white clones were picked and grown in single line pattern onto Luria-Bertani agar solid medium containing ampicillin and allowed to incubate at 37℃ for 6-7 h before single clone was picked from single-line pattern agar medium and allowed to grow in Luria-Bertani liquid medium containing ampicillin overnight at 37℃ with shaking at 150 r/min.

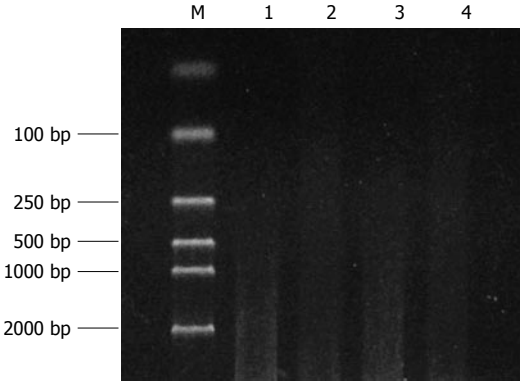

**Figure 1** The effect of *Rsa* I digestion. Lane 1, 3: cDNA of Hca-F and Hca-P cells; Lane 2, 4: cDNA of Hca-F and Hca-P cells after *Rsa* I digestion; M: DNA marker DL2000.

### *Identification of the subtracted clones*

Plasmids of candidate positive clones from subtracted cDNA library were isolated and amplified by PCR with nested primer 1 and primer 2. Meanwhile the product of PCR was detected by agarose gel electrophoresis.

### *Sequencing and BLAST homology search*

Randomly screened 14 positive clones from the subtracted cDNA library were sequenced by T7/SP6 chain termination reaction in TaKaRa (DaLian, China). Nucleic acid homology searches were subsequently performed at the National Center of Biotechnology Information (National Institutes of Health, Bethesda, Md., NCBI).

## RESULTS

### *Determination of lymph node metastatic rates of Hca-P and Hca-F*

Implanted tumors of both Hca-P tumor-bearing mice and Hca-F tumor-bearing mice were palpable on 7th day post-inoculation. On the 28th day post-inoculation, 10% Hca-P cells bearing mice developed metastatic regional lymph nodes (3/30), while 80% Hca-F cells bearing mice developed metastatic regional lymph nodes (24/30).

### *Total RNA and mRNA analysis*

The RNA samples electrophoresed on 1% agarose/EB gel exhibited 2 typical bands, corresponding to ribosomal 28s and 18s RNA, respectively, with a ratio of intensities > 2:1 and 1.9, ideal A260/A28 ratios of both samples obtained, indicating high integrity and purification of the total RNA we obtained. mRNA samples appeared as a smear with weak ribosomal RNA band: a high-quality mRNA was purified.

### *Rsa* I *digestion*

Both the digested cDNA and undigested cDNA usually presented as smears. However, their patterns were different. The digested cDNA fragments became shorter after Rsa I digestion (Figure 1).

### *Ligation efficiency analysis*

Intensity of the PCR product amplified using one gene-

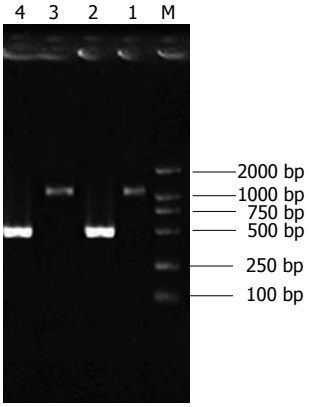

**Figure 2** Ligation efficiency analysis. Lane 1: Tester-1 as template, G3PDH 3'Primer and PCR Primer1; Lane 2: Tester-1 as template, G3PDH 3'Primer and G3PDH 5'Primer; Lane 3: Tester-2R as template, G3PDH 3'Primer and PCR Primer1; Lane 4: Tester-2R as template, G3PDH 3'Primer and G3PDH 5'Primer.

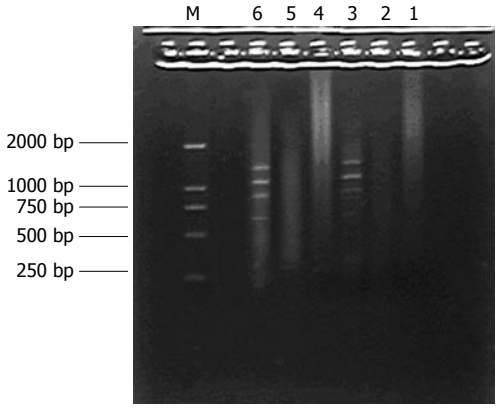

**Figure 3** The results of secondary PCR amplification. Lane 1-3: Product of primary PCR amplification, Lane 4: secondary PCR amplification product of unsubtracted cDNA, Lane 5: secondary PCR amplification product of subtracted cDNA, Lane 6: secondary PCR amplification product of PCR control cDNA, M: DNA Marker DL2000.

specific primer (G3PDH 3' primer) and PCR primer 1 was 25% more than that of PCR product amplified using two gene-specific primers (G3PDH 3' primer and 5' primer). Ligation efficiency was > 25%, ensuring enough tester cDNA in the following hybridization (Figure 2).

### *Construction of subtracted cDNA library by SSH*

PCR products of the subtracted and unsubtracted usually looked like smears with or without discrete bands. However, the patterns between them were different (Figure 3).

### *Analysis of subtractive efficiency*

Subtraction efficiency analysis showed the effectively reduced amount of non-differentially expressed genes. In unsubtracted cDNA libraries, housekeeping gene G3PDH PCR products were visible after 23 cycles of amplification and became saturated after 23-28 cycles. However, subtracted libraries required 33 cycles for G3PDH to be detected (Figure 4).

### *Differential screening of subtracted cDNA libraries*

The subtracted cDNA libraries were composed of 995 positive clones, of which 200 clones were randomly picked up and plasmids of the candidate positive clones were isolated and amplified by PCR with nested primer 1 and

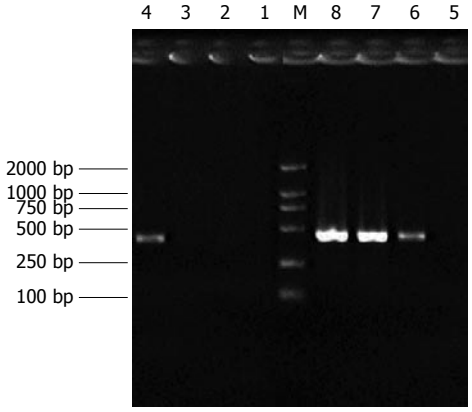

**Figure 4** Analysis of subtraction effect. PCR was performed on subtracted (Lane 1-4) or unsubtracted (Lane 5-8) secondary PCR product with G3PDH 5'Primer and 3'primer. Lanes 1, 5: 20 cycles, Lanes 2, 6: 25 cycles, Lanes 3, 7: 30 cycles, Lanes 4, 8: 35 cycles. M: DNA marker DL2000.

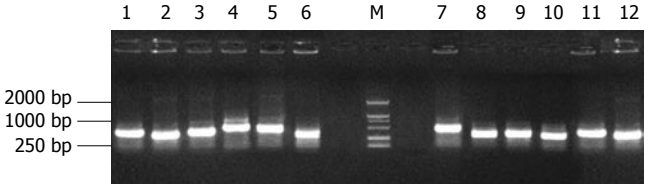

**Figure 5** The results of clone PCR amplification. There was an average insert size of 300-1000 bp. M: DNA marker DL2000.

primer 2. As a result, 189 positive clones showed PCR products of a size of 300-1000 bp (Figure 5).

### *Sequencing and homology search*

Fifteen screened clones randomly selected were sequenced and homology search (http://www.ncbi.hlm.nih.gov/BLAST/) revealed 8 known genes and 4 expressed sequence tags (ESTs). Three cDNAs showed no homology and presumably represented novel genes (Table 1).

## DISCUSSION

Tumor metastasis, as the leading cause of tumor related death, is a process involving multiple genes and their products. Elucidation of the gene expression profiles specific for tumor cells with different potential of metastasis might help in the understanding of the molecular mechanisms of metastasis. As one of the high throughput screening techniques, SSH technique has two distinct advantages: (1) it boasts a high subtraction efficiency; (2) it harbors an equalized representation of differentially expressed sequences which can separate effectively both high and low copy expressed genes mainly because of normalization[2]. von Stein *et al*[3] found about 94% positive rate in their research. Thus they considered confirmation of differentially expressed genes by Northern blot analysis for each clone obtained was probably unnecessary.

For a long time, studies have focused on the angiogenesis of tumors, but the roles of lymphatic vessels

**Table 1 Homologue searching of the sequenced cDNA fragments from SSH library**

| Clone seriel number | Size (bp) | Sequence identity |

in tumor growth and metastasis were neglected. However, it is well known that lymphatic metastasis is mainly responsible for the spread of epithelial malignant tumors, and is closely related to the prognosis of patients.

Hca-P and Hca-F are a pair of synogenetic mouse hepatocarcinoma ascites cell lines presenting a specific potential of lymphogenous metastasis with a significant difference in their potential of metastasis[1]. Candidate genes involved in lymphogenous metastasis are supposed to be among the differentially expressed genes.

Using Hca-P as a tester, Hca-F as a driver, and we employed SSH technique to identify differentially expressed genes specific for Hca-P(low metastatic potential) so as to obtain candidate suppressor genes of lymphogenous metastasis. Fifteen screened clones randomly selected were sequenced and homology search revealed 8 known genes as $TRF_1$, $TRF_2$(telomere repeat binding factor 1, 2) ; maspin; mouse 7 days embryo whole body cDNA, RIKEN full-length enriched library clone 2210102k3; mouse 5 days liver cells cDNA, RIKEN full-length enriched library, clone E330462F4; mouse chromosome 3 clone RP 6-126M1;mouse chromosome 17 clone RP 26-122M3 and mouse chromosome 4 clone RP13-110N10. Studies showed $TRF_1$, and $TRF_2$ play important roles in genome stabilization [4-11] and are down-regulated in some malignant cell lines and tumor tissues[12-18]. In hematopoietic carcinogenesis, gene expression of telomerase suppressors such as TRF and TIN2, is decreased. mRNA encoding $TRF_1$ and $TRF_2$ when gastric cancer becomes more deeply invaded**,** is significantly decreased, indicating a negative association with tumor progression. Of the 8 known fragments, one showed high homology to mouse Maspin gene. Serving as one of the few p53-targeted genes involved in tumor invasion and metastasis, Maspin, a member of the serpin family, has been reported to suppress metastasis and angiogenesis in breast and prostate cancers, and is closely correlated with their clinical manifestations[19-31]. It indicates that SSH in our study is capable of enriching metastasis related genes.

Another 5 known fragments were attributed to embryo genes. Embryo genes AFP and CEA are overexpressed in hepatocarcinoma and other malignant tumors, indicating a possible association between embryo development and tumor. Embryo genes were also found in our previously established SSH library which contains candidate tumor metastasis genes[32]. These data showed that up-regulated expression of embryo genes during metastasis is not a casual event. Their roles in tumor metastasis need to be clarified. Moreover, 4 cDNA fragments demonstrated homology with 4 ESTs-mouse and 3 cDNA fragments showed no homology and presumably represented novel genes[33].

In summary, the findings of our study suggest that the lymphatic invasiveness of tumor cells is determined by multiple genes and co-factors with complex cellular signal pathways. Further functional study of the candidate novel genes might provide clues to molecular mechanism of tumor metastasis.

## Abstract

Cytomegalovirus (CMV) colitis rarely occurs in immunocompetent patients. We report a case of disabling and life threatening diarrhea in an immunocompetent elderly woman due to CMV colitis. The diagnosis of CMV was based on histological examination of tissues biopsied at colonoscopy, positive CMV antigen and high CMV-IgM titer in peripheral blood samples and a good response to systemic gancyclovir treatment. We conclude that CMV should be considered in the differential diagnosis of colitis in elderly immunocompetent patients.

## INTRODUCTION

The seroprevalence of cytomegalovirus (CMV) in the general population is high (40%-100%)[1]. Most CMV infections are acquired in the perinatal period, infancy or early adulthood[2]. The majority of primary CMV infections in immunocompetent adults are asymptomatic or associated with mild mononucleosis-like syndrome. To our knowledge, there have been only anecdotal reports of clinically significant CMV gastrointestinal infection in healthy adults. In these cases, CMV disease developed with community acquired, acute primary infection, through blood transfusions and sexual transmission[3,4].

## CASE REPORT

A 76-year-old woman was admitted with a week history of diffuse abdominal pain and one passing of watery diarrhea a few hours before admission. She had well controlled type 2 diabetes mellitus and hypertension. Twenty years ago, she had undergone a right mastectomy and chemotherapy treatment for breast carcinoma. She had not received chemotherapy for at least 15 years. On admission, her physical examination revealed minimal tenderness in the right abdomen without reboundness. Laboratory investigations showed a leucocytosis of $15 \times 10^9$/L (normal range, 3.5-9.5 $\times$ $10^9$/L) and mildly elevated liver enzymes of SGOT 75 (normal range, 15-40) IU/L and SGPT 129 (normal range, 15-40) IU/L. Bilirubin levels were normal. HIV serology was negative.

During the initial days of her hospitalization, the diarrhea worsened and was accompanied by bloody and pussy rectal discharge. She had a mild fever of 38℃. Electrolyte disturbances (hypokalemia and hypomagnesemia) were attributed to the diarrhea and were easily corrected. Albumin levels decreased to 2.4 (normal 3.6-5.5) g/L. Stool cultures were negative, and Clostridium Difficile toxin was not detected in three stool samples. Computed tomography of the abdomen demonstrated atherosclerosis of the abdominal aorta and thickening of the sigmoid colon. Colonoscopy revealed several fibrin-coated deep ulcers in the rectum and sigmoid colon. Mucosal biopsy showed acute inflammation, ulceration and signs of regeneration with marked atypia. CMV immunostain was positive in a few cells. Active CMV infection was confirmed by high IgM CMV titer and CMV antigen in peripheral blood samples.

The patient was treated with intravenous gancyclovir for one week and then with oral valgancyclovir for additional five weeks. Her abdominal pain and diarrhea settled within a few days of initial treatment. Her blood studies normalized. The patient remained asymptomatic during 12 mo of follow-up.

## DISCUSSION

CMV colitis is associated with constitutional symptoms as well as gastrointestinal symptoms such as diarrhea, hematochezia, tenesmus, urgency and abdominal pain. The disease is usually limited to the left colon, with endoscopic findings indistinguishable from ulcerative colitis and Crohn's disease. Diagnosis requires both serologic and histologic criteria. CMV produces a characteristic cytopathic effect, consisting of a large 25 to 35 μm cell containing a basophilic intranuclear inclusion, which is sometimes surrounded by a clear halo and is frequently

associated with clusters of intracytoplasmatic inclusions[5]. Immunohistochemistry of the biopsied tissue using monoclonal antibodies and in-situ DNA hybridization enhances the sensitivity of the histopathologic analysis[6]. Positive IgM titer for CMV, CMV antigen in the blood and positive polymerase chain reaction in blood or urine confirm the diagnosis.

In a meta-analysis of outcome of CMV colitis in immunocompetent hosts (44 cases), the rate of spontaneous remission was 31.8%, but > 50% for patients less than 55 years of age. Death occurred in 31.8% of patients greater than 55 years of age[7]. The decline in humoral and cellular immunity, and the higher prevalence of co-morbidity in older patients may explain these findings. The highest mortality rates were associated with immune modulating conditions, such as diabetes mellitus, renal failure and malignancies. Young (< 55 years) and otherwise healthy patients usually are able to recover from CMV infection without the need for antiviral therapy. Antiviral therapy with gancyclovir or foscarnet is mandatory for older patients and for patients with immune modulating conditions.

In conclusion, CMV colitis, although rare in immunocompetent patients, should be considered when more common etiologies for severe diarrhea have been excluded. Timely diagnosis and treatment are essential in order to improve the outcome of elderly patients or patients with serious co-morbidities.

*World J Gastroenterol* 2006 November 14; 12(42): 6902-6904
***World Journal of Gastroenterology*** ISSN 1007-9327

# Instructions to authors

## GENERAL INFORMATION

*World Journal of Gastroenterology* (*WJG, World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc.*, from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

### *Indexed and abstracted in*

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

### *Published by*

The WJG Press

## SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

### *Online submission*

Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

### *Postal submission*

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

### Editorial Office

***World Journal of Gastroenterology***
Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com
Telephone: +86-10-85381901
Fax: +86-10-85381893

## MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

### *Title page*

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

### *Abstract*

An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc.* should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

### *Key words*

Please list 6-10 key words that could reflect content of the study mainly from *Index Medicus*.

### *Text*

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

### *Illustrations*

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 85 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

### *Tables*

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

### *Notes in tables and illustrations*

Data that are not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ should be noted ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used. Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under

illustrations should be expressed as $^1F$, $^2F$, $^3F$; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.* in a certain sequence.

### *Acknowledgments*

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

## REFERENCES

### *Coding system*

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24 ], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

### *PMID requirement*

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (http://www.wjgnet.com/cgi-bin/index.pl), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

### *Style for journal references*

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (http://www.aushome.cn/cgi-bin/index.pl)

### *Style for book references*

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

### *Inappropriate references*

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

### *Statistical data*

Present as mean ± SD or mean ± SE.

### *Statistical expression*

Express $t$ test as $t$ (in italics), $F$ test as $F$ (in italics), chi square test as $\chi^2$ (in Greek), related coefficient as $r$ (in italics), degree of freedom as $\gamma$ (in Greek), sample number as $n$ (in italics), and probability as $P$ (in italics).

### *Units*

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, $p$(B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; $CO_2$ volume fraction, 50 mL/L $CO_2$ not 5% $CO_2$; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

***Abbreviations***

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

***Italics***

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H pylori, E coli, etc.*

## SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

***Language evaluation***

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

***Copyright assignment form***

Please downloaded CAF from http://www.wjgnet.com/wjg/help/9.doc.

We certify that the material contained in this manuscript:

**Ms:**

**Title:**

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to WJG all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

**Criteria for authorship:** The WJG requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1)direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3)supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The WJG does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to WJG if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

## Abstract

Hundreds of scientific journals are published in China. However, only scores of them are included in Science Citation Index by the Institute for Scientific Information, with impact factors of only 1 or less. Thus, how to establish a first-class international scientific journal in China is an important but difficult topic that deserves extensive exploration. *World Journal of Gastroenterology* (*WJG*) sets a good example although it has experienced setbacks on the road towards success. Concepts and pursuits that affirm the overall development direction, innovation and dreams that provide impetus and aspiration for higher objectives, team work and unique pattern that assure excellent quality and service, and culture and environment that also determine the speed and direction of the development, are believed to be the major factors contributing to the success of *WJG*. It is recommended that the effective resolution to the above issue is to learn from Chinese examples such as *WJG* rather than from "how foreign journals do".

## INTRODUCTION

In 2005, China Ministry of Science and Technology organized and implemented a research project on "How to establish a first-class international scientific journal in China". This issue is indeed an important but difficult topic that deserves extensive exploration. Both the editorial workers and the administrative authorities of scientific journals should seriously respond to it. In the meantime, I believe that the effective resolution to this issue is to learn from "Chinese cases"rather than from "how foreign journals do".

*World Journal of Gastroenterology* (*WJG*) was formally established by Dr. Lian-Sheng Ma on October 1, 1995. As an administrative leader of the Science Committee of Shanxi Province which is in charge of scientific journals, I have witnessed the growth and development of *WJG* over the past 12 years, but never made any public comments on the journal. Today, I wish to make some points by incorporating the *WJG* case into the above mentioned topic.

## CONCEPTS AND PURSUITS

As a macroeconomist, I know nothing about scientific journals. However, I am astonished to find that many journals have the same weaknesses as enterprises do. Some experts have reported that many Chinese enterprises suffer from "short-life syndrome" with an average lifespan of 2.9 years. It has also been said that some large Chinese corporations suffer from "small enterprise disease" characterized by severe opportunism in the strategic plan, lack of supporting sections in organization structure, collaboration inside the teams, and the uniform core values of the corporation. Similarly, it has been said that Chinese scientific journals are in short of creative and innovative papers, and abundant in third-class and "cloned" papers, which not only is a great waste of academic resources but also results in an extremely bad impact on scientific development in China. In my opinion, Chinese scientific journals share one common weakness, i.e. lack of concept and pursuit. This is just like the situation in Shanxi Province, where the negative impact driven by so-called resource economy has become increasingly obvious. Unauthorized mining, frequent mine explosion, vicious competition and corruption all can be attributed to the lack of concepts. Shanxi economy is an example that is cursed by "its resources". The misfortune resulting from the lack of concepts is shown by the horrible economic development without any conceptual restriction. Similarly, the development of scientific journals without any conceptual restriction is disastrous since it brings about enormous scientific "rubbish" and academic corruption,

which is known as "concept-lacking syndrome"in China.

Concepts mean belief, pursuits, and direction. Its core is the concept of values. The world well-known United States Military Academy at West Point has a history of over 200 years. The Academy's special educational concepts are "nation, honor and responsibility", which represent the spirit of nation, honor for society, team and personal responsibility. With such concepts, the Academy has educated two presidents (Ulysses S. Grant and Dwight D. Eisenhower), many famous generals, and a lot of business leaders. Whether an entrepreneur pursues a career or profits is the criterion to judge his/her personality. What is the objective to establish an academic journal? I said to Dr. Ma 10 years ago that "You should not be involved in any academic journal if you just want to make money". He got what I meant very clearly. Frankly, I did not believe he was able to establish an academic journal at that time because he lacked resources. Moreover, I did not understand his intention or ambition. On the one hand, he was already a famous doctor, and made a lot of money from his herbal inventions at that time, and thus could live a very comfortable life. On the other hand, it requires quantities of human and financial resources to take many risks to establish an academic journal. To choose establishing an academic journal as a career means hard work, suffering and even tears.

With high quality and excellent service as his concepts, Dr. Ma has devoted himself to and sacrificed a lot for *WJG*. As a man in his forties, his hair has turned grey. Fortunately, he finally succeeded. In the article entitled "The reasons for *WJG*'s success", which describes that the ultimate criterion to test a scientific journal is whether or not researchers in the field put it in their reading list. *WJG* has now successfully passed the criterion. *WJG* is an open and free international journal, and also the only weekly journal in gastroenterology in the world. The latest published papers in *WJG* are always sent to doctors and researchers free of charge by email. In addition, an average of about 30 000 online visits to the *WJG* website is recorded every day.

*WJG* has proposed a higher objective. At present 47 journals in Gastroenterology worldwide are included in the Science Citation Index Expanded (SCI-E). These first-class journals are also classified into three grades. Dr. Ma plans to invest one hundred million Yuan to make *WJG* an upper-middle level journal among these journals within 5 to 10 years. He is exploring a unique way to establish an international first-class scientific journal in China with persistent pursuits for quality and services.

## INNOVATION AND DREAM

Almost all the industries find it hard to adapt to the new environment in which there is a changing process from an industrialized society to a knowledgeable society, and do not know what to do next. I attended a recent forum on education reform during which a Japanese expert introduced education reform in Japan. "The most lacking nowadays are concepts and ideas" he said emotionally. It is really difficult to depict the pattern or model of scientific journals in the future. It was reported in a survey that only less than 5% Chinese enterprises have made a professionally-standard, complete and feasible strategicaly developed plan by scientific means. More than 90% of companies have no long term plan on how to survive. There is a famous byword at Harvard University, that is, a successful man is distinguished not due to his knowledge and experience, but due to his way of thinking. It has been said that the future cannot be forecasted or adapted, but can only be created. What is a first-class international scientific journal in China? This question can only be thought and answered by ourselves. Creativity is always limited by knowledge, experience and way of thinking. As a president of a publisher or an editor-in-chief of a journal, one must have the specific ability to shape innovative thinking, and to improve his thinking to a higher level.

Over the past decade, the most that Dr. Ma and I have discussed is the creativity of *WJG*. Dr. Ma telephoned me almost every week after my retirement, telling me his new ideas, from the administrative system to the flow remodeling, from scientific editing to electronic editing, from human resources to the internal structure management, and from exiting journals to resource integration in the same field. He is pursuing innovation in every aspect of editing a journal, which is the major reason that I have been greatly interested in *WJG*. On January 9, 2006, President Jin-Tao Hu pointed out at the National Congress of Science and Technology that China shall become a country with innovation in the next 15 years. This is a new starting point to a new road. Now officials in every industry are thinking about the issue on how to exploit a path with independence, innovation and Chinese characteristics. Then, how to establish an international first-class scientific journal in China? Taking the laggard reality in China into consideration, I would suggest that innovation must be comprehensive and systematic, rather than individualized, revolutionary, and evolving, in order to catch up or even overtake the international levels. Moreover, innovation in the administrative system is much more important than innovation in technology. I believe that one can find all answers to the question if he/she sticks to the two principles of innovation.

Now *WJG* Press, based on the current achievements and experience, is building an innovative system that includes journals as the main body, and the laboratory and pharmaceutical companies as supporting points, and is exploring a new model that combines journal publication with manufacturing, education and research. Dr. Ma always tries hard to make the best *WJG* once he identifies the right way, with the strategic design and practical implementation being carried on almost at the same time. *WJG* was publicly issued on June 29, 1995 as a seasonal journal. It became bimonthly from 1998 to 2002, monthly in 2003, biweekly in 2004, and then weekly in 2005, with one big jump each year over the last three years. Despite such significant achievements, I described each jump as the "thrilling jump" (Karl Max). I have warned Dr. Ma that if the jumping failed, the injured would be Dr. Ma himself but not *WJG*. Fortunately, Dr. Ma succeeded. Now he is thinking how to integrate resources of the famous journals in the field, and is planning to publish *World Journal of Oncology* and *World Journal of Chinese Medicine*, and to create a

broader platform for medical communications. In this way, an innovative chain will be created to optimize resource allocation, just like the supply chain management in the enterprises. I believe that he will succeed again this time since the innovation will not be limited in one journal or one step, and thus will improve the whole academic level.

## TEAM AND PATTERN

Only a first-class team can publish first-class journals. The *WJG* editorial board is composed of 760 experts in gastroenterology from 52 countries. Many famous scientists have been invited to write reviews and editorials for *WJG*. Its permanent editorial team is composed of those outstanding staff with doctors, masters of bachelor degree, and has become more competitive and efficient.

There were some bad comments at the beginning of *WJG* when there were not many resources such as financial support for journals from the government and experienced editors. There was a doubt on the success of *WJG* that was run by an "individual". Sometimes, I wonder how many emergent novelties have been killed by such an attitude and way of thinking. Everything has its own developing and improving process, which is from small to large and from weak to strong. The Editor-in-Chief is the key to a journal, just like an entrepreneur to an enterprise. A recent book "The World Is Flat" by an American writer, Thomas L. Friedman, describes that the world has become smaller and smaller. In the opinion of the author, the world has experienced three "shrinking" processes. The first one took place in the fourteenth century, and is characterized by the expansion of countries. At that time, Columbus discovered the New Continent, which opened the sea route and thus reduced the distances between countries. The second one took place in the industrial revolution, and is characterized by the expansion of enterprises (multinational corporations). At that time, the development and production of the railway, electricity and telecommunication instruments further reduced the size of the world. The third one is taking place now following the significant development of information network, and is characterized by the expansion of personal power. I heard recently that there is a news agency in the United States run by a single person. Therefore, we should not underestimate or ignore the ability of any individuals. To some extent, even an individual is able to influence the whole world.

Composition of a team is always influenced by the strategic orientation and the tactical policy, and restricted by the administration system and operation mechanisms. *WJG* has two principles. One principle is to operate according to the international standards. Dr. Ma has described to us the general situation of international standards and market operation patterns in 15 aspects, such as administrative system, editing criteria, paper quality, online submission, invitations for editorials and reviews on highlighted topics, peer review, external communications, printing and distribution, *etc*. This year, 75.8% of manuscripts submitted to *WJG* were from authors outside of China. The other principle is to improve with informatization. In some senses, internationalization means internet communications. *WJG* always improves continuously its business flow in order to match its administration pattern with informatization. I read a worksheet about the editing process of *WJG*, which is composed of 29 steps for scientific editing, 36 steps for electronic editing, and more than 10 other basic steps. Scientific and strict regulations and operational patterns are the basis of a successful *WJG*. The quality of a journal must be improved with time, and its development must represent the changing world. Unfortunately, some journals are sill run with the management pattern designed for the outdated planned economy. These journals lack in vitality and compatibility despite abundant human resources and financial support. Now is the time when live fish eat dead fish, and fast fish eat slow fish, but not necessarily big fish eat small fish. This is due to the choice of the market rather than the instruction of government. I used to recommend the pattern of *WJG* to some of my friends in the field. They all made good comments on the pattern but could not learn from it very well. Structure and administrative pattern are determined by the system. Therefore, it is the issue of the system that we must resolve before we find an international first-class scientific journal in China.

## CULTURE AND ENVIRONMENT

A journal, or an enterprise or a university, or an institute, or even a development zone can only grow in a certain culture and environment. They are all the products of the culture and environment. Why is the United States of America so strong? Is it just because of its military power and technology? No, it is because of its culture based on its democratic construction and citizen quality. Michael Bott, a famous American scholar has pointed out that the advantage that is based on culture is the most difficult to copy or replace, the most fundamental, the most everlasting and thus the most pivotal advantage in competition. China is investigating how to develop the "middle part" these days. Some experts believe that the key to developing the "middle part" is reshaping of the local culture. What I learned from the growing process of *WJG* is that some aspects of our culture really need improvement. Some government officials created difficulties for *WJG*, and some authorities turned their noses at *WJG*. In addition, some "readers" abused *WJG* or even insulted the publisher with whatever words they could create on the internet, such as"*WJG* is a bad journal", "I feel shamed that my paper is published in *WJG*". What kind of culture is it where you cannot do anything? Who are the victims of such a culture? We must have courage to reflect and animadvert on the outdated culture, and investigate these details in depth in order to found an international first-class scientific journal. One may get some insight from the book "Details Determine the Success".

The culture in the Silicon Valley or the Tech-Garden of Zhongguan Village is non-traditional. Individual behavior is determined by the profits and dreams. There is no authority or god. There are only heroes from commonality. So Silicon Valley is the place for youngsters to begin their career, to carve out, and to realize their dreams. Persons in Silicon Valley always respect losers, because they know

that the losers have taken the risks and paved the path for the victors towards the hi-tech peak. Mistakes and failures are unavoidable in its growing process. *WJG* was refused to be included in SCI in 2004 and 2005, which was a big blow to Dr. Ma. He made intensive investigations, and found out the reasons. The *WJG* self citation rate of 94%, which was rather high and made its impact factor up to 2.532 in 2002, was the major reason for the refusal. High impact factor and compositor were usually induced by high self citation rate, which resulted in a misleading of the influence of *WJG* in the field. Dr. Ma reduced its self citation rate to 15.87% in 2005, and fortunately *WJG* recovered by SCI this year. This is probably a good lesson. In addition to Dr. Ma's hard work, the success of *WJG* is also attributed to the support from some related authorities, such as China Ministry of Science and Technology, National Administration of News and Publication, Natural Science Foundation Committee of Shanxi Province, and many experts and readers. Professor Fa-Zu Qiu, member of the Chinese Academy of Sciences, aged 93, and Mr. Xu-E Li, former vice-director of China National Science and Technology Committee, both gave *WJG* tremendous support. Thus, *WJG* is very fortunate to have such support. We must learn from the growing process of the international first-class scientific journals if we want to found such a journal. The processes are always more splendid than results. Every time when *WJG* steps forward, I would remind Dr. Ma that happiness of success is temporary while the suffering and challenging are everlasting. Indeed, the most valuable personality of modern entrepreneurs is willingness to pursue "suffering" and challenge.

I have studied a book "Laws Cannot Change the Society: How to Reform France", written by a famous French sociologist, Michel Crozier. In his opinion, with the development of society, communication between individuals becomes more and more complicated, the society becomes more and more fragile, and thus the outdated social administrative systems become weaker and weaker and the laws can no longer resolve the social problems. The impetus of the society is the human resources, especially those intellectuals with great potentials. Only by motivating their enthusiasm, can the social reform be performed. Generally, those who are engaged in scientific journals are the nation's backbone.

In April 2006, *WJG* held the first working meeting of the year. I was initially invited to give a lecture on the relation between morality and quality, but I was unable to attend the meeting. Later, Dr. Ma told me an interesting story. One day he attended lectures on two topics delivered by Professor Wu-Zong Zhou from University of St. Andrews, St. Andrews, the United Kingdom. The first topic was "Why to Publish Scientific Papers", and the second one was "Strict Academician Attitude Ensures the Quality of Scientific Papers". During the lecture, someone raised a comment, saying "we are coming here to learn how to write papers, not to accept moral education". Surprisingly, about two thirds of the audience applauded for the comment. Professor Zhou shook his head and could not say anything. So did I after I heard the story. There is an extensive debate on the comparison of the development between China and India in recent two years. Some people believe that intellectual community which represents the advanced productivity is better qualified in India than in China. The former American President Bill Clinton also holds this viewpoint. Last year, I read an article by Dr. Nan-Ping Yuan, the consul general of the Chinese Consulate in Bombay, India. The title was "What Is stronger in India than in China?". It describes that Indian intellectuals are determined to retain their independent personality with consistency and conscience. They do not compromise to obtain any benefits. They sympathize and help the weak. They possess excellent academic quality, without flippancy and the urge for a quick success and an instant benefit. They rarely have the concepts such as "job-hopping" and "becoming official and making money" in mind. I believe that all these characteristics that Indian intellectuals possess are the core compatibility that a journal or a region requires.

*WJG* has represented China to compete on the international academic stage without any national financial support. Many experts and scientists in Western countries praise this kind of intellectual such as Dr. Ma as "scientific fighters" and "academic faeries". At least, we should show our sympathy and respect to those who dedicate themselves to their national academy.

## Abstract

The treatment of alcoholic hepatitis remains one of the most debated topics in medicine and a field of continued research. In this review, we discuss the evolution of scoring systems, including the recent development of the Glasgow alcoholic hepatitis score, role of liver biopsy and current treatment interventions. Studies of treatment interventions with glucocorticoids, pentoxifylline, infliximab, s-adenosyl-methionine, and colchicine are reviewed with discussion on quality. Glucocorticoids currently remain the mainstay of treatment for severe alcoholic hepatitis.

**Key words:** Alcoholic hepatitis; Treatment; Glucocorticoid; Biopsy; Scoring system

## INTRODUCTION

The treatment of alcoholic hepatitis is one of the most debated topics in medicine. The prevalence of the disease, its high fatality rate, and the elusiveness of cure keeps this disease in the forefront of topic reviews and scientific investigations.

Alcoholic liver disease accounts for over 12 000 deaths per year and 300 000 years of potential life lost in the United States[1]. Age adjusted death rate from alcohol induced liver disease accounts for 40% of deaths from cirrhosis or 28% of all deaths from liver disease[2]. Alcoholic liver disease is one of the top ten leading causes of death in developed countries, responsible for 3% (1.8 million) of all deaths[3]. While alcoholic hepatitis is common, its pathogenesis, predictors for survival, and treatment remain debated.

There have been several excellent reviews on the treatment of alcoholic hepatitis in the past year[4,5]. The focus of our review is to expand on the treatment of alcoholic hepatitis while addressing the role of scoring systems and liver biopsy.

## PATHOGENESIS

While the histology of alcoholic hepatitis is well characterized, the pathogenesis remains uncertain. A number of hepatocellular and inflammatory processes including the potential involvement of innate and adaptive immunologic responses are under investigation.

The variety of treatment options in alcoholic hepatitis share a common treatment goal of blocking the myriad of innate immunologic responses which include macrophage release of chemokines and cytokines, TNF-$\alpha$, IL-1$\beta$, IL-6 and IL-8, in addition to adaptive immune responses to acetaldehyde and hydroxyethyl radical formation[6,7].

While the immunologic responses are varied, they share similar end results of apoptosis, necrosis, inflammation and fibrosis. The history and basis of treatment interventions in alcoholic hepatitis are centered on blocking one or more of the harmful mechanisms found in the animal model with the hope, in human trials, of providing survival benefit (Table 1).

## SCORING SYSTEMS

There are several scoring systems applied toward predicting survival in alcoholic hepatitis. Many clinically employed scoring systems, however, are derived from related liver diseases and later validated for alcoholic hepatitis. As patient risk stratification and allocation of treatment are entirely dependent on a system to gauge short-term mortality, it is important to develop a scoring system that accurately predicts survival versus mortality.

First developed as risk stratification method for patients undergoing shunt surgery and later refined[8,9], the Child Turcotte Pugh (CTP), score has evolved as the

**Table 1 Immunologic responses and directed therapies in alcoholic hepatitis**

| Cytokines | Mechanism | Mediators | Treatment |
|---|---|---|---|
| Cytokines | | | |
| TNFα | Via TNFR1 signaling in hepatocytes and Kupffer cells (KC) | Apoptosis, necrosis, KC production of cytokines, potential cytoprotective effect | Glucocorticoids; Pentoxifylline; Infliximab |
| IL-6, 8 | Lymphocyte and neutrophil activation, release of acute phase reactants | Inflammation, fibrosis | Glucocorticoids |
| Antigenic adduct | Oxidation of ethanol, binding to proteins forming antigenic adducts | Adaptive immunity | Glucocorticoids |
| Chemokines | Attract leukocytes and increase adhesion molecules | Inflammation | Glucocorticoids |
| Oxidative Injury | | | |
| S-adenosyl-methionine (SAMe) | Precursor for glutathione, defense mechanism against oxidative stress, increase methylation | Protective role of SAMe | SAMe |
| Hypoxia/ischemic injury | Hypermetabolic state | Insufficient oxygen | Propylthiouracil |

most clinically used prognostic tool in cirrhotic patients. Patients are stratified into three categories based on point assignment of objective and subjective measures of liver function (Appendix A). The clinical application of the CTP score applied to cirrhotic patients has been validated[10,11]. Cited over 1700 times, the CTP score remains one of the most important clinical predicting tools in patients with cirrhosis[12]. However, in the setting of alcoholic hepatitis, there is evidence that other scoring systems may better predict survival.

The Maddrey Discriminant Function (DF) score, unlike the CTP, is derived from a clinical trial studying the efficacy of corticosteroid therapy in patients with alcoholic hepatitis[13]. Admission prothrombin time and serum bilirubin are independently and significantly associated with mortality and serve as the key variables in calculating the DF score. Further modified, in combination with the presence of encephalopathy, a DF score greater than 32 predicts greater than 50% mortality[14]. The DF score has subsequently been used to stratify patients in trials studying the efficacy of corticosteroid treatment in patients with alcoholic hepatitis[14,15]. While the DF score provides risk stratification, concerns of center to center variability of prothrombin time measurement[16], significant mortality in patients with DF score less than 32 and low test specificity have led some investigators to suggest alternative scoring systems[17].

The Mayo Endstage Liver Disease (MELD) Score, like the CTP score, was developed to predict survival in patients undergoing decompressive therapy for portal hypertension[18,19] (Appendix A). Unlike the CTP score, the MELD score is derived from prospective data and lacks subjective measurements of liver function. Using a derived formula, the MELD score is calculated using prothrombin time, creatinine and bilirubin. All of which are factors Maddrey *et al* found to be significant in his original study. However, unlike the Maddrey Discriminant Function, the MELD score is employed as a continuous assessment of liver function and includes creatinine, a marker of development of hepatorenal syndrome. It would be interesting to evaluate the Maddrey DF as a continuous marker of liver function.

The MELD score has been validated in predicting survival in patients with end-stage liver disease and chronic liver disease[19,20]. Three retrospective studies suggest that MELD is equivalent to DF in predicting survival in patients with alcoholic hepatitis[22,23]. One study found MELD to be more predictive of survival if calculated after the first week of hospitalization[23]. This result may reflect the fact that patients with a higher likelihood of dying decline in the first few weeks of hospitalization rather than improved test sensitivity. In summary, admission MELD, DF and CPT did not differ significantly from each other (Table 2).

Citing concerns of low specificity of the Maddrey DF score and the difficulty of identifying an optimal cut-off point of the MELD score[24,25], Forrest *et al* introduced the Glasgow alcoholic hepatitis score (GAHS)[16] (Appendix A). Using retrospective data from patients presenting with alcoholic liver disease, the authors use stepwise logistic regression to identify variables associated with mortality. In Table 2, we include the results of Forrest *et al*.'s study with separate comparisons between GAHS *versus* DF and GAHS *versus* MELD from the validation portion of the trial. We compared the accuracies of each test *via* Chi-square analysis. GAHS is more accurate than DF in 28 and 84 d mortality prediction but equivalent to MELD in 28 d mortality prediction. The reported specificities of both MELD and DF in this study are quite low, especially in comparison with other studies. However, the reported low specificity of DF significantly affected its comparative predictive capacity, *via* chi-square analysis, against GAHS.

Alcoholic hepatitis scoring systems are in evolution. MELD and DF appear to be equivalent in predicting mortality. The higher specificity and overall accuracy of the GAHS, if confirmed, may make it a better screening tool in the clinical trial. It would be interesting to review previous studies assessing the efficacy of glucocorticoid treatment using GAHS as the scoring system. For clinicians, however, a test with a higher sensitivity would be desirable as their primary goal is to maximize the number of patients receiving a treatment benefit. Therefore, the DF score may be preferred in the clinical setting as

**Table 2 Sensitivity and specificity of scoring systems for alcoholic hepatitis: sensitivities (Sen)/specificities (Spec)**

| Study | Patients | Study design | Predictive Mortality | MELD Sen/Spec (%) | DF Sen/Spec (%) | CTP Sen/Spec (%) | Glasgow Sen/Spec (%) | Conclusions |

it captures more patients at risk of dying than does the GAHS score.

## LIVER BIOPSY

Since it was reported first by Mallory *et al*[26] the morphology of alcoholic liver disease has been well described[27]. The details and significance of morphologic progression from steatosis to cirrhosis, as it relates to survival and treatment, continue to be refined.

Employed as part of an entry and stratification criteria in a few clinical trials[13,15,28-31], liver biopsy for staging and predicting survival has been replaced by scoring systems. Although survival did not differ between the glucocorticoid trials that used pre-randomization biopsies versus scoring system, we think that clinical trials should enroll biopsy-proven cases. Biopsy confirmation of alcoholic hepatitis accurately defines the patients eligible for clinical trials and, in our view, is preferred if fever, leukocytosis and hepatic bruit are absent.

While histologic changes from steatosis and steatohepatitis to cirrhosis are known, correlating degree of steatosis with liver function and survival is currently under investigation. A study by Duvoux *et al*[32] finds a correlation between low grade steatosis and advanced liver failure as well as lowered sensitivity to steroid treatment. However, patients with low grade steatosis had higher Maddrey discriminant function scores, which can also predict poor survivals.

The role of liver biopsy in defining prognosis and treatment of alcoholic hepatitis in the clinical setting remains unclear. A thorough patient history and physical examination has a reported sensitivity and specificity of 91% and 96% in diagnosing alcoholic hepatitis[33]. However, from the above study, four cases out of 103 were misdiagnosed as alcoholic hepatitis upon review of biopsy specimen. It is generally accepted to perform a liver biopsy if the diagnosis of alcoholic hepatitis is either in question or a concomitant pathology, such as hepatitis C, is suspected[34]. Approximately 35%-40% of alcoholics are infected with HCV[35,36] and experience higher mortality rates than patients with alcoholic liver disease alone[37,38].

A patient history and physical exam cannot, however, consistently distinguish between and determine the extent of alcoholic hepatitis alone versus alcoholic hepatitis with concomitant cirrhosis. A biopsy can provide useful prognostic and diagnostic information. Patients with alcoholic hepatitis and cirrhosis have significantly higher 1- and 5-year mortality compared to patients with cirrhosis alone[39,40]. Presence of perivenular fibrosis, steatosis and giant mitochondria in a known alcoholic may herald the transition from alcoholic hepatitis to cirrhosis; a transition which could be prevented with abstinence[41-43]. In clinical practice, we recommend transjugular(given the presence of coagulopathy and/or ascites) liver biopsy in cases in which it is difficult to distinguish the contribution of alcoholic hepatitis and end-stage cirrhosis, especially when the hallmarks of alcoholic hepatitis, leukocytosis, fever and hepatic bruit are absent. Since treatments are associated with complications, we believe it is prudent to be confident of the diagnosis before using steroids.

## TREATMENT

### *Glucocorticoids*

First studied in the treatment of alcoholic cirrhosis in

[a]$P < 0.05$ for survival benefit as reported by study authors; Note percent death at 28 d in placebo *versus* steroids is shown in each box for all cases[b] and for those with hepatic encephalopathy. [c]RRR, NNT is calculated from published data of those studies that reported a significant survival benefit. HE: Hepatic Encephalopathy; DF: Maddrey Discriminant Factor; CP: Child Turcotte Pugh; N/A: non significant difference in mortality as reported by study authors; Self derived: Criteria derived by study team not including CP, DF or MELD.

1960[44], the use of glucocorticoids remains perhaps the most studied and debated intervention. Reported successes of glucocorticoids are variable and appear largely dependent on the nature of the trial.

The rationale for the use of glucocorticoids is centered upon blocking the cytotoxic and inflammatory pathways in alcoholic hepatitis. Glucocorticoids decrease circulating inflammatory cytokines such as TNF-α, ICAM-1 expression, and have demonstrated short term histologic improvement in the treatment of alcoholic hepatitis[45].

It is difficult to provide a simple summary of results for glucocorticoid trials in alcoholic hepatitis. While all trials appeared to have been controlled, few have high quality scores given the variable definition of randomization and blinding in each trial[46,47].

The trials vary by inclusion/exclusion criteria, glucocorticoid type, scoring system, length of treatment and co-interventions. The study by Mendenhall *et al* is particularly difficult to interpret as essentially three different intervention arms, oxandrolone, prednisolone and prednisone, are employed[48]. Lesesne *et al* compares prednisolone to a 1600 caloric intake diet which is below the estimated caloric needs of most hospitalized patients; his trial is not placebo controlled[49]. Furthermore, the variation in type of glucorticoid, dose, and treatment length makes it difficult to provide treatment guidelines for physicians.

We did a computerized search using the MEDLINE database from 1971 to August 2005 using the search headings of "steroids", "corticosteroids", "alcoholic hepatitis", "hepatitis, alcohol", "randomized" and "English". We obtained additional trials by manually searching through retrieved trials and review articles. Randomized trials including corticosteroids in the treatment of alcoholic hepatitis with the outcome measure of mortality are summarized in Table 3. The trial results are summarized by percentage death in each group including number of patients with hepatic encephalopathy and their percentage mortality. Relative risk reduction (RRR), number needed to treat (NNT) with their associated 95% confidence intervals are calculated for trials that reported a significant benefit in survival. Given that hepatic encephalopathy is a known predictor of mortality, we have also calculated RRR and NNT for those patients; again only in trials that reported a significant survival benefit. We employed the Jadad score as an assessment of trial quality. The Jadad score is one of the few validated measures of randomized trial quality[46,50,51]. Out of a maximum score of five, points are assigned based on the method of randomization, double blinding and description of withdrawals/drop-outs.

The results are variable. Five trials reported a significant

survival benefit with glucocorticoids[13-15,28,49]. RRR ranged from 67% to 86%, with NNT varying between 2 and 6. As reported in the above trials and noted in our table, glucocorticoid treatment significantly reduces mortality in patients with hepatic encephalopathy. The latter trials by Carithers *et al* and Ramond *et al*, selectively treated patients with discriminant function scores greater than 32, supporting a more discriminate use of glucocorticoids[14,15].

Of the trials which reported a non-significant benefit, there are four trials which report higher mortality in the glucocorticoid group[30,48,52,53]. While glucocorticoids are relatively benign in the short term for most patients, the remaining three trials remind clinicians that there are significant complications with their use. Blitzer *et al* reported a higher number of fungal infections in the steroid group contributing to the greater percentage of deaths in the steroid group when compared to placebo. However, his steroid treatment group contains a higher proportion of patients with elevated total bilirubin, when compared to placebo, which may contribute to his study result[52]. Included in our discussion of nutrition in the treatment of alcoholic hepatitis, Cabre *et al*'s study found 31% (11/35) mortality in the steroid group with 91% of deaths attributable to infection[54]. It is important to recognize the potentially serious infectious complications secondary to steroid treatment.

Subsequent meta-analyses, while still yielding conflicting results, began to delineate which patients would most benefit from glucorticoid treatment. The first meta-analysis on this topic, conducted by Imperiale and McCullough in 1990 (which antedates more recent trials), finds a protective efficacy of glucocorticoids in higher quality trials, particularly those that exclude patients with gastrointestinal bleeding but include patients with hepatic encephalopathy[55]. They found a protective efficacy of 34% overall (95% CI, 15%-48%) for patients with hepatic encephalopathy. Imperiale and McCullough's study applies quality scores which are important in the setting of such trial heterogeneity. In their paper, quality scores are assigned by independent assessors. Quality scores we use in this paper are derived from Jadad *et al*, and have been used in assessing the quality of randomized clinical trials[46]. We do not find a significant association between high Jadad score and trial survival benefit. However, Jadad *et al* score does not consider baseline equivalence of compared groups, use of co-therapies and adequate potency of principal therapy. The variance of survival amongst the trials may have more to do with patient inclusion/exclusion criteria and the self-derived scoring systems than trial quality and adherence to randomization and double blinding.

Meta-analysis conducted by Christensen *et al*, did not find an overall treatment benefit, after attempting to control for confounding variables[56]. Controlling for confounding variables without direct access to individual study data can be difficult given the heterogeneity of prior trials. A subsequent study, by Mathurin, Mendenhall, Carithers *et al*[57] pooled raw data from their respective trials based on DF score (greater than 200 patients with DF $\geqslant$ 32 in placebo versus steroids) and found a survival benefit. If the DF < 32, there was a > 90% survival without steroids. The conclusions from the above study provide a more definitive treatment guideline for clinicians. In patients with DF $\geqslant$ 32, treatment with glucocorticoids improves short term, 28 d, survival with mortality decreasing from 35% in controls to 15% with steroids.

The longer term benefit of glucocorticoids are difficult to assess given the variable long- term clinical trial definitions (1.5 mo, 6 mo, 1 year)[54,48,58] and each of the existing three trials reported different outcomes: harm, no benefit and benefit[54,48,58]. It is also difficult to assess long-term benefit as alcoholic hepatitis is likely to recur unless the patient abstains.

### Recommendations

A review of the literature supports a more discriminate use of glucocorticoids in patients with a Maddrey discriminant function score $\geqslant$ 32. If there is no evidence of gastrointestinal bleeding or infection, the frequent concomitant presence of hepatic encephalopathy provides an even stronger support for the use of glucocorticoids. A study by Mathurin *et al* suggests a simple method to identify patients who are most likely to respond to glucocorticoids. Patients with an 'early change in bilirubin levels' (ECBL), i.e. a bilirubin level at 7 d lower than the bilirubin level on the first day of treatment, were significantly more likely to survive and respond to steroid treatment[59]. Discontinuation of glucocorticoid treatment in the non-responder group, i.e. patients that did not have an ECBL at 7 d, did not appear to result in adverse events[5]. Devising methods to target the patient groups most likely to benefit are important in maximizing treatment benefit, avoiding unnecessary complications of treatment and streamlining the treatment decision process.

Glucocorticoids, while providing a benefit in a select group of patients, are not without risks and should be used with caution in patients with infectious complications and gastrointestinal bleeding. Further trials that are larger in sample size, involving multiple centers and with an active comparator, i.e. pentoxifylline, are needed to better delineate the true effect of glucocorticoids. Finally, as scoring systems are changing, repeat studies may be needed to reassess the treatment effect of glucocorticoids employing MELD and GAHS.

### Anabolic steroids

There is a measurable and clinically apparent decline in gonadal function in patients with alcoholic liver disease[60-62]. In 1938, administration of androgens appeared to enlarge the liver of cirrhotic rats, thereby suggesting that perhaps androgens could reverse the process of fibrosis[63]. This lead to the first clinical trial where 12 patients with alcoholic cirrhosis were injected with large doses of testosterone with 'some improvement'[64].

A 2003 Cochrane systematic review could not demonstrate a significant effect of anabolic-androgenic steroids on the mortality of patients with alcoholic liver disease[65]. Three trials[48,66,67] included in the analysis and two trials[68,69] excluded from the analysis are trials in which all participants have alcoholic hepatitis.

**Table 4 Infliximab trials in the treatment of alcoholic hepatitis**

| Study | Design | Patients | Treatment | Results |
|---|---|---|---|---|
| Spahr *et al*[76] 2002 | Randomized | 20 | All patients: prednisone for 28 d<br>Randomized d 0<br>R1: Infliximab 5 mg/kg<br>R2: Placebo | Improved Maddrey score<br>No significant difference in survival, histology or adverse outcomes |
| Tilg *et al*[77] 2003 | Case Series | 12 | Infliximab 5 mg/kg | 83% (10/12) survived at median 15 mo<br>No mention of infection |
| Mookerjee *et al*[78] 2003 | Case Series | 10 | Infliximab 5 mg/kg times one | 72 h assessment<br>Significant reduction in laboratory parameters<br>Increased hepatic and renal blood flow |
| Naveau *et al*[79] 2004 | Randomized | 36 | All patients: Prednisone for 28 d<br>R1: Infliximab 10 mg/kg<br>R2: Placebo | Significantly higher rate of infections in treated group<br>Non-significantly higher rate of death in treated group<br>Study stopped secondary to adverse events in treatment group |

Reflective of the conclusions derived from the systematic review, Bonkovsky *et al*'s study[67] and Mendenhall *et al*'s 1984 study[48] did not find a significant survival advantage in the anabolic steroid group in the placebo. In Mendenhall *et al*'s study, patients in the oxandrolone group were treated for 30 d. They report, however, in subgroup analysis that patients with moderate hepatitis treated with oxandrolone seemed to have survival advantage 6 mo post treatment. As the subgroup analysis did not include patients that had died within the first two months of treatment, the results should be taken with some caution.

Currently, anabolic steroids are not recommended for the treatment of alcoholic hepatitis.

### Pentoxifylline

Pentoxifylline is a suppressor of tumor necrosis factor alpha (TNF-α), prevents leukocyte adherence to vascular endothelium and down regulates the expression of intercellular adhesion molecule-1 in monocytes[70]. The main signaling pathway is through type 1 tumor necrosis factor receptor, TNFR1. Elevated levels of TNF-α are predictive of poor survival in alcoholic hepatitis[71,72]. Other effects of this drug may contribute to its action such as its effects on membrane fluidity which determine its use in peripheral vascular disease.

First studied by McHutchison *et al* in 1991, in patients with severe alcoholic hepatitis (defined as DF score $\geqslant$ 32), pentoxifylline reduced the development of hepatorenal syndrome, and as a consequence mortality, in comparison to patients who received placebo[73]. A subsequent double blind placebo controlled trial, Akriviadis *et al*, from the same center, supports McHutchison's findings[74]. There did not appear to be any complications as a consequence of pentoxifylline treatment. As noted by Dr. Mathurin[5], the latter study showed no improvement in liver function tests. The reported improved survival was accounted for by a reduction in the development of hepatorenal syndrome in the treatment group. This finding is in sharp contrast to the glucocorticoid trials which demonstrate an improvement in liver function and in survival compared to placebo.

A small sample size, retrospective, observational study by McAvoy *et al*, published as an abstract, finds a treatment benefit with pentoxifylline only in patients stratified to GAHS $\geqslant$ 9, but not in patients with DF $\geqslant$ 32[75]. As raw numbers are not available at press time, it is difficult to draw a meaningful conclusion from his study.

Recommendations: Pentoxifylline may reduce mortality from hepatorenal syndrome in the setting of severe alcoholic hepatitis but further studies are needed to confirm these findings. Aside from the need for head to head comparative trials with steroids, one wonders if the combination of the two treatments might exhibit an additive benefit.

### Infliximab

Infliximab, used in the treatment of Crohn's disease, rheumatoid arthritis and psoriasis, is a chimeric mouse/human antibody which binds to tumor necrosis alpha, blocking its effects[76]. Preliminary trial data was encouraging. Three trials reported either better survival than predicted, improved Maddrey score or laboratory parameters[76-78]. The largest and most comprehensive trial studying the efficacy of prednisone and infliximab in the treatment of alcoholic hepatitis was terminated early when a significantly higher number of deaths occurred in the treatment group[79]. The study received some criticism for its use of high dose of infliximab and infusion protocol which varied from previous studies. In this study, investigators cited prior studies in Crohn's[80] and rheumatoid arthritis[81] in which there did not appear to be a relationship between dose of infliximab and rate of infection[78]. Furthermore, Dr. Naveau contends, perhaps infliximab is not the TNF-α blocking agent for alcoholic hepatitis (Table 4).

An open label uncontrolled pilot study on etanercept in the treatment of moderate to severe alcoholic hepatitis was completed[82]. Of the 13 patients treated, 7 had Maddrey DF greater than 32 and two of the seven died within 32 d. Etanercept was discontinued in 3 patients secondary to infection, hepatorenal decompensation and gastrointestinal bleeding. Therefore, there is no particular evidence one way or the other to suggest a beneficial or detrimental effect of treatment. As etanercept targets soluble TNF, whereas infliximab targets both soluble and

membrane bound TNF, it is uncertain what the advantages/disadvantages are of this distinction in the setting of this specific disease target.

Infliximab is not currently recommended for the treatment of alcoholic hepatitis, outside of clinical trials. Although concerns have been raised about increased risk of infection, the more disturbing aspect has been recent warnings of acute liver failure in patients with Crohn's disease and rheumatoid arthritis treated with infliximab[83]. This risk may preclude its use in patients with underlying severe liver injury who are less capable of withstanding an additional insult to the liver.

### Nutrition

There are multiple etiologies for weight loss and malnutrition in patients with years of alcohol abuse. Weight loss can be reflective of years of substitution of alcohol for more than 50% of other calories[84], malabsorption of dietary fat and nutrients[85] and the induction of a catabolic state resulting in skeletal muscle depletion[86].

Recently reviewed[4] parenteral and enteral nutrition, while improving liver function in a few studies in alcoholic hepatitis[87-89] has yet to demonstrate a change in clinical outcome.

Mendenhall *et al* have done the most extensive assessment on the effect of protein calorie malnutrition (PCM) and protein energy malnutrition (PEM) on survival and liver function. The results of their interventional studies are shown in Table 5. The observed associations between degree of malnutrition, as calculated by PCM or PEM score, and severity of liver disease[90-92] as well as improvement of survival with improved PCM score[93] serve as the basis for determining the effect of nutritional intervention on survival and liver function in alcoholic hepatitis[69,94].

Nutritional interventions such as caloric amount, type, mode and duration of supplementation vary among the trials. For example, the 1600 caloric nutritional intervention in Lesesne *et al*'s study is below that of most hospitalized patients. A positive correlation between nutritional intake and survival, if present, would not be expected. Much as in the case of the glucocorticoid literature, it would be difficult to provide clinical recommendations when the treatment interventions and outcomes vary. Furthermore, it is difficult to draw meaningful clinical conclusions. While nitrogen balance improves in the nutrition intervention arm, survival remains unchanged.

The majority of trials did not find a survival advantage in nutritional support. There are two trials which showed a survival advantage. Nasrallah *et al*'s study is smaller and both groups receive a 3000 kCal diet with protein, which is an intervention treatment in some studies. Mendenhall *et al,* found a later survival advantage, 6 mo post treatment, in the moderately malnourished group. This is in contrast to Mezey *et al*'s study which did not find a survival advantage up to two years after treatment.

Recommendations: It is important to assess nutritional status of patients in order to recognize and treat the distinct nutritional deficiencies inherent in alcoholic cirrhosis and hepatitis. At this time, however, nutritional supplementation during acute presentation of alcoholic hepatitis does not appear to affect survival.

### Colchicine

The final histologic stage in alcoholic liver disease is cirrhosis. Found to inhibit liver fibrosis in rats[95], colchicine's anti-fibrotic activity presented a theoretical possibility of preventing liver fibrosis in humans.

Three clinical trials in the setting of alcoholic hepatitis[96,97] and a Cochrane database review in the setting of alcoholic and non-alcoholic liver fibrosis[98] fail to find a benefit in the treatment of alcoholic hepatitis with colchicine. Recently published and not included in the cochrane review, the largest trial studying long-term colchicine in the setting of alcoholic cirrhosis did not find a therapeutic benefit when compared to placebo, in concordance with prior literature[99]. Colchicine is not currently recommended for the treatment of alcoholic hepatitis.

### S-adenosyl-methionine

SAMe, produced from methionine by adenosylmethionine synthetase, is important in the metabolism of nucleic acids, structure and function of cell membranes and as a precursor of glutathione. Glutathione may be protective in alcohol induced liver injury[100]. However, in liver disease there is an impairment of enzyme activation of methionine which cannot be corrected by methionine supplementation[101]. In the setting of alcoholic hepatitis, there is a measurable decrease in hepatic methionine, SAMe and glutathione levels[102]. In animal studies, administration of SAMe increased glutathione levels, attenuated ethanol induced liver injury as well as liver injury caused by other hepatotoxins[103-106].

In a 2001 Cochrane systematic review[107], SAMe has yet to consistently demonstrate a significant beneficial effect on the mortality in the setting of alcoholic liver disease. None of the analyzed trials in the systematic review targeted patients with alcoholic hepatitis. The largest multi-center and highest Jadad quality scoring trial, by Mato *et al*, treated patients with alcoholic cirrhosis with SAMe for up to two years[108]. There was an overall decline in mortality in the treatment group compared to placebo, but did not reach significance. Excluding patients with Child's C cirrhosis, however, did yield a significant mortality benefit.

There are currently two NIH funded trials studying the effect of SAMe on the mortality in the setting of alcoholic cirrhosis. There has yet to be a trial studying the effect of SAMe administration on survival in the setting of acute alcoholic hepatitis.

SAMe is currently not recommended in the treatment of acute alcoholic hepatitis.

### Propylthiouracil (PTU)

Found to reduce hypoxic hepatocellular injury in ethanol fed rats[109], subsequent animal studies confirm PTU's protective role against oxidative and ischemic liver injury[110]; similar hepatic injuries are found in patients with alcoholic hepatitis[111].

In a 2001 Cochrane systematic review[112], PTU did

**Table 5 Interventional studies on nutrition and alcoholic hepatitis**

| Study | Design | Patients | Intervention | Findings |
|---|---|---|---|---|
| Lesesne *et al*[49] 1978 | Randomized | 14 patients, alcoholic hepatitis and encephalopathy | 7 controls, 1600 Kcal diet<br>7 study, prednisolone | Reduction in mortality in the prednisolone arm |
| Galambos *et al*[127] 1979 | Case series | 11 patients, alcoholic hepatitis | 4, enteral hyperalimentation<br>7, parenteral hyperalimentation | No difference in mortality<br>Increased nitrogen balance in study group |
| Nasrallah *et al*[128] 1980 | Randomized | 35 patients, alcoholic hepatitis | All received 3000 kcal 100g protein diet<br>18 control<br>17 study, 70-85 gram of intravenous amino acid | Lower mortality in the study group |
| Diehl *et al*[129] 1985 | Randomized | 15 patients, alcoholic hepatitis | All allowed to consume hospital diet ad libitum<br>10 controls, glucose solution<br>5 study, glucose solution + amino acids | Increased nitrogen balance in study group<br>No difference in clinical and biochemical markers of liver disease |
| Mendenhall *et al*[94] 1985 | Randomized | 57 patients, moderate-severe alcoholic hepatitis | 34 controls, 2500 cal diet<br>23 study, Hospital diet + Hepatic Aid | No difference in mortality<br>Improvement in nutritional parameters in intervention group |
| Calvey *et al*[130] 1985 | Randomized | 64 patients, alcoholic hepatitis | 32 controls, standard diet<br>32 study, standard diet + 2000 kCal + 10 g nitrogen | No difference in biochemical or clinical parameters |
| Soberon *et al*[131] 1987 | Case series | 14 patients, alcoholic hepatitis | 6 with adequate nutritional status, hospital diet<br>8 with poor baseline nutritional status, nasoduodenal diet, 35 kCal/kg per day | No difference in mortality<br>Increased nitrogen balance in study group |
| Simon *et al*[87] 1988 | Randomized | 12 patients, moderate alcoholic hepatitis<br>22 patients, severe alcoholic hepatitis | Moderate Group<br>6 control, standard diet<br>6 study, PPN<br>Severe Group<br>12 control, standard<br>10 study, PPN | No difference in mortality<br>Improved in biochemical tests in severe group |
| Bonkovsky *et al*[67] 1991 | Randomized | 39 patients, moderate to severe alcoholic hepatitis | 9, standard therapy<br>8, oxandrolone + standard therapy<br>10, PPN<br>12, oxandrolone + standard therapy + PPN | Improved biochemical parameters |
| Mezey *et al*[88] 1991 | Randomized | 52 patients, alcoholic hepatitis | 28 control, dextrose solution<br>26 study, dextrose + amino acid | No difference in mortality during hospitalization and 2 yr after treatment |
| Mendenhall *et al*[69] 1993 | Randomized | 273 patients, severe alcoholic hepatitis | 136 control<br>137 study, oxadrolone + enteral nutrition | No difference in mortality overall<br>Improvement in mortality in moderately malnourished group(19%) versus control (51%) at 6 mo post treatment |
| Cabre *et al*[54] 2000 | Randomized | 71 patients, severe alcoholic hepatitis | 36, prednisolone<br>35, enteral tube 2000 kCal/d | No difference in overall mortality<br>Higher early mortality in nutrition *versus* higher follow up mortality on steroids |
| Alvarez *et al*[132] 2004 | Case series | 13 patients, severe alcoholic hepatitis | 13, prednisolone + TEN 2000 kCal/d | 15% death during treatment<br>67% of patients developed infections during treatment -no deaths due to infections |

not provide a significant survival benefit in the setting of alcoholic liver disease. All of the analyzed six studies (3 of which were published only in abstract) included patients with alcoholic hepatitis[110,113-117].

Contrary to animal studies, hepatic histologic improvement with PTU administration is not replicated in clinical trial literature. PTU also does not appear to have a measurable effect on splanchnic hemodynamics in the setting of alcoholic cirrhosis[118].

While the systematic review did not find a significant association between PTU and adverse events, one trial was discontinued when higher mortality rates were observed in the PTU group[110]. Furthermore, there are case reports and several reviews on fulminant hepatic failure and hepatitis[119-123] secondary to PTU in addition to leukopenia[124] Propylthiouracil is not recommended for the treatment of alcoholic hepatitis.

## CONCLUSIONS

The treatment of alcoholic hepatitis continues to evolve as our understanding of the disease process expands. As it does so, however, it is important that our clinical trials attempt to achieve the highest quality possible. Trials

designed to replicate treatment effect should be done with treatment dosages and duration that can be employed in the clinical setting.

Further modification of scoring systems and streamlining methods to identify patients most likely to respond to treatment continue to improve as we seek to minimize risk of treatment while maximizing survival gain.

At the present, we recommend corticosteroids for patients with alcoholic hepatitis and DF $\geqslant$ 32, providing there is not evidence of gastrointestinal bleeding. In patients with active infection, we delay treatment until antibiotic control of infection is achieved. Given the various glucocorticoids and dosages employed in clinical trials, it is difficult to provide clinicians evidence based guidelines on type of glucocorticoid, dosage and length of treatment. We currently recommend using the lowest effective dose of prednisone or prednisolone studied in the literature. As prednisone is less costly, we prescribe prednisone 40 mg daily for up to 28 d. If no improvement in bilirubin is seen after 7 d, we recommend stopping glucocorticoids as suggested by Mathurin[59]; switching to pentoxifylline is a reasonable alternative in that situation. Although primary treatment with pentoxifylline holds some promise, the evidence of its efficacy is not as robust as that with steroids.

Although the focus of this article is treatment, preventing the occurrence of disease is important. From physician screening for alcohol abuse to community wide education in a culturally sensitive manner on the risks of alcohol abuse are important health service fields.

## APPENDIX A

**Child-Turcotte with pugh modification**

| Score | 1 | 2 | 3 |
|---|---|---|---|
| Prothrombin time (INR) | < 4 s (< 1.7) | 4-6 s (1.7-2.3) | > 6 s (> 2.3) |
| Bilirubin (mg/dL) | < 2 | 2-3 | > 3 |
| Albumin (g/dL) | > 3.5 | 3.5-2.8 | < 2.8 |
| Ascites | None | Slight | Moderate |
| Encephalopathy | 0 | 1-2 | 3-4 |

**Maddrey criteria**

| | Score indicating |
|---|---|
| Initial | Poor prognosis |
| 4.63 × prothrombin time (seconds) + serum bilirubin (mg/dL) | > 93 |
| Modified | |
| 4.6 (patients prothrombin time-control time) + serum bilirubin (mg/dL) | > 32 |

**Glasgow alcoholic hepatitis score**

| Score | 1 | 2 | 3 |
|---|---|---|---|
| Age | < 50 | $\geqslant$ 50 | - |
| WCC ($10^9$ /L) | < 15 | $\geqslant$ 15 | - |
| Urea (mmol/L) | < 5 | $\geqslant$ 5 | - |
| PT ratio | < 1.5 | 1.5-2.0 | > 2.0 |
| Bilirubin (mmol/L) | < 125 | 125-250 | > 250 |

GAHS $\geqslant$ 9 predictive of poor prognosis. MELD = 3.8 × $\log_e$ (bilirubin (mg/dL)) + 1.2 × $\log_e$ (INR) + 9.6 × $\log_e$ (creatinine (mg/dL)); One can also calculate the MELD score at the following internet address: www.mayoclinic.org/gi-rst/mayomodel7.html.

## Abstract

Occult hepatitis C virus (HCV) infection is a new recently characterized entity. This occult infection can be present in two different clinical situations: in anti-HCV negative, serum HCV-RNA negative patients with abnormal liver function tests and in anti-HCV positive subjects with normal values of liver enzymes and without serum HCV-RNA. This review describes recent studies of occult HCV infection in both kinds of patients.

**Key words:** Hepatitis C virus-RNA; Liver; Peripheral blood mononuclear cells

## INTRODUCTION

The etiology of liver disease is unknown in approximately 10% of patients with abnormal results on liver function tests. Some authors have reported that occult hepatitis B virus could be the cause of a proportion of these cryptogenic chronic hepatitis[1,2] cases, but no conclusive results have been yielded.

In January 2004, the role of occult hepatitis C virus (HCV) infection in chronic liver disease of unknown etiology was first described by Castillo *et al*[3]. This study included 100 patients with persistently long-standing abnormal liver function test results:alanine aminotransferase (ALT) and/or gamma-glutamyl transpeptidase (gamma-GTP). All known causes of liver diseases were excluded, and they were repeatedly anti-HCV and serum HCV-RNA negative. All these patients underwent a liver biopsy. A reverse-transcription polymerase chain reaction found that 57% of them had HCV-RNA in their liver. These results were also confirmed by *in situ* hybridization. In addition, 48/57 (84%) of these patients with occult HCV infection also had the antigenomic HCV-RNA strand in the liver tissue, indicating an ongoing viral replication. The HCV genotype found in the liver of the patients was 1b, which was demonstrated by a commercial genotyping assay and by amplification and sequencing of the HCV-core region. Moreover, 70% of the patients with intrahepatic HCV-RNA in liver also had viral RNA in their peripheral blood mononuclear cells (PBMC). Finally, liver necroinflammatory activity and fibrosis were observed in a significantly higher proportion of patients with occult HCV infection than in those without intrahepatic HCV-RNA. In summary, this paper identified a new form of hepatitis C virus infection called "occult HCV infection". It is characterized by the presence of HCV-RNA in the liver in the absence of serological markers of infection (anti-HCV and serum HCV-RNA negative).

The existence of this kind of occult HCV infection has also been found by other authors. Thus, Stapleton and colleagues have reported several studies on "seronegative" HCV infection in patients with cryptogenic liver disease and persistently abnormal results of liver tests[4,5]. Editorials or editors' comments have also been devoted to the role and significance of occult HCV infection, recognizing this infection as a new entity that should be taken into account for the diagnosis of patients with liver diseases of unknown cause[6-10].

Once occult HCV infection was identified, different research fields were developed: (1) To find an alternative to the liver biopsy for the diagnosis of occult HCV infection. (2) To study if HCV replicates or not in the PBMC of patients with occult HCV infection. (3) To compare the clinical, biochemical and histological characteristics of occult with chronic HCV infection. (4) To compare virus-specific T-cell responses in patients with occult and with chronic HCV infection. (5) To assess the possible role of occult HCV infection in the development of hepatocellular carcinoma. (6) To study the prevalence of occult HCV infection in other risk populations such as hemodialysis patients. (7) To assess the efficacy of antiviral therapy for occult HCV infection. (8) To study other possible clinical situations of occult HCV infection.

## ALTERNATIVES IN DIAGNOSIS OF OCCULT HCV INFECTION

Although HCV-RNA is also detected in the PBMC of a high percentage of patients with an occult HCV infection, the gold standard for diagnosis of this occult viral infection

is detection of HCV-RNA in liver cells. However, because of the invasive nature of the liver biopsy, other alternatives were studied in an attempt to increase the sensitivity of the diagnostic tests in serum. Taking into account previous data recorded in patients with chronic hepatitis C[11], we performed a study with 21 patients diagnosed as having occult HCV infection (HCV-RNA positive in liver but negative in serum) and compared detection of viral RNA in plasma, PBMC and whole-blood[12]. All cases had negative results for HCV-RNA in plasma. In 3 (14%) patients, viral RNA was detected in whole-blood while HCV-RNA could be detected in PBMC of 57% of the included cases. Thus, using whole-blood as the source for HCV-RNA detection does not improve the sensitivity of the diagnosis of occult HCV infection. Testing for HCV-RNA in PBMC is much more reliable in identifing patients with an occult HCV infection when a liver biopsy is not available.

## OCCULT HCV REPLICATION IN PBMC

One important question regarding the transmission of occult HCV infection was whether the virus could replicate in PBMC. To study this issue, 18 patients who had been diagnosed with occult hepatitis C by testing for HCV-RNA in their liver biopsy and who also had HCV in their PBMC were selected for this study[13]. By a strand-specific RT-PCR it was found that 61% of the patients had the antigenomic HCV-RNA strand in their PBMC, indicating that HCV was replicating in these cells. So, although the patients with occult HCV infection do not have detectable circulating virions, they could be potentially infectious.

## CHRONIC VERSUS OCCULT HEPATITIS C

Once occult HCV infection is identified, one important question is if the clinical characteristics of this infection differ from those usually found in chronic hepatitis C. Trying to answer this question, the biochemical, virological and histological features of a group of 68 patients with occult HCV infection were compared with those of a group of 69 patients with histologically proven chronic hepatitis C[14]. Groups were matched with respect to gender, age and known time duration of the disease. Triglycerides and cholesterol values were significantly higher in occult HCV infection, while alanine aminotransferase, gammaglobulin, alpha-fetoprotein and iron levels were significantly higher in patients with chronic hepatitis C. The number of patients who had necroinflammatory activity and fibrosis in the liver biopsy was significantly higher in the group with chronic hepatitis C than in the group with occult HCV infection, but no difference was found in the percentage of patients with liver steatosis between both groups. Finally, as could be expected, the percentage of HCV-infected hepatocytes (determined by *in situ* hybridization) was significantly lower in patients with occult HCV. Thus, it was concluded that occult HCV infection is a milder disease, with less liver damage than chronic hepatitis C. Nevertheless, as patients with occult hepatitis C may present dyslipidemic disorders, studies on the natural history of occult HCV infection should be performed to prove the role of occult HCV as the cause for liver injury in these patients.

## CELLULAR IMMUNE RESPONSES IN OCCULT HCV INFECTION

Why does occult HCV infection induce a less aggressive disease than chronic HCV infection? The immunological system of the patients could be involved in this situation.

Quiroga *et al*[15] have performed a study in an attempt to determine if the cellular immune response of patients with occult HCV infection is different from that of patients with chronic hepatitis C. This work compared 50 patients with occult HCV, 141 with chronic hepatitis C and 21 patients with cryptogenic liver disease (all known causes of liver disease were discarded, including an occult HCV infection). Overall, 26/50 (52%) of patients with occult HCV infection had $CD4^+$ T-cell proliferative responses. These responses were significantly more frequent in patients with occult HCV than in the group of patients with chronic hepatitis C (37/141: 26%; $P = 0.0016$) or in individuals with cryptogenic liver disease (1/21: 5%; $P < 0.001$). HCV-specific T-cells of patients with occult HCV infection proliferated more commonly in response to NS3 and NS4 proteins, and the peripheral blood mononuclear cells derived T-cell lines from these patients produced gamma interferon. Finally, patients with occult HCV infection had significantly higher amounts of HCV-specific $CD8^+$ T-cells than patients with chronic hepatitis C. In summary, HCV-specific cellular immune responses are more frequent in occult HCV infection than in chronic hepatitis C. Thus, patients with an occult HCV infection had a better immune response and this could be the cause of the milder disease that these patients have in comparison to those with chronic hepatitis.

These results seem to suggest that the clinical differences observed between occult and chronic hepatitis C are a consequence of the host's immunological system.

## OCCULT HCV INFECTION AND HEPATOCELLULAR CARCINOMA

Hepatocellular carcinoma (HCC) is one of the most common malignancies throughout the world. In a small proportion of cases, the etiology agent associated with the development of liver cancer is unknown. Two different groups, one from Japan[16] and the other from Italy[17], have reported the presence of occult HCV infection in non-tumoral and tumoral liver tissues of patients with HCC who were negative to serological HCV markers. Therefore, it seems that occult HCV infection may play a role in the development of HCC however, as discussed above, more studies on this issue should be performed.

## OCCULT HCV INFECTION IN RISK POPULATIONS

In the presence of elevated levels of liver enzymes, hemodialysis patients are screened for hepatotropic viral infections: hepatitis B surface antigen, anti-HCV and/

or serum HCV-RNA. Nevertheless, in some patients the etiology of their elevated liver enzymes cannot be established as they are negative for all serological viral markers (including serum HCV-RNA). To investigate whether these hemodialysis patients are affected by an occult HCV infection, 6 Spanish Hemodialysis Units enrolled 42 patients with abnormal liver function tests of unknown etiology[18]. By strand-specific RT-PCR and by *in situ* hybridization it was found that 26/42 (62%) of the patients had HCV-RNA in their PBMC. These patients with occult HCV infection had significantly higher ALT values than the negative ones. In addition, HCV was replicating in the PBMC of 15/26 (58%) of the cases of occult infection. In summary, although these patients are serum HCV-RNA negative they could be potentially infectious as HCV is replicating in their PBMC, thus preventive measures to avoid HCV spread in hemodialysis units must be considered.

## ANTIVIRAL TREATMENT IN OCCULT HCV INFECTION

Regarding the possible efficacy of antiviral therapy in occult hepatitis C, Pardo *et al*[19] treated 10 patients with occult HCV infection with pegylated-interferon plus ribavirin for 6 mo, followed by a post-treatment follow-up period of 6 mo. Although all the patients were infected with HCV genotype 1b, they were treated for 6 mo instead of 12 mo (the currently accepted duration of antiviral therapy for patients with chronic hepatitis C and genotype 1b), because they were serum HCV-RNA negative and the percentage of infected hepatocytes is lower than in chronic hepatitis C[14]. At the end of treatment, 80% of the patients had normalized ALT levels and cleared HCV-RNA from PBMC. However, at the end of the post-treatment follow-up only 30% of the patients maintained a complete response (HCV-RNA negative in PBMC and normal ALT levels). Five patients (2 of them were complete responders) underwent a second liver biopsy after treatment and, although none of them lost HCV-RNA in liver, a significant decrease was observed in the amount of intrahepatic viral RNA in comparison to the basal levels. Moreover, in 3 patients liver necroinflammatory activity and fibrosis score had decreased with respect to the pre-treatment histological diagnosis.

It can be concluded that, as reported in chronic hepatitis C (see below), antiviral therapy in occult HCV infection does not lead to a complete eradication of HCV infection, yet it may be useful as liver damage improves. Thus, treatment with pegylated-interferon and ribavirin of patients with occult HCV infection and a stage of liver fibrosis of 2 or more seems advisable.

## OTHER FORMS OF OCCULT HCV INFECTION

As commented before, occult HCV infection is characterized by the absence of anti-HCV and of serum HCV-RNA, but viral RNA is detectable in liver and PBMC. However, occult HCV infection may exist in other clinical situations such as in anti-HCV positive patients who are serum HCV-RNA negative and who present normal liver function tests.

One of these populations is the "healthy" HCV-carriers. These patients, who are anti-HCV positive with undetectable serum viral RNA and normal ALT levels, are considered to be subjects who have cleared HCV infection after exposure to HCV. To verify if these patients could have HCV-RNA in their liver, we performed a study with 12 "healthy" anti-HCV carriers[20]. These anti-HCV positive patients were serum HCV-RNA negative and had persistently normal ALT values for a 29 ± 19 mo follow-up period. These patients underwent a programmed interventional laparoscopy and gave their consent for obtaining a liver biopsy specimen during the laparoscopy. The genomic HCV-RNA strand was detected in the liver of 10/12 (85%) of these subjects and it was also found that HCV was replicating in the hepatocytes of the 10 patients in question. All of them were infected by HCV genotype 1b, as demonstrated by sequencing of the HCV genome amplified from the liver. Viral RNA was also found in the PBMC of 6/12 patients and 5 (83%) out of these 6 also had HCV replication in PBMC. Another research group[21] has also demonstrated the presence of HCV infection and replication either in the liver or PBMC of nearly 90% of anti-HCV positive patients with normal ALT values.

Occult HCV infection has also been identified in a similar cohort of patients: those with chronic hepatitis C who have responded to an antiviral therapy with loss of circulating HCV-RNA and normalization of ALT levels. Several papers have reported the presence of an occult HCV infection (persistence of HCV-RNA) in the liver and in PBMC of sustained responders[22-24]. However, other authors have not found viral RNA in these patients[25,26]. These discrepancies could be due to different preservation methods of the liver biopsies, to differences in the sensitivity of the methods employed for HCV-RNA detection, different geographical incidence, *etc*. Thus, further studies are needed to know the real prevalence of occult HCV in complete responder patients. One of the possible consequences of occult HCV infection is the persistence of liver necroinflammation in an important number of sustained responder patients[23,24].

The case of a patient with chronic hepatitis C who cleared serum HCV-RNA with normalization of ALT levels in whom HCV infection reactivated following prednisone therapy after 8.5 years of HCV-RNA negativity has been published. Thus, occult HCV infection should be taken into account when these anti-HCV positive patients with normal ALT levels undergo immunosuppressive therapies[25].

## CONCLUSIONS

Occult hepatitis C infection is a new entity that should be taken into account for the diagnosis of patients with a liver disease of unknown origin. Future works should deal with its possible incidence and pathologic relevance in immunosuppressed or HIV coinfected patients, drug abusers or subjects who had received multiple blood transfusions. On the other hand, it would be convenient to perform epidemiological studies on occult HCV infection

among health care staff, patients on hemodialysis, etc to know the prevalence and spread of this infection in these populations. It is also very important to determine the possible incidence and consequences of occult HCV infection in blood donated and transplanted patients.

## Abstract

Evidence has accumulated to suggest an important role of ethanol and/or its metabolites in the pathogenesis of alcohol-related liver disease. In this review, the fibrogenic effects of ethanol and its metabolites on hepatic stellate cells (HSCs) are discussed. In brief, ethanol interferes with retinoid metabolism and its signaling, induces the release of fibrogenic cytokines such as transforming growth factor β-1 (TGFβ-1) from HSCs, up-regulates the gene expression of collagen I and enhances type I collagen protein production by HSCs. Ethanol further perpetuates an activated HSC phenotype through extracellular matrix remodeling. The underlying pathophysiologic mechanisms by which ethanol exerts these pro-fibrogenic effects on HSCs are reviewed.

**Key words:** Ethanol; Acetaldehyde; Hepatic stellate cells; liver fibrosis; Type I collagen gene; Transcription factors; Transforming growth factor β-1

## INTRODUCTION

Ethanol abuse is a leading cause for morbidity and mortality throughout the world. It affects many organ systems, most notably the liver causing both acute and chronic liver disease, and the central nervous system[1-3]. Hepatic cirrhosis resulting from alcohol abuse is one of the principal causes of liver-related morbidity and mortality. In the liver, excess ethanol leads to three pathologically distinct disorders, namely fatty liver (alcohol-associated hepatic steatosis), alcoholic hepatitis and cirrhosis. Alcohol-associated hepatic steatosis is the most common form of liver injury and is reversible with abstinence[3-5]. More serious forms of alcoholic liver disease (ALD) include alcoholic hepatitis characterized by persistent inflammation of the liver, and cirrhosis, characterized by progressive hepatic fibrosis. The pathogenesis of ALD is poorly understood, in part because no simple animal model exists that reproduces the full spectrum of the human disease, including the development of cirrhosis[1,4]. In addition, there is considerable variation among individuals in their susceptibility to ALD, so that among people drinking similar amounts, only a proportion develops cirrhosis[1,3-5].

Almost all ingested ethanol is metabolized in the liver. Two major enzyme systems, namely the oxidative and non-oxidative pathways, mediate the initial phase of ethanol metabolism[1,5] (Figure 1). The oxidative pathway comprises the alcohol dehydrogenases (ADH) and members of the cytochrome P450 system (predominantly CYP2E1)[5-7]. This pathway generates acetaldehyde. Acetaldehyde is subsequently metabolized to acetate via the mitochondrial enzyme acetaldehyde dehydrogenase (ALDH). Although acetaldehyde is oxidized to acetate by ALDH, the kinetics of this reaction is sufficiently slow to allow for the accumulation of acetaldehyde in humans or animals consuming alcohol[1,2,5]. The non-oxidative pathway of ethanol metabolism involves the esterification of ethanol with fatty acids to form fatty acid ethyl esters (FAEE), a reaction catalyzed by FAEE synthases[1,5].

Ethanol and its metabolites including acetaldehyde cause liver damage through several interrelated pathways[1,2,8,9]. The oxidation of ethanol is associated with a change in hepatocyte redox homeostasis which can lead to a number of metabolic disorders including lactic acidosis, hyperlipidaemia and hyperuricaemia. Chronic ethanol consumption does not influence ADH activity, but has a profound stimulatory effect on microsomal enzymes, particularly CYP2E1[1,2]. This is in part responsible for the development in alcoholic liver diseases, a rise in oxygen consumption, the excessive production of free radicals and an increase in the metabolism of ethanol, vitamin A and testosterone. Ethanol and acetaldehyde have deleterious effects both direct and indirect, for example by generating reactive oxygen species (ROS) and causing damage to

the intestinal mucosal barrier[1,10]. Cellular oxidative stress that is caused by the relative imbalance between free radical generation and insufficient anti-oxidant defense mechanisms, including reductions in glutathione, vitamin E and phosphatidylcholine, may be a principal mediator for the progression of alcoholic liver disease[1,2,10].

Steatosis, hepatitis and fibrosis seen in persons with ALD are a consequence of complex pathophysiological events involving various cell types within the liver including neutrophils, sinusoidal endothelial cells (SECs), Kupffer cells (KCs), hepatic stellate cells (HSCs) and hepatocytes. Recently, many studies have demonstrated that ethanol and its metabolites including acetaldehyde directly activate HSCs, the principal fibroblastic cell type within the liver[8,9,11]. Ethanol and acetaldehyde directly promote the production of transforming growth factor beta-1 (TGFβ-1) and several extracellular matrix (ECM) constituents including type I collagen by HSCs[8,9,11].

This article reviews recent advances in our knowledge on the effects of ethanol and its metabolites on HSCs.

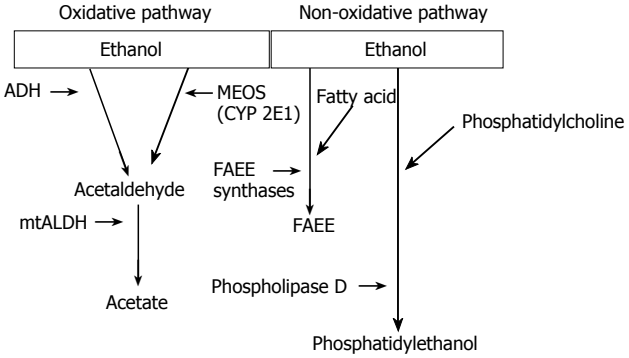

**Figure 1** Metabolism of ethanol in the liver via oxidative and non-oxidative pathways. Oxidative pathway: In the first step of oxidation, ethanol is converted to acetaldehyde. Alcohol dehydrogenase (ADH) is the major enzyme. The microsomal ethanol-oxidizing system (MEOS) involves several cytochrome P450 proteins, of which cytochrome P450 2E1 (CYP2E1) is the major constituent. In the second oxidative step, acetaldehyde is rapidly metabolized to acetate by mitochondrial acetaldehyde dehydrogenase (mtALDH). Non-oxidative pathway: The non-oxidative pathway of ethanol metabolism involves the esterification of ethanol with fatty acids to form fatty acid ethyl esters (FAEE), a reaction catalyzed by FAEE synthases. The non-oxidative pathway also generates phosphatidylethanol *via* phospholipase D.

## DIRECT EFFECTS OF ETHANOL ON HSCS

A central event in liver fibrosis is the activation of HSCs, which represents a transition from a quiescent vitamin A-rich cell type to a vitamin A-deficient, proliferative, fibrogenic and contractile myofibroblast. Activated HSCs demonstrate altered cell behaviors including proliferation, chemotaxis, fibrogenesis, contractility, matrix degradation, retinoid loss, leukocyte chemotaxis and cytokine release. In total, these changes result in excess ECM deposition which is reabsorbed, culminating in the development of liver fibrosis.

HSCs derived from the intragastric ethanol infusion model of ALD demonstrate an activated phenotype including an increase in collagen I and DNA synthesis[12], expression of α-smooth muscle actin (α-SMA) and depletion of retinyl palmitate[13].

### *Effect of ethanol on vitamin A metabolism within HSCs*

HSCs are the major site of vitamin A storage in healthy adults. Vitamin A in HSCs is in the form of retinyl esters located in cytoplasmic lipid droplets[14]. The three active forms of vitamin A, namely retinol, retinal and retinoic acid (RA) are important regulators of cell proliferation and differentiation, binding to 2 distinct families of ligand-activated transcription factors: the retinoic acid receptor (RARs: RARα, RARβ and RARγ) and the retinoid X receptor (RXR)[15]. The natural ligand for the RARs is all trans-retinoic acid (ATRA). Published data indicate that HSCs from healthy rats express mRNAs in the RARs and RXRs[16].

Nutritionally reduced levels of serum and hepatic vitamin A have been reported in persons with ALD and in animal models of the disease[17,18]. In HSCs, ethanol significantly inhibits RA production[19] and reduces the retinol level[20]. Acetaldehyde exposure results in a reduction in RARβ message and protein in HSCs[21]. There are several other possible mechanisms by which ethanol can interfere with retinoid metabolism in the liver[19], including decreased vitamin A uptake, enhanced degradation of vitamin A in the liver, enhanced vitamin A mobilization from the liver to other organs, and degradation by ethanol of RA into polar inactive metabolites *via* induction of cytochrome P4502E1.

The activation and differentiation of HSCs are characterized by proliferation and an increase in the production of ECM proteins together with a loss of cellular retinoids. Therefore, it is plausible that ethanol-induced RA metabolism in HSCs could play a role in the development of alcohol-related liver fibrosis and cirrhosis.

### *Ethanol, HSC proliferation and α-SMA expression*

Linolenic acid ethyl esters (LAEE), one of the FAEE products of non-oxidative ethanol metabolism, may promote HSC proliferation[22]. This effect is thought to be modulated through increased cyclin E and cyclin-dependant kinase 2 (CDK2) activities[22]. Ethanol, acetaldehyde and lactate, in contrast, have no direct effect on HSC proliferation[23,24].

Ethanol induces early protein expression of α-SMA in cultured HSCs compared to controls[25,26]. Chen and colleagues[27] likewise reported that α-SMA mRNA expression in HSCs is significantly enhanced by exposure to acetaldehyde. However, Poniachik *et al*[24] were unable to replicate this finding. Hence, the effects of ethanol on HSC proliferation and α-SMA expression remain controversial.

### *Effects of ethanol on ECM production by HSCs*

HSC activation is characterized by an increase in the production of ECM, mainly collagen types I and Ⅲ. In addition, HSC activation is associated with alterations in both types of collagen, matrix-degrading metalloproteinases (MMPs) and their inhibitors, tissue inhibitors of metalloproteinases (TIMPs)[28]. Failure of matrix degradation leads to ECM accumulation and progressive hepatic fibrosis[28].

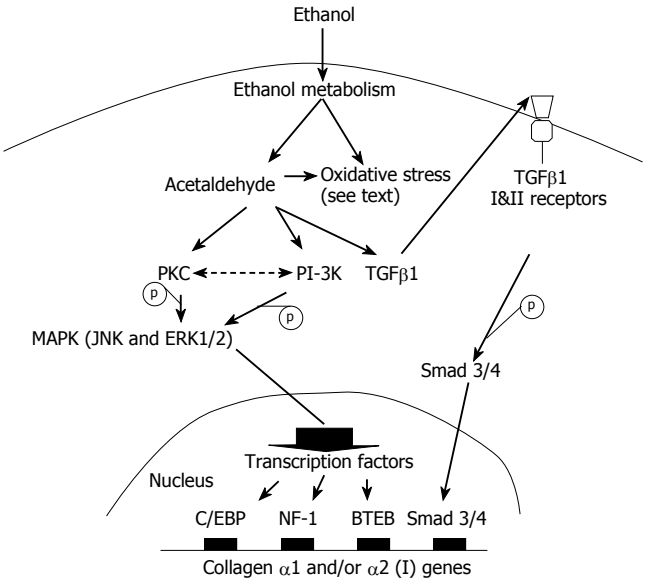

**Figure 2** Possible mechanisms for the direct profibrotic effects of ethanol on hepatic stellate cells. Acetaldehyde, together with ethanol or acetaldehyde-derived oxidative stress, induces latent TGFβ1 and TGFβ receptor activation that subsequently leads to Smad3/4 activation and binding to the promoter of collagen I genes. PKC and/or PI-3K kinases are also activated by acetaldehyde. Both kinase systems activate their downstream components, including ERK1/2 and JNK. As a result, C/EBP, NF-1 and/or BTEB transcription factors are activated and therefore up-regulate collagen I gene transcription.

Numerous studies have shown that ethanol and/or its metabolites regulate the expression of multiple components of the ECM in HSCs. Both ethanol and acetaldehyde induce α1 (I) collagen mRNA expression in HSCs[29-33] but not hepatocytes[30]. This effect is protein synthesis-independent[29]. Acetaldehyde increases the steady-stage levels of α2 (I) gene expression[21,34] and the production of type I collagen protein[29-31] in HSCs. Acetaldehyde likewise up-regulates the mRNA expression of MMP-2 and fibronectin in human HSCs[35,36].

### *Signaling pathways that mediate type I collagen gene transcription in HSCs exposed to ethanol*

The mechanisms by which ethanol and its metabolites regulate ECM gene and/or protein expression in HSCs have not been completely elucidated (Figure 2). Several centers have reported that the MAPK and PI-3K pathways are involved[35,37,38]. Anania and colleagues[37] noted that in rat HSCs, phospho-JNK is elevated following exposure to acetaldehyde. Inhibition of JNK by curcumin at low doses reduces acetaldehyde-induced steady-state levels of endogenous α1 (I) collagen mRNA expression[37]. Phosphorylated ERK and p38 are detectable but not significantly elevated. It seems likely therefore that JNK is the principal mediator of acetaldehyde-induced α1 (I) collagen gene up-regulation in rat HSCs. These finding are consistent with those previously reported by Chen *et al*[38]. In contrast, in human HSCs, ERK1/2 and the PI-3K pathway appear to be triggered by acetaldehyde, leading to α2 (I) collagen and fibronectin gene up-regulation[35].

The protein kinase C (PKC) pathway may also play a role in the up-regulation of collagen gene transcription following exposure to ethanol, since PKC is upstream of ERK1/2 and JNK[35,39,40]. Acetaldehyde-elicited α2 (I) collagen and fibronectin gene expression in human HSCs is inhibited by calphostin C (a PKC inhibitor). This PKC inhibitor also reduces the enhancing effect of acetaldehyde on α1 (I) collagen mRNA expression in cultured mouse and human HSCs[35,39]. Other experiments noted that acetaldehyde increases the translocation of PKC activity to membrane fractions[39] and both α1 (I) and α2 (I) collagen gene transcription in a calcium-independent manner[39].

### *Transcription factors that mediate type I collagen gene expression in response to ethanol*

The modulation of gene expression in response to an exogenous or endogenous stimulus occurs through alterations in any one of the steps of gene transcription, mRNA stability, protein translation or protein degradation. Transcription factors are generally classified according to the conserved motifs within either their activation- or DNA- binding domains[41,42]. The binding of transcription factors at DNA-binding sites brings them into proximity with RNA polymerase Ⅱ and components of the transcription complex that assemble in the 5'untranscribed region of genes[42,42]. Transcription factors are then able to exert either a positive or a negative influence on the rate at which the transcription complex transcribes the gene of interest. Transcriptional control of acetaldehyde-induced type I collagen gene expression might be regulated through CCAAT/enhancer-binding proteins (C/EBP), nuclear factor-I (NF-I), basic transcription element binding (BTEB) protein as well as activating protein-1 (AP-1)[34,38,43,44]. The precise mechanisms however, remain to be clarified.

A C/EBP binding site is present in the α1 (I) collagen promoter between -365 and -335 of the transcription start site[44]. Transfection of the α1 (I) collagen promoter mutated at the C/EBP binding site results in unresponsiveness to acetaldehyde, indicating that this site is essential for the collagen gene transcription effect of acetaldehyde[34,44]. C/EBP consists of 6 members. The principal form present in activated HSCs is C/EBPβ[44]. In turn, four C/EBPβ isoforms with approximate molecular weights of 45, 43, 35 and 20 kDa have been identified in activated rat HSCs, with the 35-kDa isoform being predominant[44,45]. Attard *et al*[44] noted that activation of the α1 (I) collagen promoter by acetaldehyde in HSCs is most likely consequent upon an increase in this isoform and increased protein/DNA binding to the C/EBP binding site.

Another report suggests that acetaldehyde-induced α1 (I) gene expression in rat HSCs requires the binding of the acetaldehyde-inducible transcription factor BTEB to a GC box (-1484 to -1476) on the promoter of this gene[43]. In keeping with this proposal, blocking BTEB protein production, results in a reduction in acetaldehyde-induced α1 (I) collagen gene expression[43]. In an extension of the previous report, additional data suggest that acetaldehyde can firstly induce AP-1 activation in HSCs[38,43] and then the activated AP-1 can bind to AP-1 responsive elements in the BTEB promoter to stimulate BTEB expression. The BTEB protein, in turn, stimulates the expression of the α1 (I) gene in HSCs[38,43].

Nuclear factor I (NF-I), a CCAAT binding trans-

cription factor, is also known to bind to and activate the α1 (I) and α2 (I) collagen promoters[46]. Acetaldehyde-induced enhancement of the α2 (I) collagen promoter in activated HSCs is associated with increased binding of NF-I to a consensus consequence located at -352 to -104 bp from the transcriptional start site[34,46,47].

These data suggest that the transcription factors C/EBP, BTEB and NF-1 bind to and activate type I collagen gene transcription through each of them and/or *via* synergic effects, though further characterization of these effects is required. Whether these collagen gene transcription signaling pathways (after exposure to ethanol), are regulated by acetaldehyde itself, or in concert with other profibrogenic mediators such as oxidative stress or TGFβ1 is presently uncertain. The available data are discussed below.

### *Increased oxidative stress responses and TGFβ1 play an important role in the regulation of type I collagen gene transcription in HSCs*

**Oxidative stress:** Increased oxidative stress is present in the liver after both acute and chronic ethanol administration[48]. Ethanol-induced oxidative stress within hepatocytes can occur acutely through ethanol metabolism or chronically following the induction of CYP2E1[2,10]. The oxidative metabolism of ethanol in hepatocytes elicits a range of mediators including ROS. CYP2E1 in particular has been shown to generate ROS including the superoxide anion, hydrogen peroxide ($H_2O_2$) and hydroxyethyl free radicals[2,49]. Other sources of free radical generation by ethanol include NADH oxidation by aldehyde oxidase[50].

HSCs contain the enzymes of oxidative ethanol metabolism including ADH and P450 proteins[51-53]. Yamada and Oinonen[52] observed that CYP2E1 is present in rat HSCs as high as 21% of that found in hepatocytes. CYP2E1 is also detectable in the rat hepatic stellate cell line, HSC-T6[51]. In HSC-T6 cells overexpressing ethanol-inducible CYP2E1, time- and dose-dependent induction in collagen α2 (I) mRNA together with increased $H_2O_2$ production by ethanol has been observed. Antioxidants, including catalase (an $H_2O_2$ scavenger) prevent this increase in collagen α2 (I) mRNA expression[51]. Because ethanol can be oxidized to acetaldehyde by the peroxidative activity of catalase[54], this decrease in collagen α2 (I) expression by catalase suggests that ethanol-derived acetaldehyde is not responsible for this effect. Svegliati-Baroni *et al*[11] and Greenwel *et al*[35] have also provided evidence to support the concept that increases in mouse α1 (I) and human α2 (I) collagen gene expression in HSCs by acetaldehyde are linked to elevated $H_2O_2$ production. For example, acetaldehyde-elicited type I collagen gene expression can be blocked by the addition of catalase[11,35], and is in part, TGFβ1-independent[11]. It is known that $H_2O_2$ activates MAPK pathways[49] and this activity might enhance the binding of the down stream transcription factors to acetaldehyde-responsive elements within the type I collagen promoter. Likewise, leptin induces $H_2O_2$ production and contributes to TIMP-1 expression in HSCs[55]. Collectively, these data suggest that increased $H_2O_2$ generation during the metabolism of ethanol by HSCs might play a critical role in their activation.

**TGFβ-1:** Ethanol and acetaldehyde increase autocrine TGFβ1 expression in HSCs. In turn, TGFβ1 is able to up-regulate type I collagen gene expression[32,34,38]. Anania and colleagues[34] noted that the effects of acetaldehyde-induced TGFβ1 in the regulation of α2 (I) collagen gene expression are mediated by a factor or factors that bind to nuclear factor I (NF-I) consensus sequence located at the -352 to -104 region of the α2 (I) gene promoter. Acetaldehyde further increases the secretion of both latent and active forms of TGFβ1 in cultured rat HSCs[38], and induces the expression of the type Ⅱ TGFβ receptor which is required for all TGFβ-mediated signaling events[38]. In transient transfection experiments, the combination of TGFβ1 and acetaldehyde could result in greater activation of the mouse α2 (I) collagen promoter than either TGFβ1 or acetaldehyde alone[34]. Taken together, these observations suggest that TGFβ1 could play a key role in acetaldehyde-induced collagen I gene activation.

Chen *et al*[38,43] have noted that acetaldehyde stimulates latent TGFβ1 secretion and TGFβ type Ⅱ receptor gene expression. BTEB might be the principal transcription factor binding to the GC box of the type Ⅱ TGFβ receptor gene promoter[38]. The authors proposed a model wherein acetaldehyde activates signal transduction pathways including PKC, JNK and ERK, leading to activation of AP-1. AP-1 is proposed to activate the gene expression of BTEB. BTEB then up-regulates TGFβ type Ⅱ receptor gene expression in HSCs. By stimulating latent TGFβ1 activation and secretion, as well as up-regulating the expression of TGFβ type Ⅱ receptor, acetaldehyde activates TGFβ1 signaling, which eventually enhances expression of the α1 (I) collagen gene in HSCs[38].

The precise molecular mechanisms by which acetaldehyde elicits TGFβ1 production in HSCs are largely unknown. Acetaldehyde might directly bind to the TGFβ1 gene promoter leading to its activation. Alternatively, acetaldehyde might bind to other gene promoters of transcription factors that in turn activate the TGFβ1 gene.

## OTHER DIRECT FIBROGENIC EFFECTS OF ETHANOL ON HSCS

Rodriguez-Fragoso and his colleagues[56] investigated the effects of the activity of urokinase type plasminogen activator (uPA) in the CFSC-2G stellate cell line and demonstrated that acetaldehyde (175, 250 and 350 μmol/L) enhances uPA gene expression. This is accompanied with a concomitant increase in production of type I collagen. uPA plays an important role in matrix remodeling under a wide range of physiological and pathological conditions, activates TGFβ1 and induces proliferation of HSCs[57,58]. Furthermore, profibrogenic mediators including IL-6, TNF-α, malondialdehyde (MDA) and intracellular GSSG have been reported to increase in CFSC-2G cells treated with ethanol or acetaldehyde[59-61].

Malondialdehyde-acetaldehyde (MAA) -protein adducts induce a dose- and time-dependent increase in the secretion of chemokines including monocyte chemoattractant protein (MCP)-1 and macrophage inflammatory protein (MIP)-2 as well as an increase in

the production and expression of intercellular adhesion molecule-1 (ICAM-1) in activated rat HSCs[62,63]. These effects may contribute further to the activation of HSCs and the subsequent development of alcohol-associated liver fibrosis.

## ACTIVITY OF ETHANOL/ACETALDEHYDE ON PANCREATIC STELLATE CELLS

Rat pancreatic stellate cells (PSCs) exhibit features similar to those of HSCs[64-66]. These cells are abundant in alcoholic chronic pancreatitis in humans, suggesting a central role of this cell type in pancreatic fibrosis[65]. An effect of ethanol on the modulation of PSCs has been documented. Ethanol and acetaldehyde increase α-SMA protein and type I collagen synthesis in PSCs[67], likewise enhance PSC MMP-2 and TIMP-2 gene expression as well as TIMP-2 protein secretion[67-69]. Both ethanol and acetaldehyde increase the activation of all 3 subfamilies (ERK1/2, JNK/SAPK and p38 kinase) of the MAPK pathway in PSCs. Only p38 MAPK is responsible however, for the induction of α-SMA and α1 (I) collagen gene expression[70]. Moreover, ethanol and acetaldehyde-induced MAPK activation can be blocked by the antioxidant N-acetyl-cysteine, suggesting a role of oxidative stress in signal transduction[68,71].

## CONCLUSION

Ethanol can be metabolized in hepatocytes and stellate cells to generate acetaldehyde and other metabolites. Ethanol and/or its metabolites including acetaldehyde have direct effects on HSC activation. These effects might be mediated by ethanol/acetaldehyde and/or ethanol/acetaldehyde-induced oxidative stress and TGFβ1 expression which activate relevant signaling pathways leading to the binding of transcription factors to the type I collagen gene promoter (Figure 2). As a result, ethanol augments the production of extracellular matrix proteins. Ethanol also stimulates the production of other profibrotic mediators, including IL-6, TNF-α and uPA. Taken together, these effects of ethanol/acetaldehyde on HSCs play an important role in the development of alcohol-associated liver fibrosis. Characterization of the key genes initiating and perpetuating the process of HSC activation by ethanol helps to further elucidate the molecular mechanisms of alcohol-associated liver fibrosis. In the future, it is hoped that specific, directed pharmacological agents can be selected and/or developed that target these mechanisms and thereby prevent or retard the fibrogenesis induced by alcohol.

## Abstract

Genetic abnormalities of proto-oncogenes and tumor suppressor genes have been demonstrated to be changes that are frequently involved in esophageal cancer pathogenesis. However, hypermethylation of CpG islands, an epigenetic event, is coming more and more into focus in carcinogenesis of the esophagus. Recent studies have proved that promoter hypermethylation of tumor suppressor genes is frequently observed in esophageal carcinomas and seems to play an important role in the pathogenesis of this tumor type. In this review, we will discuss current research on genes that are hypermethylated in human esophageal cancer and precancerous lesions of the esophagus. We will also discuss the potential use of hypermethylated genes as targets for detection, prognosis and treatment of esophageal cancer.

**Key words:** Methylation; Esophageal cancer; Tumor suppressor gene; Carcinogenesis

Wu DL, Sui FY, Jiang XM, Jiang XH. Methylation in esophageal carcinogenesis. *World J Gastroenterol* 2006; 12(43): 6933-6940

## INTRODUCTION

Esophageal cancer is one of the least studied and deadliest cancers, with a remarkable geographical distribution and a low likelihood of cure[1]. Therefore, the current challenges in the management of esophageal cancer are to obtain a better understanding of the underlying molecular biological alterations to provide new treatment options. Cancer of the esophagus exists in two main forms with different etiological and pathological characteristics-esophageal squamous cell carcinoma (ESCC) and esophageal adenocarcinoma (EAC)[1]. It is well known that esophageal carcinogenesis is a multistage and progressive process which includes basal cell hyperplasia (BCH), dysplasia (DYS), carcinoma in site (CIS) and advanced esophageal carcinoma[1,2]. A variety of genetic lesions are involved in esophageal carcinogenesis, including gene amplifications, loss of heterozygosity(LOH) or homozygous deletions, mutations, and chromosomal rearrangements[1,2]. From the above mentioned genetic lesions , mutations are greatly focused on. The vast majority of esophageal cancers have mutations of the TP53 and p16 genes at an early stage followed by mutations in genes such as APC, Rb and cyclin $D_1$ at later stages of progression[3]. Furthermore, the alteration of the gene mutations may show different types in ESCCs and EACs. For example, ESCCs and EACs show distinct patterns of TP53 mutations, namely a high prevalence of G > A transitions at CpG sites in EACs whereas in ESCCs a higher prevalence of G to T transversions and mutations at A:T base pairs is present[4].

Genetic mutation of genes that inhibit the formation of tumors has long been known to be one of the main driving forces in the development of cancer[1]. However, recent data have focused our attention to the contribution of epigenetics to tumorigenesis. In tumorigenesis of the esophagus, the epigenetic inactivation of genes is as an important a driving force as the inactivation of genes by mutation[5]. 'Epigenetic' events, i.e. heritable changes in gene function which cannot be explained by changes in DNA sequence, are composed of histone acetylation, the chromatin structure and DNA methylation[5]. DNA methylation seems to be the most important mechanism for "epigenetic change" at present[5,6]. Through a process of post-replicative covalent modification catalysed by DNA methyltransferases(DNMTs), the DNA of mammalian cells contains a 'fifth base', namely 5-methylcytosine. The most frequent target for this modification is cytosine in the context of the dinucleotide CpG[5]. Throughout the genome CpG dinucleotides are found at one-fifth of their predicted frequency[6]. In marked contrast to the genome-wide underrepresentation of CpGs, there are regions of the genome termed CpG islands which have maintained their expected frequency of the dinucleotides. And the CpG islands are often found within the promoter of genes[6,7]. It has been known for many years that, in general terms, there is an inverse relationship between the density of promoter methylation and the transcriptional activity of a gene[8,9]. The mechanism of gene silencing by promoter hypermethylation has recently been shown to be related to the recruitment of repressor protein complex, resulting in

de-acetylation of the chromatin and histone, thus barring access to the active transcription complex. However, the actual mechanisms by which DNA methylation modulates gene expression have remained elusive[7,10]. The assays for detection of cytosine methylation can be divided into two groups: restriction enzyme-based and bisulfite treatment-based[11,12]. The former employs the inhibition of certain restriction enzymes by methylation of their recognition sites as an indicator for the presence of methylation. The latter translates the epigenetic information of cytosine methylation in primary sequence differences by converting unmethylated cytosine to uracil whereas methylated cytosine remains unaltered. The bisulfite-converted genomic DNA can be analyzed by a wide variety of PCR-based methods[11,12]. Methylation is needed for the normal development of cells. And genome stability and normal gene expression are largely maintained by a fixed and predetermined pattern of DNA methylation[13]. Aberrant methylation confers a selective growth advantage that results in cancerous growth[13]. From various lines of evidence, it is known that the methylation pattern of the cancerous cell is associated with a broad genomic hypomethylated state that is often accompanied by a more regional and locus-specific hypermethylated pattern[7]. The presence of alterations in the profile of DNA methylation in cancer was initially thought to be exclusively a global hypomethylation of the genome that would possibly lead to massive overexpression of oncogenes whose CpG islands were normally hypermethylated[14]. Nowadays, however, this is considered to be an unlikely or, at least, incomplete scenario. The popularity of the concept of demethylation of oncogenes leading to their activation is in clear decadency[14,15]. Hypermethylation of CpG islands located in the promoter regions of tumor suppressor genes(TSGs) is now firmly established as an important mechanism for gene inactivation[16,17,18]. The particular genes that are hypermethylated in tumor cells are strongly specific to the tissue of origin of the tumor. A profile of CpG island hypermethylation exists according to the tumor type[15]. The mechanism responsible for this type of pattern remains largely unclear. Moreover, accumulating evidence indicates that CpG island hypermethylation is an early event in cancer development and, in some cases, may precede the neoplastic process[19]. Therefore, such profiles would provide invaluable insight into mechanisms underlying the evolution of each tumor type and will provide new molecular markers. This review will focus on the current understanding of DNA methylation abnormalities in esophageal cancer and discuss how this knowledge contributes to our understanding of the pathogenesis of esophageal cancer.

## STUDIES OF GENE PROMOTER HYPERMETHYLATION IN ESOPHAGEAL CANCER

Putative tumor suppressor genes, involving apoptosis, cell adherence, DNA repair, and the cell cycle, have been investigated for hypermethylation by various techniques in esophageal cancer. Below, we have chosen to describe those genes that have been most extensively studied in the past and that have been shown to undergo epigenetic changes in esophageal carcinoma.

### *p14$^{ARF}$, p15 and p16*

The 9p21 chromosomal band is one of the most frequently altered genomic regions in human cancers[20]. Within a short distance of 50 kb, a gene cluster consisting of three genes, p14$^{ARF}$, p15 and p16, is harbored. All of which have putative tumor suppressor roles[20,21,22]. Inactivation of p14$^{ARF}$, p15 and p16 genes has been observed in many types of human cancers including ESCC[21,22,23]. For example, the results from immunohistochemical analysis indicated that p16 expression was present in only 3 out of 22 ESCC cases[24]. Some studies showed that germline mutations in the p16 gene might be related to familial melanoma[25], but another study found the mutation of the p16 gene in esophageal cancer was rare[26]. Hemizygous and homozygous deletion at 9p21 are widely considered to be one of the primary mechanisms of p16/p15 inactivation[26]. Recently, however, aberrant methylation of the CpG islands at the promoter regions of p16 and p15 genes was reported in many cancers and was associated with loss of transcription[8,27]. Abbaszadegan *et al*[28] assessed a large family with clustering of ESCC in northeastern Iran and found aberrant p16 promoter methylation in 64% of ESCC family members and none in normal volunteers. By analyzing the p14$^{ARF}$, p15, and p16 genes individually in 40 ESCCs, Xing *et al*[29] detected aberrant promoter methylation of the p16 gene in 40%, of p14$^{ARF}$ in 15%, and of p15 in 13% tumor samples. They further detected homozygous deletion of p16 in 18%, of p14$^{ARF}$ in 33%, and of p15 in 40% tumor samples, and detected no mutation in the p14$^{ARF}$ and p16 genes[29]. Hardie *et al*[30] reported that hypermethylation of the p16 promoter is detected in 85% (18/21) of EACs while p16 mutations are uncommon (1.9%; 1/54). Another report found that in 50 Barrett's esophagus-associated EACs, hypermethylation of p16 was present frequently (54%), but hypermethylation of p14$^{ARF}$ was absent[27]. The above results suggest that p14$^{ARF}$, together with p15, is a primary target of homozygous deletion, whereas p16 is the hypermethylation hotspot in human esophageal cancer.

### *The FHIT gene*

The FHIT gene is located at chromosome 3p14.2 and encodes a polypeptide of 147 amino acids[31]. FHIT allelic deletions and reduced or absent FHIT protein expression have been observed in a variety of tumors suggesting a putative tumor suppressor function[31,32]. In ESCCs, the CpG island in the FHIT promoter region was hypermethylated in 25 of the 36 (69%) analyzed cases, significantly correlated with the deletion of FHIT protein expression[33]. Methylated ESCC cell lines exhibit re-expression of the FHIT gene and demethylation in the CpG islands after treatment with demethylating agent 5-aza-2'-deoxycytidine[34]. Another report showed that aberrant methylation of FHIT was found in 85 of 257 (33%) ESCCs[35]. These findings suggest that methylation of the 5' CpG islands of the FHIT gene is closely

associated with transcriptional inactivation and might be involved in tumor development of the esophagus.

### *The RARβ2 gene*

The retinoic acid receptor-beta2 (RARβ2) gene located at 3p24 has been intensively studied in many cancers and found to have defective function, thus making it a candidate TSG[36]. RARβ2 expression was detected in 88% (14/16) of normal esophageal tissues and only 54% (84/162) of esophageal carcinomas[36]. And 14 of 20 (70%) ESCC samples had hypermethylation of the RARβ2 promoter[37]. Another group reported that 34 of 47 (73%) primary resected ESCC samples showed RARβ2 methylation[38]. After 5-aza-2'-deoxycytidine treatment the expression of RARβ2 was reversed in two RARβ2-downregulated ESCC cell lines[39]. These results identified methylation as the underlying mechanism for this frequent loss of RARβ2 in esophageal cancer.

### *The APC gene*

The adenomatous polyposis coli (APC) gene, located on chromosome 5q21, is a TSG in the wnt signaling pathway[40]. APC shows frequent LOH in esophageal carcinomas, and the prevalence of mutations in the APC gene in esophageal carcinomas is low[41]. Hypermethylation of the promoter region of the APC gene occurred in abnormal esophageal tissue in 48 of 52 (92%) patients with EAC, in 16 of 32 (50%) patients with ESCC, but not in matching normal esophageal tissues[41]. So methylation of the promoter region of this gene constitutes an alternative mechanism of gene inactivation in esophageal carcinoma.

### *The ER gene*

The estrogen receptor (ER) gene at chromosome 6q, which has growth and metastasis suppressor activity in many different cell types, is widely expressed in tissues other than breast, and is methylated in 51% of EAC patients[42].

### *The MGMT gene*

The human enzyme $O^6$-methylguanine-DNA methyltransferase (MGMT) is located on chromosome band 10q26, and protects the cell from guanine methylation by irreversibly transferring the alkyl group of the $O^6$-methylguanine to a specific cysteine residue within the molecule[43]. Approximately 20% of tumor cell lines lack MGMT activity and are highly sensitive to alkylating agents[44]. In established cancer cell lines, MGMT expression appears to be correlated with methylation in the promoter of the gene[44]. The gene has been shown to be methylated in 46/119 (39%) ESCC, but all 21 normal esophageal tissues had unmethylated MGMT[45]. Another report studied the role of DNA hypermethylation in the loss of expression of MGMT during the development of ESCC, and found that 5 of 17 (29%) normal esophagus, 10 of 20 (50%) BCH, 8 of 12 (67%) DYS, and 13 of 18 (72%) ESCC samples had DNA hypermethylation in the MGMT promoter region, showing a gradual increase with the progression of carcinogenesis, while the frequency of the loss of MGMT mRNA and protein expression progressively decreased from normal to BCH, DYS, and ESCC, and it was highly correlated with MGMT promoter hypermethylation[46].

### *The E-cadherin gene*

E-cadherin gene on chromosome 16q22.1 encodes a Mr 120 000 transmembrane glycoprotein expressed on the surface of epithelial cells. In epithelial tissues, E-cadherin mediates homophilic, $Ca^{2+}$-dependent intercellular adhesion that is essential for the maintenance of normal tissue architecture[47]. Loss of E-cadherin expression occurs in a variety of human tumors and is correlated with invasion and metastasis, and activation of E-cadherin results in the growth inhibition of tumor cell lines[48]. E-cadherin can be targeted by both genetic and epigenetic means. Moreover, the hypermethylation of E-cadherin was seen frequently in most tumor types, but mutations only frequently in a small number of specific subtypes[48]. In esophageal carcinoma, downregulation of E-cadherin is common and is associated with an increase in invasive and metastatic potential, but mutations of the gene are rare[49]. E-cadherin was methylated in 26 of 31 (84%) EAC specimens, 16 of 20 (80%) ESCC samples and 4 of 6 ESCC cell lines[49,50,51]. And treatment of E-cadherin-negative carcinoma cells with the demethylating agent, 5-aza-2'-deoxycytidine, induced re-expression of the gene[51]. These data suggest that epigenetic silencing via aberrant methylation of the E-cadherin promoter is the critical mechanism for inactivation of this gene in esophageal cancer.

### *The TSLC1 gene*

The TSLC1 (tumor suppressor in lung cancer) gene located on 11q23.2 was first characterized as a TSG in human non-small cell lung cancer(NSCLC) and termed TSLC1[52]. The tumor suppressor role of this gene has been demonstrated in the cell lines of NSCLC, hepatocellular carcinoma, pancreatic cancer and ESCC[52,53]. Loss of TSLC1 expression was observed in 75% of the ESCC cell lines and 50% of the primary tumors from ESCC patients[53]. Ito *et al*[53] examined the methylation status of six cytosine residues of CpG sites in a putative promoter sequence upstream from the TSLC1 translation initiation site by bisulfite sequencing in four cell lines, including KYSE270, which expressed TSLC1, and KYSE410, KYSE520, and KYSE960, which did not express it. They also found all of the cytosine residues in KYSE270 DNA were unmethylated, whereas all of the six cytosine residues in KYSE520 DNA and five residues in KYSE410 and KYSE960 DNA were methylated. Especially, the cytosine residues in KYSE520 DNA were all hypermethylated. However, the report about the status of the promoter methylation of TSLC1 gene in esophageal cancer tissue has not been available.

### *The RASSF1A gene*

Many known RAS effectors are oncoproteins on their own. Less is known about Ras effectors possessing tumor suppressor properties[54]. Recently, a new family of genes

encoding a putative Ras effector, the Ras-association domain family 1 (RASSF1) gene, has been identified within the critical lung and breast cancer deletion region at 3p21.3. The RASSF1 locus encodes several major transcripts by alternative promoter selection and alternative mRNA splicing: RASSF1A, RASSF1B and RASSF1C. Many studies have suggested that RASSF1A was a new putative TSG[54,55]. RASSF1A acts as a negative effector of Ras in a pro-apoptotic signaling pathway. Interestingly, mutational inactivation of this gene is very rare (< 2%), and the main mechanism of its inactivation is through promoter methylation and LOH[56]. The RASSF1A isoform is highly epigenetically inactivated in lung, breast, ovarian, kidney, prostate, thyroid, esophagus and several other carcinomas[54]. Hypermethylation of RASSF1A was detected in 73% of ESCC cell lines and 51% of primary ESCCs, whereas only 4.3% of RASSF1A hypermethylation were detected in corresponding noncancerous tissues[38]. There was a statistically significant correlation between the presence of hypermethylation and tumor stage[57]. Wong *et al*[58] also found that RASSF1A was partially methylated in 3/7 (43%) esophageal cancer cell lines; 22/64 (34%) ESCCs and 3/64 (4.7%) corresponding non-tumor samples; and was not methylated in 2 immortalized normal oesophageal epithelial cell lines and 6 normal esophageal epithelium samples. These findings suggest that epigenetic silencing of RASSF1A gene expression by promoter hypermethylation could play an important role in ESCC carcinogenesis.

Besides the above mentioned genes, there are hypermethylations of some other genes involving esophageal cancer, including hMLH1[59,60], VHL[38], TIMP3[42,61], DAP-kinase[42], pRb[62], ECRG4[63], Chfr[64], HLA class I[65], EYA4[66], CDH13[67], SFRP1[68] and PGP9.5[69]. Table 1 gives a summary of the profile of gene hypermethylation in human esophageal cancer.

From the above mentioned reports, we find that there is obvious different methylation frequency in a gene from different authors in some cases, which may be due to different assay methods and different specimen resources. And the geographical difference may be due to variable carcinogens in the different areas. Furthermore, there seems to be obvious difference of methylation frequency of some genes between ESCCs and EACs. For example, hypermethylation of the promoter region of the APC gene occurred in 48 of 52 (92%) patients with EAC, but in 16 of 32 (50%) patients with ESCC[41], which suggests that hypermethylation of the APC gene has distinct roles in ESCC and EAC.

**Table 1 Compilation of genes hypermethylated in esophageal cancer *n* (%)**

| Gene | Entity of pathology | Incidence of methylation | | Reference |
|---|---|---|---|---|
| | | Cancer tissue | (Adjacent) nonmalignant tissue | |
| $p14^{ARF}$ | ESCC | 6/40 (15) | ND | 29 |

## METHYLATION IN SERUM DNA FROM ESOPHAGEAL CANCER PATIENTS

Despite advances in diagnosis and treatment of various cancers, early detection and treatment of cancer remain a challenge. One potential early detection biomarker is DNA methylation of the promoter region of certain cancer-associated genes[70]. Genetic analysis has shown that cell-free circulating DNA in plasma or serum of cancer patients shares similar genetic alterations to those described in the corresponding tumor[70,71]. Numerous studies have demonstrated the presence of promoter hypermethylation of tumor suppressor genes in the serum DNA of patients with various cancers[72]. Hypermethylated APC DNA was observed in the plasma of 13 of 52 (25%) EACs and 2 of 32 (6.3%) ESCCs[41]. Hibi *et al*[73] found that aberrant promoter methylation of the p16 gene was detected in 31 of 38 (82%) ESCCs, and 7 of these 31 (23%) patients with a p16 alteration in the primary tumor had the same methylation changes in the corresponding serum DNA. This study yielded a promising result: a tumor associated DNA alteration could be detected in the serum of 18% of ESCC patients (7 of 38 patients) using p16 methylation as a target. Moreover, the clinical sensitivity of this assay can be potentially improved by incorporating other possibly methylated target genes, which have been

estimated in other tumor types. For example, Esteller *et al*[74] analyzed primary NSCLCs and serum from 22 patients for the methylation pattern of four TSGs (DAPK, GSTP1, p16, and MGMT). Methylation of at least one of these genes was detected in 68% of NSCLCs. Comparing primary tumors with methylation and matched serum samples, 73% of the matched serum samples were found to be methylated[74]. In addition, none of the sera from patients with tumors not demonstrating methylation were positive[74]. Therefore, combined detection of aberrant promoter hypermethylation of cancer-related genes in serum may be useful for esophageal cancer diagnosis or the detection of recurrence.

## PROGNOSTIC SIGNIFICANCE OF GENE HYPERMETHYLATION

In the past few years, numerous attempts have been made to establish a genetic technique for reliably predicting tumor prognosis, but these attempts have been hindered by two main problems. First, only a few genes are somatically mutated in solid tumors and, second, because cell populations of primary neoplasms are heterogeneous, no single marker can accurately predict the behavior of the tumor[13]. Fortunately, emerging evidence suggests a possible prognostic value of gene promoter hypermethylation[75]. Lee *et al*[35] reported that aberrant methylation of the FHIT promoter in ESCC was found to be significantly associated with a poor prognosis for stage 1-2 cases. Mandelker *et al*[69] reported that PGP9.5 methylation was an independent prognostic factor for ESCC survival ($P = 0.03$) . Kawakami *et al*[41] reported that high plasma levels of methylated APC DNA were statistically significantly associated with reduced EAC patient survival. Brock *et al*[42] analyzed the methylation status of seven genes (including APC, E-cadherin, MGMT, ER, p16, DAP-kinase and TIMP3) of 41 EAC samples and found that DNA methylation of some genes individually showed only trends toward diminished survival, whereas patients whose tumors had > 50% of their gene profile methylated had both significantly poorer survival and earlier tumor recurrence than those without positive methylation. The data suggest that combined detection of methylation status for multiple genes is an effective strategy for prediction of esophageal tumor behavior. Although some genes that are frequently inactivated by methylation and are of prognostic impact for esophageal cancer patients have already been found, additional genes need to be identified. Thus, patients with a worse prognosis could be selected. These patients might benefit from a more aggressive treatment strategy.

## ABERRANT DNA METHYLATION IS AN EARLY EVENT IN ESOPHAGEAL CARCINOGENESIS

In many tumors, it has been proved that aberrant DNA methylation frequently occurs in precancerous tissue as well as cancer tissue, and both factors, genetic and epigenetic, lie at the origin of carcinogenesis[76]. The relative contribution of each varies significantly in different human tumors[76]. Nie *et al*[77] compared hypermethylation of p16, p15, p14, HLA-A, -B, -C, hMLH1, E-cadherin, FHIT and VHL genes in precancerous esophageal tissues and found that in 48 biopsy samples with BCH or DYS, the most frequent hypermethylated genes were p16 (19%) and $p14^{ARF}$ (15%), and seventeen out of these 48 samples (35%) contained hypermethylation of at least one gene. In the resected tissues, 52% of the BCH and 81% of the tumors showed hypermethylation of at least one gene. Another study reported that 2 of 17 (12%) normal esophagus, 9 of 21 (43%)BCH, 7 of 12 (58%) DYS, and 14 of 20 (70%) ESCC samples had hypermethylation of the RAR$\beta_2$ promoter region[37]. As to progression of EAC, it has been reported that, methylation of the p16 promoter was detected in 18 of 22 (82%) EAC and 10 of 33 (30%) premalignant lesions, whereas no methylation of the p16 promoter was found in normal esophageal epithelia[78]. Hardie *et al*[30] reported hypermethylation of the p16 promoter was detected in 77% (14/18) of Barrett's epithelia, and in 85% (18/21) of EACs. These data suggest that aberrant DNA methylation participates early in the development of esophageal cancer. Recently, the lab of professor Yang CS reported that EGCG, the major polyphenol from green tea, inhibited DNMT activity and reactivated several methylation-silenced genes, including p16, RAR$\beta_2$, MGMT and hMLH1, in human esophageal cancer KYSE 510 cells, accompanied by the expression of mRNA of these genes[79]. The result suggests that methylation might be a new target of chemopreventive activity. In the last two decades, it has been proven that many drugs, such as tamoxifen, aspirin, COX-2 inhibitors, possess positive chemopreventive activity against esophageal cancer[2]. However, the exact mechanisms have not been elucidated so far. Therefore, it will be very attractive to examine the effect of these drugs on promoter methylation status of key genes in esophageal cancer cells, esophageal cancer tissue, and especially precancerous tissue of the esophagus.

## HYPERMETHYLATION AS A TARGET OF THERAPEUTIC INTERVENTION

It has been reported that demethylating agents 5-azacytidine and 5-aza-2'-deoxycytidine can restore the normal demethylated state of several types of TSGs and increase their expression in various cancers, including esophageal cancer, *in vitro* and *in vivo*[13,14,15,39,54]. Since methylation and transcriptional status are inversely correlated, the use of demethylating agents appears to be a promising option for the treatment of tumors. Methylation of genes in tumor cells could provide a tumor-specific target for new therapies[80,81,82]. In fact, these demethylating agents have exhibited significant activity in the treatment of patients with myelodysplastic syndrome, chronic myeloid leukaemia and acute myeloid leukaemia[83,84]. However, preliminary experience with these agents in solid tumors has been relatively low[85]. Esophageal tumor shows a high prevalence of TSG hypermethylation, and the above studies demonstrated that gene expression could be restored after treatment of esophageal tumor cells

with demethylating agents *in vitro*. However, up to date the clinical trial about demethylating agents in esophageal cancer is unavailable. Although it is too early to make any expectation about the effect of these drugs on esophageal cancer, this is a very promising concept and needs to be tested in clinical trials.

## CONCLUSION AND PERSPECTIVES

Esophageal carcinogenesis is a stepwise process of the accumulation of genetic and epigenetic abnormalities. It has become clear that promoter hypermethylation of TSGs is as important for this multistep process as genetic changes in the progression of esophageal carcinogenesis. The steadily growing list of genes inactivated by promoter hypermethylation in esophageal carcinoma provides not only new insights into the molecular basis of the diseases but also a long list of interesting candidate genes for the development of molecular markers which might contribute to the improvement of diagnosis and also prognosis. In addition, the fact that methylation can be reversed *in vitro* and the effect of the demethylating agent 5-aza-2'-deoxycytidine *in vitro* raise hope for new treatment strategies for esophageal cancer patients. Furthermore, understanding of the significance of aberrant DNA methylation in the precancerous stage may show that a new strategy, correction of aberrant DNA methylation, can prevent esophageal cancer in people with premalignant lesions, such as Barrett's esophagus, BCH and DYS.

## Abstract

Since the relationship between angiogenesis and tumor growth was established by Folkman in 1971, scientists have made efforts exploring the possibilities in treating cancer by targeting angiogenesis. Inhibition of angiogenesis growth factors and administration of angiogenesis inhibitors are the basics of anti-angiogenesis therapy. Transfer of anti-angiogenesis genes has received attention recently not only because of the advancement of recombinant vectors, but also because of the localized and sustained expression of therapeutic gene product inside the tumor after gene transfer. This review provides the up-to-date information about the strategies and the vectors studied in the field of anti-angiogenesis cancer gene therapy.

**Key words:** Anti-angiogenesis; Tumor growth; Cancer gene therapy

## INTRODUCTION

Angiogenesis is the formation of new blood vessels from pre-existing ones. Many developmental and pathological processes require angiogenesis[1]. As proposed by Folkman in 1971, angiogenesis is required for tumor growth[2]. Angiogenesis consists of several steps: endothelial cell (EC) proliferation, migration, basement membrane degradation, and new lumen organization[3]. This multi-step process is determined by a net balance between pro- and anti-angiogenesis regulators in the circulation blood, which are released from activated ECs, monocytes, smooth muscle cells and platelets[3].

The growth of tumor depends on new blood vessel growth and involves three steps: angiogenesis, vasculogenesis and intussusception[4]. Without angiogenesis, a solid tumor rarely grows larger than 2 to 3 mm[5]. As shown in Figure 1, ECs and tumor cells release angiogenesis regulators like vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF) and transforming growth factor (TGF) to mediate angiogenesis. The result is the development of invasive tumor. In addition to the presence of angiogenesis factors, activation of oncogene and loss of tumor suppressor gene are also essential for an angiogenesis phenotype that supports tumorigenicity[6]. As a result, anti-angiogenesis has been regarded as a target for cancer therapy.

There are already several extensive reviews on the development of anti-angiogenesis cancer gene therapy[3,7-10]. In the 2001 review, Liau *et al*[7] compared and contrasted the gene approach and recombinant protein approach. In the editorial written by Lau and Bicknel[9], the authors compared the delivery of the genes of anti-angiogenic factors with that of the therapeutic proteins. They suggested that the delivery of genes can allow a high local expression of the protein at the sites of active tumor growth[9]. El-Aneed pointed out in his review, which summarizes the strategies in cancer gene therapy, that the ease of accessing ECs of the blood vessels is one of the main advantages of gene delivery approach[10]. Figure 2 shows that the delivery of the anti-angiogenesis gene into tumor cells or ECs can inhibit tube formation, EC migration and proliferation. This can result in tumor necrosis. In this review, updated information on the development of cancer anti-angiogenesis gene therapy is discussed.

## ANTI-ANGIOGENESIS CANCER GENE THERPAY STRATEGIES

### *RNA interference*

RNA interference (RNAi) is the sequence-specific gene

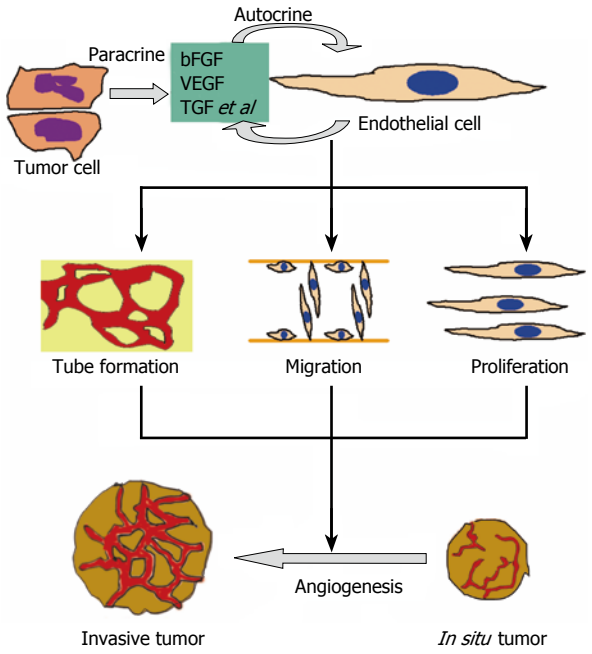

**Figure 1** Release of angiogenesis factors mediates the development of invasive tumor.

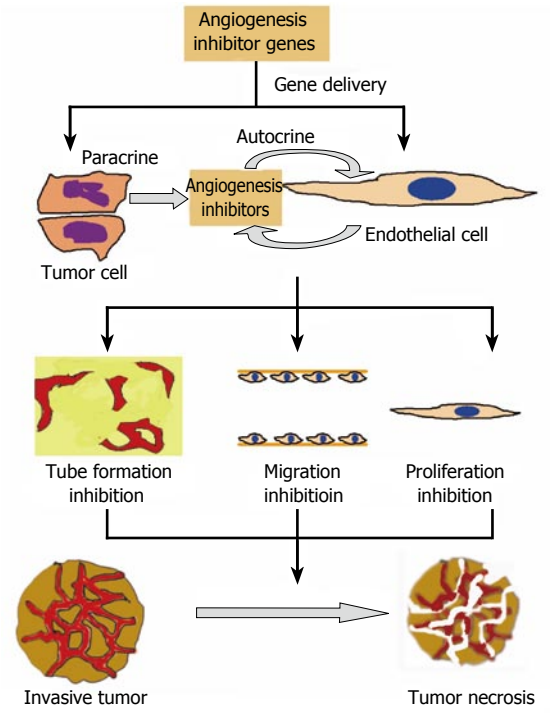

**Figure 2** Therapeutic actions of anti-angiogenesis gene therapy.

silencing induced by double-stranded RNA. Introduction of 21-23 small interfering RNAs (siRNAs) of the nucleotide can knock-out the expression of a particular gene[11]. A recent review written by Izquierdo[12] pointed out that siRNA against expression of vascular growth factor receptor (VGFR) can reduce tumor volume by blocking angiogenesis. Kwon and co-workers[13] described a method that can suppress the expression of VGFR-A at both transcriptional and post-transcriptional levels by a combination of zinc finger protein and siRNA. Gondi and co-workers[14] have demonstrated the potential application of RNAi in gene cancer therapy by inhibiting angiogenesis in both *in vivo* and *in vitro* human glioma cell models. Furthermore, it is possible to include more than one antiangiogenesis siRNA into a single retroviral vector because of the small size of siRNA, which could inhibit multiple pathways[12].

### *Antisense oligodeoxynucleotide*

Antisense oligodeoxynucleotide (ODN) is a synthetic molecule that blocks mRNA translation. The blockade of translation of mRNA of pro-angiogenesis factor genes can result in inhibition of tumor growth. Recently, ODN blocking of the expression of VEGF has been shown to be a promising cancer gene therapy. For example, Wang *et al*[15] have successfully reduced VEGF protein expression by 45% in human osteosarcoma cell line by transducing a eukaryotic expression plasmid containing antisense VEGF. Lipiodol is an effective treatment for unresectable liver cancer through transcatheter arterial embolization of the hepatic artery[16]. When VEGF antisense ODN is mixed with lipiodol, this combinational approach is better in inhibiting liver cancer growth, VEGF expression and microvessel density[16].

### *Expressing the genes of angiogenesis inhibitors*

Table 1 summarizes the genes of candidate angiogenesis inhibitors that have been studied recently. In the review published in the *Journal of Translational Medicine*[3], the authors made a thorough account of several candidates. To avoid overlapping of information, we only discuss those candidates that are not covered or recently have demonstrated significant advancement.

**Maspin:** The Maspin gene is a tumor suppressor gene which is under transcriptional control by p35 and DNA methyltransferase inhibitors. Its gene expression level decreases with malignancy and is lost in metastatic cells[17,18]. Transfection of maspin gene to nude mice could reduce the ability of cells to induce tumors and metastasis[19]. Recently, Watanabe *et al*[18] have shown that adeno-associated virus 2-mediated expression of human maspin can efficiently suppress tumor growth by inhibition of angiogenesis in prostate cancer.

**Human ribonuclease inhibitor:** Human ribonuclease inhibitor (hRI) is an acidic protein with a molecular weight of 50 kDa. It can inhibit the activity of pancreatic RNase (RNase A)[20]. It is proposed that hRI inhibits angiogenesis by forming a tight complex with its counterpart angiogenin (Ang) which is an angiogenesis factor[21]. Fu *et al*[20] demonstrated that hematopoietic cells carrying the *ri* gene can effectively inhibit tumor growth (by 47%) and reduce tumor microvessel density in mice. They concluded that hRI has the potential utility as a novel antiangiogenesis agent[20].

**Survivin:** Survivin has been identified as an anti-apoptosis gene over-expressed in cancer and lymphoma[22]. It has been shown that survivin is minimally expressed in endothelium of non-proliferating capillaries of normal skin, whereas it becomes massively up-regulated in newly formed blood vessels of granulation tissue *in vivo*. As a result, manipulation of survivin expression and function in endothelium may influence tumor angiogenesis[23]. Recently, a DNA vaccine targeting survivin and an adeno-associated

viral vector carrying survivin Cys84Ala mutant have been employed to demonstrate the anti-angiogenesis effect on lung tumor and colon cancer cells respectively[24,25].

**Soluble FMS-like tyrosine kinase receptor 1:** Soluble FMS-like tyrosine kinase receptor 1 (sFlt-1) has been identified as a receptor of vascular endothelial growth factor (VEGF)[26]. It functions by sequestering VEGF and forming inactive heterodimers with other membrane-spanning VEGF receptors both in *in vitro* and *in vivo*[26]. Intramuscular injection of recombinant adeno-associated virus (rAAV) vectors carrying the sFlt-1 gene into nude mice can protect against the human ovarian cancer cell line with increased disease-free survival[27].

**Interleukin-12:** In 2004 and 2005, Heinzerling *et al*[28] and Imagawa *et al*[29] showed that direct intratumoral injection of interleukin-12 (IL-12) gene produces a reduction in vessel density or angiogenesis in a murine head and neck cancer model and in patients with metastatic melanoma[28,29]. It is worth noting that a few cytokines, like IL-12, have recently been reported to participate in the regulation of the angiogenic switch[30]. These cytokines are related to inflammation. Whether there are relationships between angiogenesis and inflammation may be an interesting topic among scientists in the future.

**Pigment epithelium-derived factor:** Pigment epithelium-derived factor (PEDF) is a neurotrophic protein and belongs to the serine protease inhibitor (serpin) family[31,32]. It is believed to be a potent inhibitor of angiogenesis[33]. A full-length human PEDF expression vector has been used to transfect the glioma cell line U251, resulting in up-regulation and down-regulation of angiogenesis inhibitors and activators[34].

**Tissue inhibitors of metalloproteinase:** In 2004, adeno-associated virus-mediated gene transfer of tissue inhibitor of metalloproteinase (TIMP) to animal's tumor also showed that it can inhibit vascular tumor growth and angiogenesis[35].

**Angiostatin:** Angiostatin is a 38 kD kringle domain of plasminogen and is the most potent and well characterized body's angiogenesis inhibitor[3]. Recently, the effectiveness of co-administration of the mouse angiostatin kringle and the endostatin genes using cationic liposome has been investigated *in vitro* and *in vivo* by Kim *et al*[36].

**Melanoma differentiation-associated-7 gene or interleukin-24:** Melanoma differentiation-associated-7 (mda-7) gene is a novel melanoma differentiation-associated gene that modulates human melanoma differentiation, growth and progression. It was identified by subtractive hybridization in human melanoma cells by Jiang *et al*[37]. It has been demonstrated that the mda-7 gene functions as a multi-modality anti-cancer agent, possessing both pro-apoptotic and anti-angiogenic properties, and the adenovirus-mediated over-expression of mda-7 gene has the potential therapeutic effects in human lung cancer[38]. More recently, Nishikawa *et al*[39] performed a combination therapy on non-small-cell lung cancer (NSCLC) cell lines and showed that the combination of mda-7 gene therapy and radiotherapy may be a feasible and effective strategy for treatment of NSCLC.

**Fragments of hepatocyte growth factor:** NK4 is the N-terminal hairpin domain and subsequent four-kringle domains of hepatocyte growth factor (HGF). It was reported that HGF possesses anti-angiogenesis property[40]. A latest trial has been done using hydrodynamics-based gene delivery of naked NK4 plasmid into colon cancer cells in mice. HGF can efficiently express NK4, inhibit liver metastasis and subsequent invasive growth of colon cancer and prolong survival of mice[41]. In addition to NK4, recombinant kringle 1 domain of HGF (HGFK1) has been shown to inhibit bovine aortic endothelial cell proliferation stimulated by basic fibroblast growth factor (bFGF) in a dose-dependent manner[42]. These studies present the potency of the fragments of HGF in inhibiting angiogenesis.

**NC1 domains of collagen:** Endostatin (from collagen XVIII), restin (from collagen XV), arrestin (α1 chain of collagen IV) and canstatin (α2 chain of collagen IV) are all NC1 domains as reviewed by Tandle *et al*[3]. Recently it has been shown that vastatin, the NCI domain of collagen VIII (α1) possesses anti-angiogenesis ability in bovine aortic endothelial cells[43]. This provides another promising candidate for caner anti-angiogenesis gene therapy.

**Table 1 Genes of canadidate angiogenesis inhibitors**

| Candidate | Reference(s) |
|---|---|
| 16 kD prolactin fragment[1] | 3 |
| Angiostatin[1] | 3, 36 |
| Arresten[1] | 3 |
| Canstatin[1] | 3 |
| Endostatin[1] | 3 |
| Endothelial-monocyte activating polypeptide-Ⅱ (EMAP-Ⅱ)[1] | 3 |

| Vastatin[1] | 43 |

[1]Candidates that have been covered in Tandle *et al*[3].

## GENE DELIVERY SYSTEMS

The viral vectors used for tumor vascular targeting therapy are summarized in a recent review[44]. Tandle *et al*[3] have also discussed some non-viral gene delivery vectors. Again, we will focus on those newly studied viral vectors showing advancement. Table 2 summarizes the vectors that are

**Table 2 Gene delivery vectors**

| Vector | Brief description | Reference (s) |
|---|---|---|
| Cationic liposomes | Spherical vesicle made of positively charged lipids, efficient uptake of DNA by the cell | 46, 47 |
| Low Voltage Electroporation | Entry of DNA into the cell whose membrane is permeabilized by electric field, efficient gene transfer is ensured | 48, 49 |
| Nanoparticles | Submicron-sized particle with the therapeutic agent situated within the matrix or on the surface | 3, 45 |
| Measles virus | Contains negative strand RNA molecule, can enter tumor cells without the defensive responses of the tumor | 44 |
| Herpes simplex virus | Dobule stranded DNA virus, wide host range, large transgene capacity, long-lasting effect | 3, 44 |
| Lentivirus | Derived from HIV, can achieve stable integration of the gene in non-dividing cells | 3, 44 |
| Retrovirus | Based on murine leukemia virus, foreign cDNA can be incorporated into host cell genome with high efficiency | 3, 44 |
| Replication-competent Retrovirus (RCR) | Modified retroviral vector that can replicate in solid tumor model so the transfer efficiency is enhanced | 55, 56 |
| Semliki Forest Virus (SFV) | One type of alphavirus, modification of its RNA genome yield a new expression vector that transfers transgene into tumor | 50, 51, 52, 53, 54 |
| Recombinant adenovirus (rAdv) | Double stranded DNA virus, can be produced in high titres and deliver transgene efficiently Special engineered adenovirus: oncolytic and gutless | 3, 57, 58, 59, 60, 61, 62, 63, 64 |
| Recombinant adeno-associated virus (rAAV) | Possess the advantages of rAdv and retrovirus, low level of immune response | 3, 25, 65, 66, 67, 68 |

recently used in cancer antiangiogenesis gene therapy.

**Nanoparticles:** Polymeric drug carriers are used to deliver low molecular mass drugs, oligonucleotides and peptides, which has attracted attention in recent years[3]. Due to their small sizes, nanoparticles penetrate into even small capillaries and are taken up by cells that can deliver targeted drugs to cells or tissues[3]. In 2005, Schiffelers *et al*[45] constructed self-assembling nanoparticles with siRNA as a means to target tumor neovasculature expressing integrins and to deliver siRNA which inhibits VEGF-R2 expression and thereby tumor angiogenesis. They pointed out that this mode of delivery overcomes the pharmacological hurdles of local administration of aqueous siRNA for cancer therapy.

**Cationic liposome:** The advantages of using a cationic liposome as a vehicle for drug delivery are the enhancement of delivery and expression of the transfected gene. The positive charge significantly increases the uptake of liposome by the endothelial cells of blood vessels in tumor tissues, which has made the cationic liposome useful for delivering tumor targeted drugs[46]. A recent successful case of angiogenesis inhibition using angiostatin and endostatin genes delivered by a cationic liposome has been reported. In addition, modified liposome targeting membrane type-1 matrix metalloproteinase (MT1-MMP) molecules expressed specifically on angiogenesis endothelium and tumor cells, enhances its binding to and accumulates ECs in tumor compared to unmodified liposome[47].

**Low voltage electroporation:** Electroporation is the formation of pores on the cell surface induced by electric pulse. Direct delivery of plasmid DNA into cells relies on electroporation. *In vivo* electroporation is a novel non-viral means of gene transfer and offers several advantages over viral means such as none of immunogenicity, ease of handling and high gene transfer efficiency[48]. Uesato and co-workers[49] have successfully demonstrated the anti-tumor effect of antiangiogenesis genes, mouse angiostatin and mouse endostatin, delivered to tumors by low-voltage electroporation in 26 models of mouse colon. They have also reported a decrease in microvessel density of tumors[49].

**Semliki forest virus:** A new expression vector system derived from semiliki forest virus (SFV) was introduced in 1994[50]. This system has been utilized in delivering glycoproteins in a recombinant vaccine study[51]. The vector has also been shown to be a candidate medium for human cancer gene therapy[52]. More recently, SFV vector carrying murine IL-12 gene demonstrated by Doppler ultrasonography, could cause B16 tumor regression through anti-angiogenesis[53]. After this, two IL-12 gene subunits cloned from mouse splenocytes and inserted into an enhanced SFV vector (pSFV10-E) could show complete tumor regression in mice[54].

**Replication-competent retroviruses:** Retroviruses are a class of virus which has a genome of a single stranded RNA molecule. Vectors derived from murine leukemia virus, a simple retrovirus, have been used in *in vivo* gene transfer in gene therapy. However, the limited efficiency of replication-defective retrovirus vector is a major obstacle in cancer gene therapy[55]. Logg's group in Los Angeles thus developed a replication-competent retrovirus (RCR) vector derived from murine leukemia virus[55]. This vector is able to replicate and transmit a transgene both in culture and in a solid tumor model *in vivo*. By taking advantages from RCR vectors, Sun *et al*[56] transduced RCR vectors carrying the human interferon-inducible protein-10 (IP-10) gene to tumor cells *in vivo* and *in vitro*, showing sustained production of IP-10 in culture and reduced angiogenesis in mice.

**Recombinant adenovirus:** Adenovirus has a double stranded DNA genome. Recombinant adenovirus (rAdv) vectors containing exogenous genes for *in vivo* transfer derived from adenovirus type 5 are made replication deficient by deletion of the E1 region[57]. rAdv is currently the most widely used gene delivery vector because it

enjoys several advantages like high delivery efficiency into both dividing and non-dividing cells, large ability to package foreign genes, easy to grow to high titers and to be purified, non-oncogenic and high expression of the transgenes[58]. In recent years, phase Ⅰ trials have been undertaken using adenoviral p53 (Adp53) for patients with ovarian cancer[59]. In China, phase Ⅰ and Ⅱ trials using recombinant Adp53 to treat laryngeal cancer (phase Ⅰ), head and neck squamous cell carcinoma (phase Ⅱ) and nasopharyngeal carcinoma (phase Ⅱ) have been undertaken extensively[60-62].

Oncolytic adenovirus is a specially engineered adenovirus which exhibits lytic property of virus replication[63]. This adenoviral system not only offers the advantage of high gene delivery efficiency, but also the ability to select infections of tumor cells[63]. As a result, an amplification effect of the therapeutic gene can be achieved through the lateral spread of the progeny vector[63].

The latest generation of adenoviral vector is the gutless adenovirus. It has become an attractive agent for gene therapy because of the reduction of *in vivo* immune response[64] and long-term sustained expression. However, because of the lack of all viral coding regions, the packaging of this virus requires the presence of helper virus which presents the possibility of contamination[64].

**Recombinant adeno-associated virus:** Recombinant adeno-associated virus (rAAV) has the advantages of broad host range, low level of immune response, and longevity of gene expression that enable the initiation of a number of clinical trials using this gene delivery system[65]. As reviewed recently, there are 8 well-defined serotypes (serotypes 1-5 and 7-9), and more than 100 variants[66]. The underlying mechanism of the selective tissue tropism of different serotypes remains elusive[66]. For anti-angiogenesis cancer gene therapy using rAAV, recent research examples are focusing on treating colon cancer (*in vitro* and *in vivo*), ovarian cancer (*in vivo*) and human glioblastoma (*in vitro*)[25,67,68].

## TUMOR SPECIFICITY AND GENE DELIVERY: LESSONS FROM CLINICAL TRIALS

While previous studies on gene targets are limited to pre-clinical stages, the recombinant proteins of some of these targets have entered clinical trials. Can we learn lessons from the trials to optimize the specificity and efficiency of the candidate gene therapeutics?

Recombinant endostatin is currently the most studied angiogenesis inhibitor in the clinical setting. The earliest phase Ⅰ trials were published in 2002 and 2003[69-72]. However, the results were disappointing. Two very recent reports stated that although the endostatin trials have confirmed the safety of endostatin as a pharmacological agent, it is difficult to establish the biologically effective dose of the recombinant protein[73,74]. To address the problem of effective dose of endostatin, Tjin Tham Sjin *et al*[75] recently demonstrated that adeno-associated viruses carrying canine endostatin can dose-dependently express transgene in the circulation after intramuscular injection in mice. Elevated levels of endostatin remain stable in the circulation for at least 4 mo[75]. Therefore, adeno-associated virus-mediated endostatin gene therapy appears to be a potential therapeutic regime with specific and sustained delivery efficiency.

IL-12 is another widely studied agent with anti-angiogenesis activity in clinical trials. Recombinant human IL-12 protein has entered phase Ⅰ and Ⅱ studies in Germany and United States, respectively[3]. Due to the occurrence of dose-limiting toxicity in some patients, the direction of study has switched to gene therapy approaches[3]. A phase Ⅰ trial involving an adenoviral vector encoding human IL-12 gene has been conducted[76], showing that dose-limited toxicity is significantly increased in tumor infiltration by effector immune cells. Despite the lower anti-tumor power of IL-12 gene therapy in human trials, the concept of stimulation of immune response by specific production of IL-12 inside a tumor is proved[77].

Recently, attention has been paid to combination therapy in which anti-angiogenesis treatment is combined with chemotherapy as well as radiotherapy[78]. Approaches like combination of endostatin and VGFR-2 tyrosine kinase inhibitor and even tri-combination of anti-angiogenesis, chemotherapy and radiotherapy have also been tested[79,80]. Co-targeting of tumor and tumor micro-environment can effectively suppress angiogenesis and tumor growth in the prostate cancer model[81]. A Chinese phase Ⅲ trial using recombinant endostatin in combination with chemotherapy in NSCLC has exhibited a significant increase in response rates and time to progression[73].

Specificity and safety of the vectors are the two main issues that should be addressed in the future. Development of vectors that exhibit superior safety and direct the therapeutic transgene to the right target position of the genome without any random insertion side effects would be a direction for studying human gene therapy against cancer.

## CONCLUSION

Targeting angiogenesis is a promising approach in suppressing tumor growth and metastasis. Due to the need for long term administration of the inhibitors, gene therapy has become an alternative which theoretically ensures a sustained availability of the anti-angiogenesis agents. Up till now, researches on anti-angiogenesis cancer gene therapy remain in pre-clinical stage. It is anticipated that when better vectors are developed and the molecular mechanisms of angiogenesis inhibitors against tumor growth are better understood, clinical trials will be undertaken in the future.

## Abstract

**AIM:** To study the differential gene expression profiles of target cells in primary gastric cancer and its metastatic lymph nodes using laser microdissection (LMD) in combination with cDNA microarray.

**METHODS:** Normal gastric tissue samples from 30 healthy individuals, 36 cancer tissue samples from primary gastric carcinoma and lymph node metastasis tissue samples from 58 patients during gastric cancer resection were obtained using LMD in combination with cDNA microarray independently. After P27-based amplification, aRNA from 36 of 58 patients (group 1) with lymph node metastasis and metastatic tissue specimens from the remaining 22 patients (group 2) were applied to cDNA microarray. Semiquantitative reverse transcriptase polymerase chain reaction (RT-PCR) and immunohistochemical assay verified the results of microarray in group 2 and further identified genes differentially expressed in the progression of gastric cancer.

**RESULTS:** The expression of 10 genes was up-regulated while the expression of 15 genes was down-regulated in 22 gastric carcinoma samples compared with that of genes in the normal controls. The results were confirmed at the level of mRNA and protein, and suggested that four genes (OPCML, RNASE1, YES1 and ACK1) could play a key role in the tumorigenesis and metastasis of gastric cancer. The expression pattern of 3 genes (OPCML, RNASE1 and YES1) was similar to tumor suppressor genes. For example, the expression level of these genes was the highest in normal gastric epithelium, which was decreased in primary carcinoma, and further decreased in metastatic lymph nodes. On the contrary, the expression pattern of gene ACK1 was similar to that of oncogene. Four genes were further identified as differentially expressed genes in the majority of the cases in the progression of gastric cancer.

**CONCLUSION:** LMD in combination with cDNA microarray provides a unique support foe the identification of early expression profiles of differential genes and the expression pattern of 3 genes (OPCML, RNASE1 and YES1) associated with the progression of gastric cancer. Further study is needed to reveal the molecular mechanism of lymph node metastasis in patients with gastric cancer.

**Key words:** Gastric cancer; cDNA microarray; Laser microdissection; Reverse transcriptase polymerase chain reaction; P27

## INTRODUCTION

Gastric cancer is one of the leading causes of cancer death in the world, its clinical behavior depends on the potential metastasis of the tumor, and the prognosis of advanced gastric cancers remains very poor. Until now, several molecules have been reported to play an important role in gastrointestinal tumorigenesis and tumor metastasis[1-3], but the molecular mechanisms involved in tumor development and progression remain unclear in gastric cancer[1-3].

In this study, using the combined methods of laser microdissection (LMD), P27-based RNA amplification, and cDNA microarray, we evaluated the differentially expressed genes in primary carcinoma cells and lymph node metastatic cells in 36 of 58 patients. Moreover, we further identified four differentially expressed genes in the remaining 22 patients with progression of gastric cancer by semiquantitative reverse transcriptase polymerase chain reaction (RT-PCR), and the expression patterns of these

four genes were similar to those of tumor suppressor genes or oncogenes.

It has been widely accepted that many malignant tumors contain heterogeneous subpopulations of cells. This heterogeneity exhibits a wide range of genetic, biochemical and immunologic characteristics. It is likely that specific tumor cells or colonies within larger heterogeneous tumor specimens are the forerunners of distant metastases[4]. Therefore, many biologic differences exist in tumor cells of primary carcinoma and metastatic lesions. Furthermore, interaction of tumor cells with their living environment may add more differences to these tumor cells[5]. As a result, tumor metastasis-related genes can be identified by comparing their gene expression profiles.

LMD and cDNA microarray are two of the new emerging techniques in the post-genomic era. LMD is an innovative technique which offers researchers a simple, reliable, rapid and accurate tool for precise and contamination-free procurement of cell groups from tissue sections under direct visualization[6,7].

Large-scale analysis of gene expression with cDNA microarray allows us to evaluate the gene-expression profiles of hundreds to tens of thousands of genes in a single experiment[8]. This techniques is a powerful tool for analyzing the expression of genes which may be correlated with pathological phenotypes of various diseases. However, the expression profile of a specific cell type may be primarily masked or even lost because of the bulky surrounding cells. Therefore, LMD in combination with cDNA microarray can provide a unique opportunity to study gene expression of subpopulations of cells in their native tissue environment *in vivo*.

## MATERIALS AND METHODS

### Patients with gastric cancer and their pathological samples

Fifty-eight advanced gastric adenocarcinoma (TNM stage Ⅲ-Ⅳ) patients with lymph node metastasis diagnosed by postoperative pathology were investigated in this study. There were 30 male and 28 female patients, whose ages ranged from 45 to 68 years with an average age of 58.7 ± 3.46 years (Table 1). Histologically, 38 patients had moderately differentiated adenocarcinoma and 20 had poorly differentiated adenocarcinoma. All patients underwent gastrectomy with regional lymph nodes dissected and informed consent to participate in this study was obtained from each patient. Tissue blocks of normal gastric epithelium (> 5 cm away from the edge of the tumor), primary tumors and corresponding metastatic lymph nodes were obtained within 30 min after removal from the patient. Each block was cut into 2 pieces, one for routine pathologic diagnosis, and the other for molecular analysis. The latter samples were frozen in liquid nitrogen immediately and stored at -260℃ until use.

**Table 1 Characteristics of the studied patients ($n$ = 58)**

| Characteristics | $n$ (%) |
|---|---|
| Age (yr) | |
| Range | 48-68 |
| mean ± SD | 58.7 ± 3.46 |
| Median | 59 |
| Mode | 59 |
| Gender | |
| Male | 30 (52) |
| Female | 28 (48) |
| Tumor location | |
| Gastric antrum | 38 (66) |
| Gastric body | 10 (17) |
| Gastric cardia | 10 (17) |
| Anemia | |
| Yes | 48 (83) |
| No | 10 (17) |
| Abdominal pain | |
