## Abstract

Primary biliary cirrhosis (PBC) is an autoimmune disease of the liver characterized by progressive bile duct destruction eventually leading to cirrhosis and liver failure. The serological hallmark of the disease is the presence of circulating antimitochondrial antibodies (AMA). These reflect the presence of autoreactive T and B cells to the culprit antigens, the E2 subunits of mitochondrial 2-oxo-acid dehydrogenase enzymes, chiefly pyruvate dehydrogenase (PDC-E2). The disease results from a combination of genetic and environmental risk factors. Genetic predisposition is indicated by the higher familial incidence of the disease particularly among siblings and the high concordance rate among monozygotic twins. Environmental triggering events appear crucial to disrupt a pre-existing unstable immune tolerance of genetic origin allowing, after a long latency, the emergence of clinical disease. Initiating mimotopes of the vulnerable epitope of the PDC-E2 autoantigen can be derived from microbes that utilize the PDC enzyme or, alternatively, environmental xenobiotics/chemical compounds that modify the structure of native proteins to make them immunogenic. A further alternative as a source of antigen is PDC-E2 derived from apoptotic cells. In the effector phase the biliary ductular cell, by reason of its

## INTRODUCTION

Primary biliary cirrhosis (PBC) is a chronic cholestatic liver disease of autoimmune origin characterized by a striking female predominance, high titer serum anti-mitochondrial autoantibodies (AMA), disease-specific antinuclear autoantibodies (ANAs), and an autoimmune-mediated destruction of the small and medium size intrahepatic bile ducts<sup>[1]</sup>. PBC is a peculiar, yet representative, organ-specific autoimmune disease. The presence of serum AMA and autoreactive T and B cells, in conjunction with the co-occurrence of other autoimmune diseases, all point to an autoimmune pathogenesis for PBC. Although most patients with PBC have AMA against the E2 subunit of the mitochondrial pyruvate dehydrogenase complex (PDC), there is no direct correlation between the titer of AMAs and disease severity. However, certain disease-specific antinuclear antibodies (ANAs) are present in about one third of patients and these carry a risk for more severe and progressive disease<sup>[2]</sup>.

A multifactorial genetic background is suggested by a higher incidence of the disease among first-degree relatives<sup>[3]</sup>, by the high concordance rate among monozygotic twins<sup>[4]</sup>, and by an apparent role for X chromosome defects in PBC, based on the observation that women with PBC have preferential loss of one X chromosome

in peripheral white blood cells<sup>[5,6]</sup>. A vital question in the pathogenesis of PBC is why biliary epithelial cells (BEC) in particular are the primary target of pathology despite the ubiquitous presence of the PDC autoantigen in all tissue cells. Recent studies suggest that enhanced apoptosis in BEC is a critical step in ductular destruction in PBC<sup>[7,8]</sup>, and some clues exist on mechanisms by which apoptosis in BECs cause the tissue-specific autoimmune reactivity characteristic of PBC.

## GENETICS IN PBC

It is currently accepted that PBC pathogenesis is multifactorial, with genetic and environmental factors interplaying to determine disease onset and progression. Although the etiology of PBC remains enigmatic, there are several items of data indicating that genetic predisposition contributes strongly to the overall pathogenesis of PBC. The lines of evidence are these: (1) Data from monozygotic twins indicate that the concordance rate of PBC in monozygotic twins is 63%<sup>[4]</sup>, among the highest reported for autoimmunity; (2) Approximately 6% of patients with PBC have a first-degree relative that also suffers from PBC<sup>[3]</sup>; (3) There is a high female:male disease incidence ratio (8:1), with suggestions of a significant role for X chromosome defects in PBC, based on the observation that women with PBC have a significantly enhanced monosomy X frequency in peripheral white blood cells compared to age-matched healthy women<sup>[5]</sup> and that the X chromosome loss is preferential<sup>[6]</sup>. Interestingly, similar genetic defects were also found in women with systemic sclerosis and autoimmune thyroid disease<sup>[9]</sup>, but not with systemic lupus erythematosus<sup>[10]</sup>. Future studies should assess whether haploinsufficiency for specific X-linked genes may lead to loss of tolerance; (4) PBC is exceptional among autoimmune diseases in having controversially variable associations with alleles of the major histocompatibility complex (MHC, HLA); only a weak and regional association with HLA *DRB1\*08* has been widely confirmed<sup>[11]</sup>, although there is growing evidence on a protective association with HLA *DRB1\*11* and *\*13*<sup>[12,13]</sup>.

Several association studies have attempted to identify gene loci associated with PBC but no family study of genetic linkage has been performed. Associations are often not applicable to all populations but available evidence suggests that a “multi-hit” genetic model might apply to PBC, with different genetic variants conferring initial susceptibility, and others influencing subsequent disease progression. Genetic influences operative in PBC may reflect mutations transmitted through germline genes, or conceivably, somatic mutations in hemopoietic precursor cells<sup>[14]</sup>.

In summary, a susceptible genetic background is considered to be necessary, but is not sufficient to explain either PBC onset or the strong female predominance<sup>[15]</sup>. Thus several environmental factors have been invoked as additional elements in tolerance breakdown.

## ENVIRONMENTAL FACTORS

Bacterial infection in various settings has been repeatedly invoked in the etiopathogenesis of PBC. This etiology is usually linked to the concept of molecular (epitope) mimicry. The cross-reactivity of AMA with prokaryotic antigens has been reported for a number of microbes. This cross-reactivity is not particularly surprising given the conserved sequence of PDC-E2 across all species, from eubacteria to mammals.

We provided experimental evidence suggesting that *Novosphingobium aromaticivorans*, a ubiquitous xenobiotic-metabolizing Gram-negative bacterium, is the best microbial candidate yet for the induction of PBC<sup>[16,17]</sup>. Briefly, we can extrapolate theories on microbial molecular mimicry in PBC as follows. The microbial motif CpG enhances IgM production in peripheral blood mononuclear cell cultures, with CD27+ memory B cells in PBC patients being responsible for this IgM production through Toll-like receptor (TLR) 9 signaling. Also, CpG can stimulate AMA production and expression of TLR9, CD86, and one of the potassium channels, KCa3.1, in B cells of PBC patients. Moreover upregulated expression of TLR9 and CD86, and AMA secretion induced by CpG, can be suppressed by a specific blocker of the KCa3.1 channel, namely TRAM. These data indicate that B-cell immunity of PBC patients depends on an enhanced innate immune response and imply that TRAM-34 can influence B-cell autoimmunity in PBC<sup>[18]</sup>.

Another source of antigenic mimicry is xenobiotics. These are foreign compounds that may either alter or complex to defined self or non-self proteins, inducing a change in the molecular structure of the native protein sufficient to induce an immune response<sup>[19]</sup>. Such immune responses may then result in the cross-recognition of the self molecule, which could in turn perpetuate the immune response, thus leading to chronic autoimmunity. Interestingly, most xenobiotics are metabolized in the liver, thereby increasing the potential for liver-specific alteration of proteins. Recent data demonstrate that certain chemical/xenobiotic compounds can induce AMA and are in fact recognized by PBC sera with higher affinity compared to the analogous self protein and that such compounds are found in products in common use as food flavorings and cosmetics<sup>[20-23]</sup>. This implicit involvement of cosmetics could contribute to the female predisposition to PBC.

## ROLE OF BEC

PBC is characterized by destruction of the small and medium size intrahepatic bile ducts, lined by BECs (cholangiocytes). BECs express cell surface adhesion molecules which permit adhesion and recognition of lymphocytes. Moreover, several studies have demonstrated that BECs of both healthy and diseased liver have the capacity to increase the expression of adhesion molecules, ICAM-1 and others, MHC class I and II, TNF-alpha, interferon (IFN) -gamma

and IL-1<sup>[24-26]</sup> upon stimulation with proinflammatory cytokines<sup>[27]</sup>. Up-regulation of VCAM-1 and LFA-1 can also be identified<sup>[28]</sup>. Adhesion molecules expressed on the BEC surface, and the up-regulation by proinflammatory cytokines, which are abundant in the course of inflammatory reactions, allow BECs to modulate the intensity and localization of inflammatory reactions. The other immune feature attributed to the BECs is a capacity to act as APCs. Several studies demonstrate that BECs express HLA class II<sup>[27,29]</sup>, and such expression is increased after injury and after stimulation with IFN- $\gamma$  and IL-1. BECs also express accessory molecules responsible for the second (co-stimulatory) signal to T cells, CD80, 86 (B7-1, B7-2)<sup>[30]</sup>. These interactions with T cells might also be responsible for bile duct loss, one of the fundamental characteristics of progression of disease.

Data obtained in recent years point towards apoptosis as a leading mechanism for ductopenia. Years ago, Harada and colleagues demonstrated susceptibility to apoptosis via the perforin/granzyme B pathway, and this was enhanced by interaction of CD95 (Fas) with CD178 (FasL) in BECs of patients with PBC<sup>[31]</sup>. The hypothesis was further confirmed when apoptotic BECs were shown to express CD40, and Fas and FasL, with transcriptional up regulation of the latter molecules after stimulation with CD154 (CD40L), culminating in apoptosis<sup>[32]</sup>. Odin and colleagues discovered that glutathiolation of the lysine-lipoic acid moiety of PDC-E2 was dramatically reduced by serum AMA<sup>[33]</sup>. Recently it has been demonstrated that apoptotic cells are phagocytosed by BECs and consequently could be an endogenous source of autoantigens from BECs<sup>[34-36]</sup>. Importantly, these findings support the concept that

tissue specific damage in PBC is due to cell type-specific differences in apoptosis, and phagocytosis of apoptotic cells.

Antigenicity of BEC self-molecules, or highly homologous epitopes, could also be related to their role in mucosal immunity. Like other epithelial cells, BECs actively transfer IgAs, and in PBC these IgAs have specificity for PDC-E2. These specific IgA-type AMA can be detected in almost all body fluids of patients with PBC, including saliva, urine and bile<sup>[37,38]</sup>. Further, Fukushima and colleagues<sup>[39]</sup> detected deposits representing co-localization of such antibodies with PDC-E2 (or a highly homologous molecule) at the apical surface and in the cytoplasm of BECs, and also detected their presence in liver allografts in patients with recurrent PBC after receiving a liver transplant. To assess the direct pathogenicity of the IgA antibody class, Matsumura and colleagues exposed canine kidney cells transfected with the human polymeric Ig receptor to highly purified AMA-IgAs, thereby inducing caspase up-regulation, and thus providing evidence for direct toxic effects<sup>[40]</sup>. The immunogenic characteristics of BECs in PBC are summarized in Table 1. Finally, the still unknown role of autophagy in autoimmunity could in the future provide interesting data for the pathogenesis of PBC<sup>[41]</sup>.

## B CELLS AND AUTOANTIBODIES

As mentioned, the presence of serum AMA and autoreactive B cells strongly endorses the concept of an autoimmune pathogenesis of PBC<sup>[42-44]</sup>.

AMA is highly specific for PBC and can be detected in nearly 100% of patients, when sensitive diagnostic methodologies based on recombinant antigens are used<sup>[45]</sup>. They are directed against members of the 2-oxoacid dehydrogenase complexes (2-OADC) existing in the inner membrane of mitochondria. Among them, the major autoantigen is the E2 subunit of the pyruvate dehydrogenase complex (PDC-E2). The epitopes for this antibody to the E-2 subunit localize to three domains of PDC-E2 component: (1) the inner (and outer) lipoic acid (lipoyl) domains; (2) the E3 binding domain; and (3) the catalytic and E2-binding domain<sup>[46]</sup>. Reactivity at lower frequency is also found against other 2-oxoacid dehydrogenase complexes (2-OADC), the 2-oxo glutarate dehydrogenase (OGDC-E2) and the branched-chain 2-oxo acid dehydrogenase (BCOADC-E2), involved respectively in the citric acid cycle and in amino acid catabolism. The 2-OADC autoantigens in PBC are summarized in Table 2.

Although the E-2 subunits of the three E-2 subunits are structurally similar, immunochemical studies have shown that the reactivities are independent, and do not depend on cross-reactivities, at least at the antibody level<sup>[47]</sup>. Antibodies to PDC-E2 and to the other 2-OADC enzymes are capable of inhibiting PDC-E2 enzyme activity *in vitro*, but this has not been shown to occur *in vivo*. Targeting of enzymes is a common feature of autoantibodies detected in patients with autoimmune

**Table 2 Mitochondrial and nuclear autoantigens in PBC**

Autoantigens		
Mitochondrial antigens	E2 subunits of 2-OADC	PDC-E2

		BCOADC-E2
		E3BP
Nuclear antigens	Pyruvate dehydrogenase complex	PDC E1 $\alpha$
	Nuclear pore complex	gp210
		nucleoporin 62
	Multiple nuclear dots	Sp100
	Anticentromere	PML

2-OADC: 2-oxo-acid dehydrogenase complex; PDC: Pyruvate dehydrogenase complex; OGDC: Oxoglutarate dehydrogenase complex; BCOADC: Branched chain 2-oxo-acid dehydrogenase complex; E3BP: Dihyrolipoamide dehydrogenase (E3)-binding protein.

diseases, as is the inhibition of their activity by these autoantibodies. A pathogenic role for AMA is uncertain, since no clinical correlations with levels of AMA can be found, and in certain experimental animal models there is occurrence of serum AMA but no overt PBC-like liver lesions<sup>[14]</sup>. The role of the lipoic acid co-factor attached to lysine<sub>173</sub> (K<sub>173</sub>) in the composition of the epitope recognized by AMA is unclear. Both lipoylated and non-lipoylated PBC-E2 react with AMA and the question is to what degree does lipoic acid serve to enhance antigenicity.

In addition to AMA, PBC sera can present other disease-specific autoantibodies, particularly anti-nuclear (ANA) specificities<sup>[2]</sup>. PBC-specific ANA reactants include nuclear pore glycoproteins of the inner nuclear membrane, gp210<sup>[48]</sup> and p62<sup>[49]</sup>, with a detection rate up to about 30% and with an apparently higher prevalence among AMA-negative PBC. This subtype of PBC-specific ANA has been shown to correlate with disease severity and progression<sup>[50,51]</sup>. Other PBC-specific nucleoprotein reactants include the Sp100-promyelocytic leukemia (PML) autoantigen antigen that gives the characteristic fine nuclear dot pattern by immunofluorescence<sup>[52]</sup>; both appear specific for PBC, but the prevalence differs, being from about 20% to 30%. Finally anti-centromere antibodies occur in PBC (~10% of cases) often in association with a limited scleroderma syndrome. Recently, it has been demonstrated that anti-centromere antibodies were a significant predictive factor in PBC for the development of portal hypertension<sup>[51,53]</sup>. Table 2 specifies the nuclear autoantigens in PBC.

There seems no way of incorporating the co-occurrence of AMA and ANA into a unifying theory of pathogenesis of PBC, other than specifying both reactivities as reflecting a systemic failure of maintenance of immune tolerance.

## T CELLS

Autoreactive CD4<sup>+</sup> and CD8<sup>+</sup> T cells are demonstrably involved in the pathogenesis of PBC and, histologically, infiltration of presumably autoreactive T cells in the liver

and periductular spaces is one of the major features of the disease<sup>[54,55]</sup>. Both CD4<sup>+</sup> and CD8<sup>+</sup> T lymphocytes can be purified from biopsy samples of PBC patients and both subsets recognize epitopes of PDC-E2<sup>[56]</sup>; moreover, using recombinant fragments of PDC-E2 it has been demonstrated that there is a sequence overlap in the PDC-E2 specific T and B cell epitopes<sup>[57]</sup>. The minimal T-cell epitope for CD4<sup>+</sup> T cells was identified as amino acid residues 163 to 176 (GDLLAEIETDKATI), within the inner lipoyl domain of PDC-E2<sup>[57]</sup>. Phenotypically, the PDC-E2<sub>163-176</sub> T-cell clones were positive for CD4, CD45RO, and T cell receptor (TCR)  $\alpha\beta$ . The MHC Class II human leukocyte antigen (HLA) -restriction molecules for this epitope have been identified as HLA-DR53 (B4\*0101)<sup>[58]</sup>. In addition, PDC-E2<sub>163-176</sub>-specific CD4<sup>+</sup> T-cell clones recognize other functionally related mitochondrial autoantigens, including OGDC-E2 and BCOADC-E2, and also E3BP<sup>[59]</sup>. More specifically, these T-cell clones were cross-reactive with the amino acid residues 100 to 113 of OGDC-E2, residues 90 to 103 of BCOADC-E2, and residues 34 to 47 of E3BP, all located in the respective E2-lipoyl domain of these enzymes; thus the suggestion is that OGDC-E2<sub>100-113</sub>, BCOADC-E2<sub>90-103</sub>, and E3BP<sub>34-47</sub> all represent CD4<sup>+</sup> T-cell epitopes.

CD8<sup>+</sup> T cells (CTLs) from peripheral blood of patients with PBC have been studied in the context of MHC Class I HLA-A2.1 restriction, and have been found to identify amino-acid residues 159-167 and 165-174 of PDC-E2<sup>[57]</sup>. Specific MHC class I restricted CTLs can also be generated by *in vitro* stimulation with antigen pulsed dendritic cells<sup>[60]</sup> from blood of patients with PBC, but not from healthy controls, indicative of the presence in PBC of specific precursors of PDC-E2 -reactive T cell clones in peripheral blood. Interestingly, there was a greater increase in numbers of CTL precursors in blood in early *versus* advanced stages of PBC, and in the same study there was a 10 -fold increase in specific CTLs in the liver compared to the peripheral blood, supporting the role of these cells and their specific recruitment in the evolution of bile duct injury in PBC. Thus the two major subsets of T cells recognize the same or very close amino acid sequences within the same epitope regions in the lipoyl domain, thus supporting the hypothesis of a common etiological trigger mechanism, potentially molecular mimicry, associated with other particular immune modifications.

Coming now to CD4<sup>+</sup>CD25<sup>high</sup> natural regulatory T cells (Tregs), a decreased reactivity appears to contribute to a number of human autoimmune diseases<sup>[61-65]</sup> including PBC. A relative reduction of Tregs compared with healthy controls was detected and, as well, the ratio of hepatic Tregs over hepatic CD8<sup>+</sup> cells in PBC patients was lower than that in patients with chronic hepatitis C or autoimmune hepatitis<sup>[66,67]</sup>.

## INNATE IMMUNITY IN PBC

Innate immunity is a first line of defense against

infections and neoplasms, but its importance for adaptive immunity has been appreciated only recently, and its role in the induction of autoimmunity is only partially known<sup>[68]</sup>. The cellular components of innate immunity, including dendritic cells (DC) and other professional APCs<sup>[69]</sup>, and natural killer T cells (NKT), are known to have a regulatory function by modulating the quality and quantity of subsequent adaptive immune responses, including antigen-specific antibody and T cell responses. Innate immunity in PBC patients is characterized by an increased response to pathogen-associated stimuli, as indicated by higher levels of pro-inflammatory cytokines secreted *in vitro* by monocytes after exposure to micro-organisms<sup>[70]</sup>.

NK/NKT cells have been linked to autoimmune diseases in murine models, including autoimmune diabetes in NOD mice and experimental autoimmune encephalomyelitis, a model of multiple sclerosis<sup>[71]</sup>, and the role of such cells in autoimmunity in general is attracting increasing attention. In PBC, Chuang and colleagues recently demonstrated a marked increase in the frequency and absolute number in blood and liver of NK cells. Moreover, in the same study, the cytotoxic activity and perforin expression by isolated NK cells were significantly increased, associated with increased levels of plasma IL-8 and the expression of CD128a (IL-8 receptor) on such cells. In contrast, the levels of IFN- $\gamma$ , IL-6 and IL-8 synthesized by NK cells were significantly decreased in PBC compared to controls<sup>[72]</sup>.

Hyper-responsiveness of the innate immune system of itself would be insufficient to account for the breakdown of natural immune tolerance, but these alterations might come to influence the initiation and perpetuation of the subsequent adaptive autoimmune response.

## CYTOKINES

In PBC, a Th1 cytokine predominance has been reported in serum and liver<sup>[73]</sup>, and a high prevalence of INF- $\gamma$ , a Th1 cytokine, has been detected as a transcriptional up-regulation<sup>[74]</sup>. Moreover, BECs of patients with PBC overexpress TNF- $\alpha$  and the corresponding receptor, thus favoring the idea of a paracrine activity of, and effect on these cells, leading to their proliferation and, potentially, to apoptosis<sup>[75]</sup>. Recent findings further suggest the involvement of cytokine-cytokine receptor interactions in the effector stages of the pathogenesis of PBC<sup>[72]</sup>. Whilst T cells and NKT cells are major sources of cytokines, B cells, endothelial cells, macrophages and other cell types also contribute to cytokine production. Furthermore, different types of APC, genetic background, availability of costimulator molecules, and types and amounts of antigenic stimuli may also influence the differentiation of Th0 cells into either the Th1 or Th2 cell pathways, each with their particular cytokine profiles. Of course, cytokines also come into play in the earlier inductive stages of PBC, in particular transforming growth factor-beta (TGF- $\beta$ ). Deficiency of TGF- $\beta$  is

prejudicial to immunoregulatory functions, as illustrated by recent mouse models of PBC (see below).

## ANIMAL MODELS

The occurrence of a spontaneous animal model would be extremely helpful in elucidating causation and progression of PBC, but none has been identified, and there is some element of "artificiality" with induced models. However, recently, there have been developed three informative genetically manipulated mouse strains that simulate features of human PBC<sup>[76]</sup>.

The first of these mouse models is a congenic variant of the non-obese diabetic (NOD) mouse designated NOD.c3c4 that presents as an autoimmune larger bile duct cholangiopathy and PBC-like serology, with AMA positivity of 50%-60% and ANA positivity of 80%-90%<sup>[77]</sup>. Histologically, there is lymphocytic infiltration within portal tracts with appearances of chronic nonsuppurative destructive cholangitis and epithelioid granuloma formation, although certain features of the bile duct lesions differ from those in human PBC, particularly the occurrence of cystic changes<sup>[77]</sup>. Detailed analysis of the introgressed genetic intervals that determine the autoimmune switch from pancreatic insulinitis to cholangitis is awaited.

The second of the mouse models was derived by transgenic introduction of a dominant negative form of TGF- $\beta$  receptor II (dnTGF- $\beta$ R II)<sup>[78]</sup>. These mice have inflammatory cholangitis and show 100% AMA positivity against PDC-E2. TGF- $\beta$  receptor II is essential for signal transduction of TGF- $\beta$ , which regulates activation of lymphocytes. This model suggests a specific dysfunction of T cells with impaired TGF- $\beta$  signaling which, in the presence or absence of B cells, is implicated in the pathogenesis of a PBC-like disease, at least in mice<sup>[78]</sup>. Interestingly, it has been demonstrated that CD1d-restricted NKT cells in these mice are a critical factor in liver injury<sup>[79]</sup>.

The third of the mouse models depends on knockout of the gene for the IL-2 receptor (IL-2R $\alpha$  knockout mouse)<sup>[54]</sup>. These mice have inflammatory cholangitis with lymphocyte infiltration around the portal tracts accompanied by cholangiocyte injury, and show 100% AMA positivity against PDC-E2 and 80% ANA positivity. The IL-2R $\alpha$  is the CD25 molecule which, when highly expressed on CD4<sup>+</sup> T cells, is a marker for cells with immunoregulatory activity. This model further implicates deficiency of TGF- $\beta$ -dependent regulatory pathways in the pathogenesis of PBC.

Another useful model has been developed by experimental immunization with xenobiotically modified molecular variants of the PDC-E2 epitope region. Such immunization appears promising in that AMA have thus been elicited in different animal species, rabbits, guinea pigs and mice, as recently reviewed<sup>[14]</sup>.

## PATHOGENIC MECHANISMS

Several theories have been proposed for the

**Figure 1** Model of pathogenic mechanisms in primary biliary cirrhosis (PBC). PBC is initiated by an autoantigenic stimulus (upper, right) provided either by a bacterial mimic of the autoepitope of PDC-E2, a xenobiotically modified PDC-E2, or “spillage” of native mitochondrial autoantigens derived perhaps from apoptotic cells. Hyper-responsiveness of innate immunity (top, centre) can facilitate autoantigenicity; bacterial CpG enhances IgM production and cellular expression of TLR9. Genetic susceptibility is critical overall, and depends particularly on multiple inherited deficits in immune tolerance, mostly as yet undefined. APCs that become activated (lower, right) by stimulation through TLRs present immunogenic self peptides (or mimics) via MHC Class II molecules to autoreactive CD4<sup>+</sup> T lymphocytes (centre) which in turn activate CD8<sup>+</sup> cytotoxic T lymphocytes and B lymphocytes that produce AMA. Treg lymphocytes (lower, centre) that normally restrain activated autoreactive T cells are deficient in PBC, thus further impeding T cell tolerance. Effector mechanisms converge on the target cell in PBC, the BEC (lower left), which can be damaged by injurious cytokines (IFN- $\gamma$ ) from CD4<sup>+</sup> T cells, direct cytotoxicity (Fas-L, perforin, granzyme B) from CD8<sup>+</sup> T cells, or transcytosis of IgA-AMA. A toxic effect might even be supplied by activated eosinophils (centre, left) by release of eosinophil MBP. BECs thus undergo apoptosis and in doing so contribute immunogenic mitochondrial PDC-E2 autoantigen to sustain a self-perpetuating autoimmunization process and, by reason of a BEC-specific anomaly of apoptosis retain PBC-E2 intact in apoptotic blebs (see text), so conferring particular vulnerability on these cells. Ags: Antigens; AMA: Antimitochondrial antibodies; ANA: Antinuclear antibodies; APC: Antigen-presenting cell; BEC: Biliary epithelial cells; CTL: Cytotoxic T lymphocytes; ICs: Immune complexes; IL: Interleukin; IFN: Interferon; IP-10: Interferon- $\gamma$ -inducible protein 10; LTA: Lipoteichoic acid; LPS: Lipopolysaccharide; MIG: Monokine induced by  $\gamma$ -interferon; MBP: Major basic protein (primary cytotoxic granule protein); NKT: Natural killer T cells; PDC-E2: Pyruvate dehydrogenase complex E2; TGF: Transforming growth factor; TLR: Toll-like receptor; Treg: Regulatory T cells.

etiopathogenesis of the immune-mediated tissue injury observed in PBC (Figure 1). Such theories are not necessarily independent, but rather each may be directed to different phases of etiopathogenesis. In other words, we need to consider processes particular to initiation; processes particular to perpetuation, notably deficiencies in immune tolerance; and processes particular to the selective destruction of BECs, with the assumption that these express the target of the disease in an accessible form, namely the AMA autoantigen PDC-E2.

### Initiation

Initiation has been considered already and possibilities include microbial infection or chemical-xenobiotic modification of the PDC-E2 epitope sequence with tolerance-breaking effects due to molecular mimicry. Alternatively mere spillage of autoantigen after cellular injury and apoptosis could suffice, as shown recently in our laboratory<sup>[80]</sup>.

### Perpetuation

Perpetuation involves particular consideration of genetically-based tolerance deficits in PBC, and here more data are sorely needed. Consideration was given to this aspect in a recent review from this laboratory<sup>[14]</sup>. We can refer here to studies on the critical role of CD4<sup>+</sup> CD25<sup>high</sup> regulatory T cells (Tregs) in the prevention of autoimmune disease in murine models. It is postulated that Tregs are important for the prevention of autoimmunity and maintenance of self-tolerance, and studies have demonstrated that the transfer of T cells lacking the Treg subset into athymic nude mice results in the development of various T cell-mediated autoimmune diseases<sup>[61,81]</sup>. PBC patients display significantly lower frequencies of Tregs as percentages of total TCR- $\alpha\beta^+$ /CD4<sup>+</sup> T cells, which may contribute to the failure in tolerance in PBC<sup>[66,82,83]</sup>.

### Destruction

Destruction involves a multilineage attack by CD4<sup>+</sup> and CD8<sup>+</sup> T cells, and B cells, on the vulnerable biliary

ductile, and here our hypothesis would state that the immunodominant AMA autoantigen PDC-E2, which is normally located in the mitochondrial inner membrane, is aberrantly expressed on the cell surface of the BEC and thus is immunologically recognized. Several possibilities have been visualized. First, although *in situ* hybridization studies of *PDC-E2* mRNA showed no significant difference in the amount of PDC-E2 transcript present in PBC liver compared with other liver diseases, PDC-E2 may be selectively overexpressed in small bile duct BECs perhaps as a result of aberrations of apoptosis<sup>[14]</sup>. Second, variants of PDC-E2 may cause an abnormal turnover of the molecule, leading to the accumulation of PDC-E2 in these subpopulations of cells. It is possible that toxic substances disposed of by the liver may accumulate in the biliary epithelium and potentially modify the PDC-E2 molecule locally, leading to the production of such variants. Third, altered *PDC-E2* mRNA could be produced by the abnormal transcription of PDC-E2. For example, it is possible that abnormal splicing during synthesis of *PDC-E2* mRNA would substitute an endoplasmic reticulum targeting signal instead of a mitochondrial targeting signal, thereby enabling PDC-E2 to be delivered into the endoplasmic reticulum and Golgi apparatus via a secretory route to be expressed on the cell surface of biliary ducts, instead of into mitochondria. Although direct evidence supporting these mechanisms is currently lacking, it remains possible that the molecules that are expressed and identified on the ductular surface of BECs, and recognized by anti-PDC-E2 antibodies, may not be PDC-E2 itself, but are PDC-E2 mimics that cross-react with human PDC-E2. Some experimental data seem to support this hypothesis.

Another hypothesis that might explain the selective targeting of bile ducts in PBC is that the autoantigen-specific immunoglobulin A (IgA) antibody plays a role. IgA is the principal isotype of immunoglobulin in epithelial surfaces, including biliary epithelium. If AMA-IgA autoantibodies are responsible for the specific destruction of BECs in PBC, it is possible that this occurs by disrupting cell metabolism of the cells i.e. the AMA-IgA bound to the mitochondrial antigen induces cellular dysfunction and so accounts for the tissue specificity. Interestingly, IgA from PBC patients colocalized with PDC-E2 inside the cells and on the apical membrane of BECs<sup>[84]</sup>. These data support the idea that both the aberrant polar expression of PDC-E2 and the trafficking of IgA in BEC are possible mechanisms for selective damage of BECs. Thus, the apical staining of BECs revealed by anti-PDC-E2 monoclonal antibodies could also be accounted for by the presence of an immune complex formed from secreted IgA and mitochondrial enzyme autoantigens.

## CONCLUSIONS AND FUTURE PERSPECTIVES

There have been many substantial advances in the understanding of PBC since the molecular identification

in 1988 of PDC-E2 as the major reactant for characteristic AMA response. Possible initiators of PBC have emerged as environmental chemical xenobiotics, or microorganisms that utilize the shared culprit autoantigen PDC-E2. Strong genetic predisposition is certain from case study data, noting here the female predisposition and family clustering, but formal genome wide studies are not yet available. It is highly likely that multiple deficits in immune tolerance will prove important, and that these will be genetically based; recent mouse models are certainly pointing in this direction. Other unexplained features of PBC include susceptibility to infections, likely associated with the aberrant humoral and cellular reactivities<sup>[85,86]</sup>. It is crucial to ascertain whether there is a pathogenic role of AMA in the bile duct damage of PBC and, if so, how this is mediated. Further investigation of innate immune mechanisms in PBC is called for, as is the role of the BEC itself in stimulation and perpetuation of the peribiliary inflammatory process.

It is almost a truism that only knowledge of the etiopathogenetic mechanisms will open the door to effective therapies for diseases such as PBC<sup>[87]</sup>, yet the major advance in the therapy of PBC with UDCA<sup>[88]</sup> has come without insight into primary causes of the disease, just as successful biotherapies of rheumatoid arthritis have emerged without knowledge of the primary cause of that disease. Currently, we should press on with development and study of animal models, encourage the application of predictably informative genomic studies, and seize on the clues we have to environmental provocations.

At the practical level, clinicians should be alert to the need for early diagnosis, during the long latent period of the disease, in the susceptible middle-aged female population to ensure that such subjects do gain benefit from disease-retarding therapy, at whatever stage their disease may be<sup>[88]</sup>. To a degree, this is already happening if we compare what PBC was like 20 years ago<sup>[89]</sup> to what it is today<sup>[90]</sup>.

## Abstract

Primary sclerosing cholangitis is a chronic cholestatic liver disease characterized by inflammation and fibrosis of the bile ducts, resulting in cirrhosis and need for liver transplantation and reduced life expectancy. The majority of cases occur in young and middle-aged men, often in association with inflammatory bowel disease. The etiology of primary sclerosing cholangitis includes immune-mediated components and elements of undefined nature. No effective medical therapy has been identified. The multiple complications of primary sclerosing cholangitis include metabolic bone disease, dominant strictures, bacterial cholangitis, and malignancy, particularly cholangiocarcinoma, which is the most lethal complication of primary sclerosing cholangitis. Liver transplantation is currently the only life-extending therapeutic alternative for patients with end-stage disease, although recurrence in the allografted liver has been described. A PSC-like variant attracting attention is cholangitis marked by raised levels of the immunoglobulin G4 subclass, prominence of plasma cells within the lesions, and steroid responsiveness.

## INTRODUCTION

Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease characterized by fibrosing inflammatory destruction of the intrahepatic and/or extrahepatic bile ducts<sup>[1]</sup>, leading to bile stasis, hepatic fibrosis, and ultimately to cirrhosis, end-stage liver disease, and need for liver transplantation. The majority of cases occur in association with inflammatory bowel disease (IBD), which often precedes the development of PSC<sup>[2]</sup>. The etiology of PSC is undefined, apart from an increasing body of evidence that points to an immunologic disturbance as a component of the disease. However, PSC lacks the features of a typical autoimmune disease and responds poorly, if at all, to typical immunosuppressive therapies<sup>[3]</sup>. No effective medical therapy for halting disease progression has been identified, but ursodeoxycholic acid is being assessed. A median duration of 12 to 18 years from the time of diagnosis before patients develop end-stage liver disease has been observed. Among eligible patients, liver transplantation (LT) is currently the only life-extending therapy for patients with end-stage PSC, although the disease can recur in the allografted liver and be a cause of morbidity post-transplant<sup>[4]</sup>.

## CLINICAL FEATURES

### Clinical manifestations

PSC affects primarily young and middle-aged men, especially patients with underlying inflammatory bowel disease. Approximately 70% to 80% of PSC patients in the United States have ulcerative colitis (UC)<sup>[5-10]</sup>.

Conversely, approximately 2% to 7.5% of patients with UC<sup>[11]</sup> and 1.4% to 3.4% of patients with Crohn's disease<sup>[12]</sup> develop PSC. IBD can be diagnosed at any time during the course of PSC, and PSC can occur at any time during the course of IBD<sup>[13]</sup>. In general, however, IBD is diagnosed several years earlier than PSC<sup>[13]</sup>. PSC may also develop many years after proctocolectomy for colitis and IBD can develop many years after liver transplantation due to advanced PSC<sup>[11]</sup>. Whether PSC is a distinct entity in patients with and without IBD might be a clinically significant issue<sup>[14,15]</sup>, but at present, there are not sufficient data to conclude that PSC occurring in patients without IBD is an entity separate from PSC found in association with IBD<sup>[11,16]</sup>.

Asymptomatic patients represent about 15% to 40% of the patients at time of diagnosis in early studies<sup>[2]</sup>. More recently, more patients are identified at an earlier stage of the disease with fewer symptoms. One study showed that the majority of patients (greater than 55%) initially present with asymptotically elevated liver enzymes<sup>[17]</sup>. Due to its close association to IBD, many cases come to medical attention when patients with IBD are screened for liver disease.

The clinical course of PSC is typically one of insidious worsening of cholestasis and eventual development of jaundice and end-stage liver disease<sup>[3]</sup>. As such, asymptomatic patients with PSC are at increased risk for developing symptoms over time. Fatigue and pruritus are reported as the most common symptoms. Jaundice, pain, fever and weight loss, cholangiocarcinoma, or manifestations of portal hypertension in advanced stages of liver disease are uncommon initial manifestations. In one recent study, the most common presenting symptoms were described as abdominal pain (20%), pruritus (10%), diarrhea (8%), jaundice (6%), fatigue (6%) and fever (4%)<sup>[17]</sup>. Another recent study from Sweden suggested that more patients without IBD are identified and the patients are older at diagnosis<sup>[18]</sup>. Symptoms of bacterial cholangitis usually are not manifested until patients undergo endoscopic intervention or surgical exploration of the biliary tract<sup>[19]</sup>. Cholangiocarcinoma develops in up to 23% of patients<sup>[20]</sup> and can occur relatively early and before onset of cirrhosis<sup>[3]</sup>.

Impairments in health-related quality of life among individuals with PSC compared to the general population were confirmed in two independent populations<sup>[21,22]</sup>. Patients with cirrhosis form primary hepatocellular disease, however, reported lower health-related quality of life scores compared to patients with cholestatic liver disease<sup>[21]</sup>.

### Biochemical features

A cholestatic picture of liver function with elevations in serum alkaline phosphatase values are the biochemical hallmark of PSC. Increases between 3 and 10 times the upper limit of normal occur in 95% of cases. Serum alanine and aspartate aminotransferase levels are usually 2-3 fold higher than normal levels. The serum total bilirubin level is normal in 60% of individuals at diagnosis<sup>[2]</sup>. The liver function tests, however, may

**Figure 1** Cholangiographic finding in PSC. Cholangiogram demonstrating multifocal strictures with intervening saccular dilatation of both intrahepatic and extrahepatic bile duct characteristic of PSC. (Photograph courtesy of Dr. Rahul Pannala).

be normal and can fluctuate during the course of the disease<sup>[23]</sup>.

Several prognostic models for PSC have been developed, most of which include age, serum bilirubin and histologic staging<sup>[5,7,9,10,24]</sup>. Most recently, a Mayo model for predicting the survival has been refined<sup>[25]</sup>. This uses the age of the patient, total serum bilirubin, aspartate aminotransferase levels, presence or absence of variceal bleeding and serum albumin as independent variables, and can be used in early stages of PSC, before onset of cirrhosis. The limitations of prognostic models include the inability to account for the development of cholangiocarcinoma and health-related quality of life<sup>[19]</sup>. Once decompensated cirrhosis is present, the Model for End-Stage Liver Disease (MELD) score<sup>[26]</sup> more accurately predicts survival and is more appropriately used in prioritizing patients for liver transplantation<sup>[3]</sup>.

### Serologic features

Currently, testing for specific autoimmune antibodies does not contribute to the diagnosis of PSC. The prevalent autoantibody reactivity is a perinuclear antineutrophilic autoantibody (pANCA), present in approximately 80% of patients but lacking in diagnostic specificity<sup>[27-30]</sup>. The unidentified antigenic reactant is not the proteinase (myeloperoxidase) of conventional pANCA. Other autoantibodies such as antinuclear antibodies and smooth muscle antibodies occur in 20% to 60% of patients, usually in lower titers than those observed in autoimmune hepatitis<sup>[31]</sup>; their fine antigenic specificity has not been established. Antimitochondrial antibodies are rarely found in patients with PSC<sup>[6]</sup>, in keeping with the lack of overlap between PSC and primary biliary cirrhosis (PBC). The serological markers of autoimmune liver diseases are covered in more detail in other articles in this series.

### Radiographic features

Cholangiography is considered to be the gold standard for the diagnosis of PSC<sup>[6]</sup>. In experienced hands, endoscopic retrograde cholangiopancreatography (ERCP) is successful in demonstrating the intra- and extra-hepatic biliary tree in 95% of the cases<sup>[3]</sup>. Segmental fibrosis of intrahepatic and/or extrahepatic bile ducts with saccular dilatation of normal intervening areas results in the characteristic beads-on-a-string appearance (Figure 1). Intrahepatic duct involvement is nearly universal with most patients affected

**Figure 2** Cholangiographic findings in PSC. Magnetic resonance cholangiography demonstrating findings of PSC.

by intrahepatic and extrahepatic disease<sup>[19]</sup>. Procedure-related complications from ERCP can occur in 3% to 8% of patients and include abdominal pain, pancreatitis, bleeding, common bile duct perforation, biliary sepsis and death<sup>[32-34]</sup>.

The use of magnetic resonance cholangiography (MRC) for detecting PSC has been evaluated as a rapid, noninvasive examination of the biliary tract (Figure 2). MRC has no significant morbidity when performed in appropriately selected individuals, and avoids the potential adverse effects of radiation exposure and contrast media associated with ERCP<sup>[35]</sup>. For the detection of PSC, MRC has been found to be accurate and comparable to ERCP<sup>[36-39]</sup>. Moreover, one study has suggested it also results in cost savings when used as the initial test strategy for diagnosing PSC<sup>[34]</sup>. Factors that lead to difficulties in interpreting the MRC compared to ERCP include the presence of cirrhosis and PSC limited to the peripheral intrahepatic bile ducts<sup>[36]</sup>. The major disadvantage of MRC is that it is a purely diagnostic examination, although it can be used to identify patients who would benefit from subsequent therapeutic ERCP<sup>[19]</sup>. Although biliary tree changes on MRC aid in the diagnosis of PSC, they do not correlate with survival, as predicted by the Mayo Risk Score<sup>[38]</sup>.

### Histologic features

PSC is histologically characterized by damage, atrophy, and, ultimately, loss of medium- and large-sized bile ducts, within or outside the liver<sup>[40,41]</sup>. These are not typically captured in a percutaneous liver biopsy. The histological picture is complicated by the fact that separation of the disease process itself from the effects of distal obstruction of bile ducts can be challenging<sup>[41]</sup>. The smaller ducts are affected by the resultant obstruction and gradually disappear (ductopenia). The characteristic pathologic features of PSC are concentric periductal fibrosis ("onion-skinning") that progresses to a narrowing and then obliteration of the small bile ducts leaving a bile duct scar (Figure 3), but this is found in less than 15% of the patients with PSC<sup>[42]</sup>. Many of the biopsy changes, such as bile stasis, pseudoxanthomatous changes, Mallory bodies and copper accumulation, lack specificity for diagnostic

**Figure 3** Fibro-obliterative lesions in PSC. Image shows an expanded portal area without two distinct fibro-obliterative lesions (arrows) in end-stage primary sclerosing cholangitis. There is no intact bile duct present in this portal area, only cross-sections of portal vein and hepatic artery branches (H&E, original magnification, 100 ×). Inset: Higher magnification of the fibro-obliterative lesion (Masson trichrome, × 400). (Photograph courtesy of Dr. Schuyler Sanderson).

purposes<sup>[41]</sup>, and can occur with chronic extra-hepatic bile duct obstruction from any cause<sup>[43]</sup>. Several stages can be recognized histologically, ranging from stages I to IV: cholangitis and portal hepatitis (stage I); periportal fibrosis or periportal hepatitis (stage II); septal fibrosis, bridging necrosis or both (stage III); and biliary cirrhosis (stage IV)<sup>[44]</sup>. Sampling error is a significant limitation of liver biopsy<sup>[41]</sup>.

Liver biopsy in patients with radiographic evidence of PSC is not needed for diagnosis, although it may help in excluding other diseases<sup>[45]</sup>. Histological staging may be complementary to ERCP evaluation, but most times is not necessary. Liver biopsy should probably be limited to patients with a challenging presentation or those being investigated for small duct PSC or possible overlap syndrome with autoimmune hepatitis<sup>[17]</sup>. The presence of biliary dysplasia on liver histology has been proposed as a marker for eventual cholangiocarcinoma in PSC<sup>[46,47]</sup>, but its use in clinical practice is limited by poor reproducibility of findings on pathologic interpretation<sup>[47]</sup>.

## VARIANT FORMS OF PSC

### Small duct PSC

Small duct PSC refers to disease that affects bile ducts that are too small to be identified by ERCP. This entity is characterized by a consistent liver histology and radiographically normal bile ducts<sup>[48,49]</sup>. The proportion of small duct PSC to "large duct PSC" has been described as approximately 5%-15%<sup>[50,51]</sup>. Small duct PSC is believed to be a distinct entity from the large duct form, with a less aggressive course and less likely to lead to cholangiocarcinoma<sup>[50,52]</sup>.

### Overlap with autoimmune hepatitis

PSC with overlap features of autoimmune hepatitis has been reported both in the pediatric and adult populations of patients with PSC. In adults, the therapeutic response to immunosuppressants, in particular the autoimmune

hepatitis- or hepatocellular component of the overlap syndrome, can be excellent, and can lead to complete remission of disease activity<sup>[53]</sup>. The response to therapy might be dependent on the predominance of AIH or PSC features. The overlap syndromes of autoimmune liver diseases, including overlap of AIH and PSC in childhood are covered in more detail in other articles in this series.

### ***IgG4-related sclerosing cholangitis***

During the past decade, patients with steroid responsive sclerosing cholangitis have been described, often but not always associated with autoimmune pancreatitis<sup>[54]</sup>. Histological findings of lymphoplasmacytic infiltration and infiltration of IgG4-bearing plasma cells, and high serum IgG4 levels have been consistently observed and frequently required for diagnosis of autoimmune pancreatitis<sup>[55,56]</sup>, and have also been observed in the hepatobiliary system. Described hepatobiliary changes have included stenosis of the bile ducts, biliary duct wall thickening, stenosis of the portal vein, portal fibrosis<sup>[57]</sup>, and hepatic inflammatory pseudotumor<sup>[58]</sup>. Hepatobiliary involvement without pancreatic involvement suggests that IgG4-related sclerosing cholangitis could be a distinct entity from autoimmune pancreatitis<sup>[58]</sup>. IgG4-related sclerosing cholangitis is similar to PSC with regard to cholangiographic features, but, in contrast to PSC, is susceptible to steroid therapy and is reversible<sup>[58]</sup>. Therefore, identifying patients with IgG4-related sclerosing cholangitis and distinguishing them from patients with PSC could have major therapeutic implications<sup>[59]</sup>. Although very limited data exists on the prognosis and natural history of IgG4-related sclerosing cholangitis, it seems that the prognosis of these patients is more favorable than that of patients with PSC<sup>[54]</sup>.

## **DISEASE-MODIFYING TREATMENTS**

Different forms of medical treatment have been tried, but until now, no treatment has been proven efficient in randomized controlled studies.

### ***Ineffective or unproven therapies***

Several drugs, such as penicillamine<sup>[60]</sup>, methotrexate<sup>[61]</sup>, budesonide<sup>[62]</sup>, colchicine<sup>[63]</sup>, cladribine<sup>[64]</sup>, cyclosporine<sup>[65]</sup>, mycophenolate mofetil<sup>[66,67]</sup>, etanercept<sup>[68]</sup>, oral and transdermal nicotine<sup>[69,70]</sup>, silymarin<sup>[71]</sup>, pirfenidone<sup>[72]</sup>, and pentoxifylline<sup>[73]</sup>, have been evaluated in the treatment of this condition, but none of them has demonstrated convincing evidence of benefit and some are associated with significant side effects<sup>[62,66]</sup>.

Tacrolimus was shown in a pilot study to cause significant improvement in serum liver biochemistries including alkaline phosphatase<sup>[74]</sup>. A subsequent study from Mayo Clinic supports previous observations that oral tacrolimus is associated with significant reductions in alkaline phosphatase levels in PSC<sup>[75]</sup>. However, in this study, the drug was not well tolerated, and the clinical benefit with oral tacrolimus with respect to disease activity in PSC appears to be limited.

Biologic therapy has been a major advancement in the current therapy of inflammatory bowel disease. There are no controlled trials evaluating the role of biologic therapy (e.g. infliximab and adalimumab) in the management of PSC.

### ***Ursodeoxycholic acid***

Multiple controlled studies have suggested that ursodeoxycholic acid (UDCA) has beneficial effects on liver biochemistries of patients with PSC<sup>[76-85]</sup>. A few studies have documented an improvement in liver histological appearance<sup>[76,79,82]</sup>. Other studies have not included liver histology as an outcome mainly because of sampling issues<sup>[85]</sup>. However, UDCA has not yet proven to prolong survival or improve outcome of PSC. All the trials performed to date have been limited by small number of patients and relatively short follow-up periods.

In an open label study performed at Mayo Clinic, 30 patients with PSC received high-dose (25-30 mg/kg per day) UDCA<sup>[83]</sup>, and substantial reduction not only in serum hepatic biochemistries but also Mayo risk score were observed after 12 mo of therapy. Differences in expected 4-year survival based on Mayo Risk Score were substantial between historical placebo and high-dose UDCA groups. A previous placebo-controlled study conducted at Mayo Clinic in which 51 patients received lower doses of UDCA (13-15 mg/kg per day)<sup>[77]</sup> had showed beneficial effects limited to serum hepatic biochemistries, but no difference in predicted survival. An independent, double-blind, placebo-controlled trial<sup>[82]</sup> of UDCA at 20 mg/kg per day involving 102 patients observed improvement in liver biochemistries, cholangiographic appearance and liver histology after 2 years of therapy, but failed to have any significant effect on survival. No significant UDCA related adverse events were reported from either study. On the other hand, a European study<sup>[85]</sup> with 219 patients who were randomized to receive either high-dose UDCA (17-23 mg/kg per day) or placebo for 5 years did not observe any significant decrease of serum alkaline phosphatase in the UDCA-treated patients. There was no significant benefit from UDCA on survival without liver transplantation or prevention of cholangiocarcinoma, but the study was too small to exclude a significant beneficial effect on survival. A large, multicenter National Institutes of Health sponsored randomized trial of high-dose UDCA is currently underway<sup>[86]</sup>.

### ***Combination therapy***

Combination therapy is a relatively new avenue of clinical research in the treatment of chronic cholestatic diseases. Drugs in monotherapy are often limited by efficacy and dose-related toxicity; combination therapy may hold the potential for improved efficacy through additive or synergistic effects, with the potential minimization of drug toxicities<sup>[87]</sup>. A controlled but nonrandomized study with 12 patients treated with a combination of low-dose prednisolone and colchicine failed to find any benefit in PSC<sup>[88]</sup>. The combination of UDCA and methotrexate was studied in 19 patients with

PSC and no changes in biochemistries from baseline values were seen compared to patients receiving UDCA alone<sup>[89]</sup>. An 8-wk pilot study evaluating the combination of prednisone or budesonide combined with UDCA failed to demonstrate significant beneficial effects to justify its use in patients with PSC<sup>[90]</sup>. In a small study with 15 patients, positive results were obtained with the combination of UDCA, prednisolone and azathioprine in decreasing liver biochemistry values<sup>[91]</sup>, but evidence supporting long-term use of this therapy is lacking. Most recently, a study with 80 PSC patients randomized to either UDCA alone or the combination of metronidazole and UDCA showed that combination therapy led to improved serum alkaline phosphatase and Mayo Risk Score, but no significant effect on disease progression compared to UDCA alone<sup>[92]</sup>.

### **Innovative approaches to medical therapy**

Trials of antibiotics such as metronidazole and minocycline have been promising but inconclusive. A small study of docosahexaenoic acid (DHA) which improves CFTR function<sup>[93]</sup> is currently underway. Most promising for the near future are inhibitors of TNF action, antifibrotic agents (such as angiotensin-converting enzyme [ACE] inhibitors, sirolimus/rapamycin), and inhibitors of formation of toxic bile (such as 24-norursodeoxycholic acid)<sup>[94]</sup>.

### **Endoscopic therapy**

Some patients present with clinical and biochemical deterioration and exhibit a dominant stricture that involves the larger extrahepatic biliary ducts. Such lesions may be amenable to endoscopic or radiologic dilatation with or without a biliary drainage procedure, such as sphincterotomy and stenting<sup>[45]</sup>. This leads to improvement of clinical symptoms, liver biochemistries and cholangiographic findings. However, the endoscopic treatment of PSC has generated controversy, not only with regard to optimal management, but also its overall influence on survival. The use of endobiliary stents has been compared to balloon dilatation alone in patients with PSC<sup>[95,96]</sup>, and a greater frequency of intervention-related complications including acute cholangitis was observed in patients with endobiliary stent placement. Repeated balloon dilatations of dominant biliary strictures resulted in improved actual survival rates compared to survival rates predicted by Mayo risk score<sup>[97,98]</sup>.

### **Biliary surgery**

Dominant strictures can also be managed surgically by dilatation or choledochojejunostomy, but this treatment has become uncommon with more recent advancement of endoscopic techniques and growing success of liver transplantation. At present, biliary surgery in patients with PSC, other than simple cholecystectomy, should be minimized and reserved for the selected rare noncirrhotic patients who have marked cholestasis or recurrent cholangitis caused by a dominant extrahepatic or hilar stricture not amenable to endoscopic or percutaneous dilatation<sup>[45]</sup>. In patients who may undergo

liver transplantation, prior biliary surgery has been associated with a significantly longer operation time, greater intraoperative blood loss, and a higher incidence of biliary complications post-liver transplantation compared with those patients with no history of biliary surgery<sup>[99-103]</sup>.

### **Liver transplantation**

Although PSC is an uncommon disease, advanced-stage PSC remains among the most common indications for LT in the United States and in Europe<sup>[20]</sup>. Unique circumstances that require evaluation for possible LT include recurrent bacterial cholangitis despite intensive medical and endoscopic therapy, severe extrahepatic biliary obstruction that precludes operative repair, and uncontrolled peristomal variceal bleeding. Intractable pruritus may also be an indication for liver transplantation. Liver transplantation should be considered before the disease is too advanced, in order to enhance the long-term survival rates post-liver transplantation<sup>[104]</sup>. Prognostic models can aid in the timing of liver transplantation. Reports from single centers performing LT in PSC patients have demonstrated excellent survival rates of 90%-97% at one year, and 83%-88% at 5 years<sup>[105,106]</sup>. However, retransplantation rates seem to be higher for patients with PSC than other diagnoses<sup>[3]</sup>.

Recurrence of PSC in the liver graft has been documented. Diagnosis of recurrence can be challenging, as non-specific bile duct injuries and strictures caused by allograft reperfusion injury, ischemia, rejection and recurrent biliary sepsis can mimic the findings of PSC post-transplantation and need to be carefully excluded before the diagnosis of recurrence can be established<sup>[107,108]</sup>. The frequency of recurrent PSC after liver transplantation remains controversial. The frequency of recurrent disease is estimated between 10% to 20% of patients<sup>[109]</sup>, but a recent systematic review has indicated that publication bias might be a concern regarding this topic<sup>[4]</sup>. PSC might recur earlier at a higher ratio after living donor liver transplantation, particularly when the liver graft is obtained from a biologically related living donor<sup>[110]</sup>. Proposed risk factors for recurrent PSC include inflammatory bowel disease, prolonged cold ischemia time, number of cellular rejection episodes, previous biliary surgery, cytomegalovirus infection, and lymphocytotoxic cross-match<sup>[4]</sup> but these require further investigation. As more liver transplant recipients survive longer, the recurrence of disease may become the primary cause of morbidity and mortality in PSC<sup>[4]</sup>.

Liver transplantation in autoimmune liver diseases is covered in more detail in another article in this series.

## **DISEASE-RELATED COMPLICATIONS**

### **Fatigue and pruritus**

Pruritus is a prevalent problem in patients with chronic cholestatic disease<sup>[111]</sup>. Cholestyramine is effective in 80% to 90% of the patients, and represents the first-line of treatment<sup>[112]</sup>. Other drugs that have been commonly used for the treatment of pruritus include rifampin<sup>[113]</sup>,

opioid antagonists<sup>[114,115]</sup> and ondansetron<sup>[116]</sup>. Sertraline has been demonstrated to have positive effects on pruritus in cholestatic liver disease in a small study<sup>[117]</sup>. Etanercept has also had positive effects on pruritus in patients with PSC in a small study not originally designed to primarily assess the effect of that drug on pruritus<sup>[68]</sup>. In controlled trials, UDCA has not been associated with improvement in pruritus, but those studies were not specifically designed for that purpose. Intractable pruritus may be an indication for LT<sup>[119]</sup>.

Fatigue is also noted to be a prevalent problem in patients with chronic cholestatic disease, and a major determinant of impaired health related quality of life<sup>[118]</sup>. However, no medical therapy is available for treatment.

### Metabolic bone disease

Severe bone disease in PSC patients is more common than expected, but less frequent than that reported in primary biliary cirrhosis<sup>[119]</sup>. Patients with longer duration of IBD, and more advanced liver disease were found to be at higher risk of severe osteoporosis<sup>[119]</sup>. In this same study, Angulo *et al.*<sup>[119]</sup> found that the severity of osteopenic disease in PSC seems to increase as liver disease advances, but this finding was not confirmed in a subsequent study by Campbell *et al.*<sup>[120]</sup>. Bone mineral densitometry measurements are the only test helpful in evaluating progression of osteopenia in patients with PSC, and the presence, severity and progression of the bone disease cannot be accurately evaluated by routine clinical, biochemical, or histological variables<sup>[119]</sup>. This is important since most patients with PSC and advanced liver disease undergo liver transplantation. Early post-transplant bone loss remains a clinically significant problem and frequently leads to fracturing in a third of patients with PSC when the pre-transplant bone mineral density is below the fracture threshold<sup>[119,121]</sup>.

For treatment of osteoporosis and osteopenia, calcium and vitamin D supplementation are recommended, and in selected cases, bisphosphonates may be indicated. Many new drugs have become available for the treatment of post-menopausal osteoporosis, and more studies are needed to determine the role of these treatments in primary sclerosing cholangitis.

### Gallbladder stones and polyps

Cholelithiasis has been noted in 26% of individuals with PSC, with the majority being asymptomatic<sup>[122]</sup>. Consideration should be given to performing a cholecystectomy if cross-sectional imaging results in the identification of gallbladder polyps given the potential for neoplastic transformation in PSC<sup>[123]</sup>.

### Peristomal varices

A special complication of portal hypertension in PSC patients with an ileal stoma is the development of peristomal varices<sup>[45]</sup>. Those develop within the adhesions between the ileal (portal) veins and the anterior abdominal wall (systemic) veins. Patients bleeding from peristomal varices often present with recurrent hemorrhagic

episodes. Bleeding from the peristomal varices is more difficult to treat than bleeding from esophageal varices. Local treatment to control and prevent bleeding is usually unsuccessful in the long term. Liver transplantation should be considered for treatment. If that is not possible, peristomal variceal bleeding can be controlled with a portosystemic shunt<sup>[2]</sup>.

### Dominant stricture

A dominant stricture, defined by Stiehl *et al.*<sup>[124]</sup> as a diameter in the common duct of less than 1.5 mm and in the hepatic duct of less than 1 mm, is a frequent finding and occurs in 45% to 58% of patients during follow-up. Stenotic lesions in PSC are thus far more often benign than malignant in nature<sup>[124]</sup>. Endoscopic treatment of dominant stenoses improves cholestasis and prolongs survival in comparison to predicted survival<sup>[97,125]</sup>. Prophylactic antibiotic administration prior to endoscopic manipulation of the biliary tree is recommended by the American Society for Gastrointestinal Endoscopy in the setting of bile duct obstruction to prevent contamination during the cannulation of the bile duct<sup>[126]</sup>.

### Bacterial cholangitis

Bacteriobilia is found in the majority of PSC patients<sup>[127]</sup>, but, as previously mentioned, bacterial cholangitis usually is not manifested until patients undergo endoscopic intervention or surgical exploration of the biliary tract. Bacterial cholangitis is common in patients with dominant stricture and requires antibiotic treatment<sup>[45]</sup>. It may also occur after endoscopic procedures or in patients with bile duct stones or tight strictures<sup>[128]</sup>, warranting prophylactic antibiotic administration prior to endoscopic manipulation of the biliary tree. Most biliary infections in patients with obstructive disease of the biliary tract are caused by aerobic enteric organisms such as *Escheria coli*, *Klebsiella* species, and *E. faecalis*<sup>[129]</sup>. Recurrent episodes of bacterial cholangitis can be an indication for liver transplantation in patients with otherwise preserved liver function. Prophylaxis with antibiotics has not been proven to be of benefit<sup>[128]</sup>, but patients with recurrent cholangitis should be advised to seek medical attention rapidly and start antibiotics at the first sign of biliary infection.

### Malignancy

**Cholangiocarcinoma:** Primary sclerosing cholangitis carries an increased risk of hepatobiliary malignancy, especially cholangiocarcinoma (CCA)<sup>[8,130]</sup>. The development of CCA is the most lethal complication of PSC. Cholangiocarcinoma can arise at any stage of PSC, although, in general, the incidence is higher in more advanced disease<sup>[5,131]</sup>. There are no clinical features that predict the diagnosis of CCA, and diagnosis can be challenging.

The cumulative life-time incidence of CCA is estimated as 6% to 23%<sup>[20]</sup>. The reported prevalence of CCA in explanted livers and autopsy is much higher, approximately 30% to 42%<sup>[9,132]</sup>. Overall, up to 50%

of CCA cases are detected synchronous with the PSC diagnosis or within one year of diagnosis of PSC<sup>[130,133-136]</sup>. Based upon the same reported series, the incidence of CCA during follow-up, starting at 1 year after the diagnosis of PSC, can be calculated as being between 0.5% and 1.5% per year. The malignancy usually develops in the fourth decade of life, whereas CCA in patients without PSC usually develops much later in life, in their seventh decade of life<sup>[20]</sup>.

Risk factors for the development of CCA in PSC have not been clearly identified, but older age, longer duration of IBD and smoking behavior have been associated with an increased risk for development of CCA in patients with PSC. Finding biliary dysplasia on liver histology has also been proposed as a precursor in the development of cholangiocarcinoma<sup>[46,47]</sup>.

The diagnosis of CCA can be challenging. The role of serum CA19-9 level in the diagnosis of CCA is controversial. There are no tumor markers which are specific for cholangiocarcinoma. In the context of PSC, a serum CA19-9 level greater than 100 U/mL has been reported to have a sensitivity of 75% and a specificity of 80% for presence of cholangiocarcinoma<sup>[137,138]</sup>. A recent study from the Mayo Clinic found that a serum level greater than 129 U/mL provided a sensitivity of 78.6% and specificity of 98.5% for CCA in PSC<sup>[139]</sup>. Even though these studies suggest CA 19-9 is an accurate test to diagnose cholangiocarcinoma, CA 19-9 was only found to identify patients with advanced, unresectable CCA, and thus its use is not appropriate as a screening test<sup>[139]</sup>. Ultrasonography, computed tomography, and magnetic resonance have inadequate sensitivity to distinguish CCA from PSC. Endoscopic biopsy and biliary brushing for cytology, digital image analysis, and fluorescent *in situ* hybridization are noted for good specificity but poor sensitivity in detecting CCA<sup>[19]</sup>.

Patients with PSC and CCA have a very poor outcome, with median survival of approximately 5 to 11 mo<sup>[20,135,140]</sup>. Even though survival of patients in whom CCA was found incidentally by histological examination of the explanted liver has been reported to be good<sup>[5]</sup>, in general, LT for patients with CCA results in a low success rate<sup>[141-144]</sup>. However, more recent data from investigational protocols have suggested better outcomes in highly selected individuals. The use of pretreatment radiotherapy and subsequent capecitabine for 2 to 3 wk prior to LT at Mayo Clinic has yielded a 3- and 5-year actuarial survival of 82%<sup>[145]</sup>. The use of brachytherapy and continuous 5-fluoracil infusion before liver transplantation in Nebraska resulted in 45% long-term cancer-free survival after follow-up for a median of 7.5 years<sup>[146]</sup>. Curative resection among individuals with early-stage cholangiocarcinoma may also be of benefit in PSC<sup>[133]</sup>, although recent data suggest that transplant with neoadjuvant chemoradiation with localized, node-negative hilar CCA may achieve better survival with less recurrence than conventional resection<sup>[145,147]</sup>.

Recent studies have suggested that the incidence of CCA in patients with PSC treated with UDCA is lower

than expected and decreases with time of therapy<sup>[141,148]</sup>. Further studies are needed to confirm this finding.

**Colonic dysplasia and carcinoma:** Whether the presence of PSC increases the risk of colonic dysplasia and carcinoma in ulcerative colitis is controversial<sup>[149,150]</sup>. Patients with PSC and UC have been found to have an increased incidence of colonic carcinomas compared to patients with ulcerative colitis alone in a few studies<sup>[136,151-153]</sup>, however, contradictory results have also been presented<sup>[154,155]</sup>. The size, design, end-points, and populations involved in these studies have varied, and critical review suggests that colorectal cancer is more common in the setting of PSC<sup>[150]</sup>. Furthermore, PSC patients with UC remain at an increased risk for developing colorectal dysplasia and carcinoma after they have undergone liver transplantation<sup>[11,156]</sup>. The immunosuppressive treatment after liver transplantation may have an impact on the development of cancer.

Two studies have indicated that UDCA reduced the incidence of colonic dysplasias and/or carcinomas<sup>[157,158]</sup>.

**Gallbladder neoplasia:** Dysplasia, adenomas and carcinoma of the gallbladder have been described in PSC but are less common than cholangiocarcinoma. PSC is recognized as one of the major risk factors for both gallbladder and bile duct carcinoma<sup>[159]</sup>. A recent study reported statistically significant association between hilar/intrahepatic biliary neoplasia and gallbladder neoplasia, suggesting a “field effect” in the intrahepatic and extrahepatic biliary tree in PSC<sup>[160]</sup>. Identification of gallbladder polyps on cross-sectional imaging should lead to consideration for cholecystectomy<sup>[123]</sup>. Large studies on this subject have not been performed.

**Hepatocellular carcinoma:** Although patients with cirrhotic stage PSC may also be at risk for developing hepatocellular carcinoma, this malignancy occurs infrequently<sup>[131,136,161]</sup>.

## PREGNANCY AND PSC

Little is known regarding the natural history and potential complications of pregnancy in patients with PSC. There are very few case reports<sup>[162,163]</sup> and one small series of thirteen pregnancies in 10 patients with PSC<sup>[164]</sup> that describe the fetal and maternal outcome of pregnancy in PSC. Although previously described, it appears that hepatic disease activity is not significantly worsened during the gestational period<sup>[2]</sup>. Nonetheless, patients with PSC who become pregnant require close monitoring<sup>[162]</sup>. Regular blood tests, including serum bilirubin and aminotransferase levels, are essential. In the event that the patient develops symptoms worrisome for obstruction, an ultrasound is a safe diagnostic test and may detect the presence of dominant strictures or stones; it lacks sensitivity however. MRC might have an emerging role in pregnancy, and more invasive tests such as ERCP might be required.

## CONCLUSION

Primary sclerosing cholangitis is a presumed immune-mediated liver disease of young men associated with significant morbidity and mortality. However, there is no proven medical treatment available for it. Further studies are needed for better understanding of the pathophysiology of the disease and for development of an optimal therapeutic strategy for patients with PSC to improve health related quality of life and halt progression of disease, thereby decreasing incidence of complications of advanced liver disease, and the need for transplantation.

## Abstract

Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease of unknown etiology but lymphocytic portal tract infiltration is suggestive of an immune-mediated basis for this disease. Associations with inflammatory bowel disease (IBD) especially ulcerative colitis (UC), and with particular autoimmune diseases, as well as the genetic associations further suggest PSC may be an immune-mediated disease. The immunogenetics of PSC have been the subject of active research and several HLA and non-HLA associated genes have been implicated in the development of the disease. Lymphocytes derived from the inflamed gut may enter the liver *via* the enterohepatic circulation to cause hepatic disease. PSC may be triggered in genetically susceptible individuals by infections or toxins entering the portal circulation through a permeable colon and hence evoking an abnormal immune response.

## INTRODUCTION

Primary sclerosing cholangitis (PSC) is a chronic disease of the intra and/or extrahepatic bile ducts. It is characterized by a concentric obliterative fibrosis

that leads to bile duct strictures (Figure 1). In many, this in turn progresses to biliary cirrhosis and hepatic failure. Approximately one third of patients will develop cholangiocarcinoma<sup>[1]</sup>. PSC is frequently associated with inflammatory bowel disease (IBD) usually ulcerative colitis (UC) and those with Crohn's have disease predominantly affecting the colon. Approximately three quarters of the Northern European population with PSC have concomitant IBD particularly extensive UC<sup>[2]</sup>. 4.0%-7.5% of patients with UC have PSC<sup>[3]</sup>.

The term "secondary sclerosing cholangitis (SSC)" is used for a disease with similar clinical features to PSC but where a direct causative agent for the pathological process is known. Such agents include choledocholithiasis with intraductal stones, surgical damage to bile ducts, ischaemia from hepatic artery occlusion, infections, and chemical agents such as drugs. Table 1 comprises a full list of possible causes of SSC with a section also showing the conditions which can mimic sclerosing cholangitis on cholangiography. There is little good data on the natural history of SSC and very little information regarding the immunological processes occurring during the progression of SSC is known although liver biopsies often show similar changes to those of PSC with ductopenia and patchy inflammation. The remainder of this chapter will concentrate on the etiopathogenesis of PSC.

The etiology and pathogenesis of PSC remain very poorly understood. The insidious onset of the disease makes the identification of an aetiological agent very unlikely. As the disease is associated with autoantibodies and HLA haplotypes as well as being closely related to IBD it would appear to be immune mediated. An autoimmune mediated destructive process is also suggested by lymphocytic infiltration into areas of portal damage.

PSC is not however a classical autoimmune disease, as it occurs with a 2:1 male predominance compared with the female predominance found in classical autoimmune diseases such as primary biliary cirrhosis (PBC) and autoimmune hepatitis (AIH). Moreover PSC does not have the characteristic response to immunosuppressive treatment as seen in classical autoimmune disease (Table 2).

Circumstantial evidence that PSC may be immune mediated comes from the independent association of PSC with a number of autoimmune diseases. 119 patients with PSC were studied by Saarinen *et al*<sup>[4]</sup>. Each

**Figure 1** Cholangiogram showing beading and dilatation of the intra and extra hepatic bile ducts- the diagnostic features of primary sclerosing cholangitis (PSC).

**Table 1** Causes and mimics of secondary sclerosing cholangitis (SSC)

	SSC
Causes	Surgical trauma to bile ducts Ischaemic injury eg after transplantation Hepatic arterial chemotherapy eg floxuridine Intraductal gallstones <sup>[3]</sup> Viral or bacterial infection eg CMV or cryptosporidiosis Caustic injury eg formalin treatment of hydatid disease Congenital abnormalities eg cystic fibrosis
Conditions mimicking sclerosing cholangitis on imaging	Malignancy eg metastatic carcinoma Hypereosinophilic syndrome Choledochal cyst

**Table 2** The features of primary sclerosing cholangitis compared with classical autoimmune disease

Characteristic	Classical autoimmune disease	Immune-mediated inflammatory disease (such as IBD, psoriasis)	Primary sclerosing cholangitis
Age	Children and adults	Children and adults	Children and adults
Sex	Female predominance	No gender predilection	Male predominance
Autoantigens	Yes	No	No
Autoantibodies	Yes (pathogenic)	Yes (markers)	Yes (probably markers)
Associated autoimmune disease	Yes	Yes	Yes
HLA associations (class I and II)	Yes	Yes	Yes
Response to immunosuppression	Usually good	Often good	Good in children Poor in adults

PSC patient with IBD was matched to an IBD patient without PSC; 24% of the PSC patients had one or more autoimmune disorders outside the liver and colon compared with only 9% in the IBD group without PSC. Nine patients in the PSC group had 2 or more autoimmune diseases compared with only 2 in the IBD group. Diabetes mellitus and thyroid diseases were the most common in both groups. It is noteworthy that associated autoimmune disease did not seem to influence the outcome or clinical presentation of PSC<sup>[4]</sup>.

Simultaneous or sequential occurrence of PSC and AIH has been described in both adult and pediatric populations<sup>[5]</sup>. The reported prevalence of this overlap syndrome is variable from 8%-54% and depends on the age of the study population, the type of scoring system used for diagnosis and the completeness of the analysed data.

In general, sclerosing cholangitis in children is characterized by more pronounced autoimmune features with a clinical overlap with AIH. This condition “autoimmune sclerosing cholangitis in childhood” has been addressed elsewhere in this issue (see Miele Verghani).

## AUTOANTIBODIES

Atypical anti-neutrophil cytoplasmic antibodies (ANCA) are present in the serum of up to 88% patients with PSC (33%-88%)<sup>[5]</sup>. They are however not specific for PSC and are found in UC (60%-87%), and AIH (50%-96%)<sup>[6]</sup>. These ANCA are distinct from perinuclear-staining

antineutrophil cytoplasmic antibody (p-ANCA) found in microscopic polyangiitis and cytoplasmic-staining antineutrophil cytoplasmic antibody c-ANCA in Wegener's granulomatosis.

Immunoblotting showed reactivity in 92% of IBD or hepatobiliary disease patients with an atypical p-ANCA to a myeloid specific nuclear protein with a molecular mass of 50 kDa<sup>[7]</sup>. The target antigen in PSC for these atypical ANCA is probably a neutrophil nuclear envelope protein, viz tubulin-beta isotype 5<sup>[8]</sup>. Terjung and colleagues have suggested that the term p-ANNA is therefore more appropriate as the recognised antigen is not cytoplasmic but originating in the nuclear membrane<sup>[7]</sup>.

The importance of these autoantibodies in the development of PSC is unknown. Titres of ANCA correlate with disease activity in the systemic vasculitides, whereas in contrast there is a poor correlation between ANCA and clinical parameters in PSC<sup>[9-11]</sup>. Titres of ANCA remain unchanged after a transplant in PSC and after a colectomy in UC. Current evidence suggests that they are unlikely to play a role in the pathogenesis of PSC.

A high proportion of non-specific autoantibodies in addition to p-ANNA are found in patients with PSC (Table 3). They are of unclear relevance and unhelpful in diagnosis. These include anti nuclear antibodies (20%-67%), antimitochondrial antibodies (< 10%) and antithyroperoxidase antibodies (7%-16%)<sup>[5]</sup>. Anticardiolipin antibodies were found in 66% of PSC patients compared to 4% controls by Angulo but no

**Table 3** Autoantibody prevalence in primary sclerosing cholangitis

Antibody	Prevalence (%)
Anti-nuclear antibody (ANA)	7-77
Anti-smooth muscle antibody (ASMA)	13-20
Anti-endothelial cell antibody (AECA)	35
Anti-cardiolipin antibody	4-66
Thyroxperoxidase	7-16
Thyroglobulin	4
Rheumatoid factor	15

Anti-mitochondrial antibody is only rarely detected in PSC (< 10%). This is useful in differentiating PSC from primary biliary cirrhosis (PBC). Data taken from Angulo *et al*<sup>[12]</sup>.

resultant associations with thrombotic disease were demonstrated<sup>[12]</sup>.

Significantly more PSC patients have autoantibodies to surface antigens expressed on biliary epithelial cells (BEC) than patients with PBC, AIH or normal controls. These induce increased expression of CD44 on the BEC and increased production of IL-6 by BEC<sup>[13]</sup>. Anti-BEC autoantibodies may be both IgM and IgG. IL-6 induces BEC proliferation *in vitro* and suppresses BEC apoptosis, and it is increased in the bile in cholangitis and in the serum in cholangiocarcinoma. Persistent IL-6 production may be in part, responsible for the bile duct changes seen in PSC.

Antibodies to the baker's yeast, *Saccharomyces cerevisiae* (ASCA) have been reported in IBD especially active Crohn's disease. ASCA are not autoantibodies but there does seem to be some genetic predisposition to their presence. ASCA has also been seen in autoimmune liver disease including PSC but no conclusions can be drawn from their presence<sup>[14]</sup>.

## IMMUNOGENETICS

PSC is not attributable to one gene locus and is a non-Mendelian (complex) disorder. A number of associations have been made with HLA haplotypes as well as a number of other genes. There is controversy as to whether there is a primary susceptibility allele but PSC is probably acquired through inheriting a combination of genetic polymorphisms that act together to cause susceptibility to disease. The genetics of PSC is still the subject of active research.

### Major histocompatibility complex (MHC) genes in PSC

The MHC gene on the short arm of chromosome 6 encodes HLA molecules. Case control association studies have identified various HLA molecules and other immunoregulatory genes as determinants of disease susceptibility and progression in PSC. HLA molecules are highly polymorphic and have a central role in the T cell response. Class I molecules encode HLA A, B and Cw and class II encode the DR, DQ and DP families. The Class III region encodes a number of peptides which are active in the immune response including genes for TNF $\alpha$  and TNF $\beta$ , complement proteins C4, C2

**Table 4** Key HLA haplotypes in PSC<sup>[27]</sup>

	HLA haplotypes	Odds ratio
3 HLA haplotypes associated with an increased risk	B8-MICA*008-TNFA*2-DRB3*0101-DRB1*0301-DQB1*0201	2.69
	DRB3*0101-DRB1*1301-DQA1*0103-DQB1*0603	3.8
	MICA*008-DRB5*0101-DRB1*1501-DQA1*0102-DQB1*0602	1.52
	DRB4*0103-DRB4*0401-DQA1*03-DQB1*0302	0.26
3 HLA haplotypes associated with reduced risk (protective)	DRB4*0103-DRB1*0701-DQA1*0201-DQB1*0303	0.15
	MICA*002	0.12

and Bf and MHC class I chain-related (MICA) and MICB genes encoding the MHC class I chain related molecules  $\alpha$  and  $\beta$ . Normal biliary cells express HLA class I and not class II. HLA-DR, DQ and DP are aberrantly expressed on target cells in PSC.

There is an increased frequency of HLA B8 and DR3 (HLA DRB1\*0301) in PSC compared with healthy controls as first described in 1982 and then confirmed in other studies<sup>[15-17]</sup>. A later study by Donaldson showed a secondary association with DR2 in DR3 negative patients<sup>[18]</sup>. An increase in HLA-DR6 has also been observed in PSC patients<sup>[19,20]</sup>. HLA B8 and DR3 are in linkage disequilibrium. The HLA B8, DR3 haplotype is also associated with several organ specific autoimmune diseases including lupoid chronic active hepatitis, type I diabetes mellitus, myasthenia gravis and thyrotoxicosis. There is no difference in class II typing between PSC patients with and without autoimmune diseases outside the liver and colon suggesting association of PSC with autoimmune disease is not secondary to HLA but rather a primary phenomenon<sup>[4]</sup>.

HLA DR4 is less common in PSC than in control populations and the significance of this is disputed<sup>[20]</sup>. Studies have suggested that although it has a protective effect against PSC development, when present it is associated with poor prognosis and possibly cholangiocarcinoma<sup>[19,21]</sup>.

In rheumatoid arthritis (RA) more severe disease has also been seen with certain DR4 alleles. Gow described the association of RA and PSC in 4 cases<sup>[22]</sup>. In three, the liver disease was unusually progressive, proceeding to cirrhosis in 14, 18 and 48 mo from diagnosis. It has been suggested therefore that RA in association with PSC may be a marker of patients at high risk of progression to cirrhosis. PSC also needs to be considered in all RA patients with cholestatic liver tests. The DR3, DR2 heterozygote has been shown to be associated with an increased risk of death or liver transplant and a DQ6 encoding haplotype in DR3, DR2 negative individuals was associated with a reduced risk<sup>[19]</sup>.

Molecular genotyping has identified 6 haplotypes that encode for peptides involved in the immune response in PSC (Table 4)<sup>[23]</sup>.

The finding of multiple haplotypes associated with PSC indicates a complex relationship with the MHC. Susceptibility appears to involve either a combination

of *DR*, *DQ* and *MHC class I chain-like (MIC)* alleles or perhaps *MIC* alone. There is controversy concerning which allele or alleles within each haplotype may form the primary association.

*MICA* genes are a group of polymorphic genes on chromosome 6. They are localised in the class I region between *HLA-B* and *TNFA*. *MICA* molecules are stress and heat shock inducible and are expressed in non-diseased liver and on thymic and gastrointestinal epithelia. *MICA* has been identified as a ligand for  $\gamma\delta$  T cells, natural killer (NK) (CD56+) cells and cells expressing the NKG2D activatory receptor. Increased numbers of both  $\gamma\delta$  and NK cells have been documented in PSC livers<sup>[24,25]</sup>.

An association between the *MICA\*008* allele and PSC has been demonstrated by Norris *et al*<sup>[26]</sup> (which is due to an increased frequency of patients with 2 copies of this allele (i.e. homozygous). *MICA\*008* is the main allele carrying the *MICA5.1* microsatellite allele. PSC has been found to be significantly associated with both the *MICA5.1* and the *MICB24* (*MICB* microsatellite) markers. The association was lost when stratified for *DR3* or *B8* positive and negative individuals. However, *B8* and *DR3* were associated with PSC only in the presence of these markers<sup>[27]</sup>.

*MICA\*002* has a strong negative association with disease and is the functional opposite of *MICA\*008*. The *MICA\*002* allele carries the *MICA9* microsatellite allele which is also therefore less common in PSC patients compared with controls as this allele has been shown to be protective. One copy of the *MICA\*002* allele prevents PSC in most cases and so the resistant allele may be dominant<sup>[26,27]</sup>.

Bernal first concluded that genetic susceptibility to PSC might be determined by polymorphism within the *TNF* genes<sup>[28]</sup>. The *TNF- $\alpha$*  gene is located in the class III HLA region between the *HLA-B* and *DRB3* loci<sup>[29]</sup>. Increased frequency of the rare allele -308A (termed *TNF2*) of the *TNF* gene promotor has been reported in autoimmune disorders that include RA, systemic lupus erythematosus and coeliac disease. Individuals with this allele may produce high levels of *TNF- $\alpha$* . *TNF2* is in linkage disequilibrium with the extended *HLA-B8-DR3-DQ2* haplotype. The G to A substitution at position -308 in the *TNF- $\alpha$*  promotor has been shown by Mitchell *et al* to be associated with susceptibility to PSC, but this was secondary to the association with the *B8-DR3* haplotype<sup>[30]</sup>.

### Non-MHC genes in PSC

HLA haplotypes do not account for all of the susceptibility to develop PSC and genes outside the HLA region may also have a role in disease pathogenesis. Studies of non-MHC genes have failed to show an association between PSC and cytokine genes including *IL-1 $\beta$* , *IL-1RN* and *IL-10*<sup>[30,31]</sup>. The *CD95 (FAS)* gene (*TNFRSF6*), the gene encoding *CCR-5*, genes encoding *CTLA4* and the *Nod2* gene have also been examined in PSC. Karlsen *et al* have shown that genetic polymorphisms conferring susceptibility to IBD are not found in PSC/IBD patients.

viz *CARD15*, *TLR-4*, *CARD4*, *SLC22A4*, *SLC22A5*, *DLG5* and *MDR1*<sup>[32]</sup>. The chemokine receptor-5 (*CCR5*) data are contradictory. *CCR5-Delta32* is a 32 base pair deletion associated with significant reduction in cell surface expression of the receptor. Melum *et al* showed no association of *CCR5-Delta32* with susceptibility or resistance to PSC contradicting earlier reports suggesting an association<sup>[33,34]</sup>. Cytotoxic T lymphocyte antigen-4 (*CTLA-4*) is expressed on activated T lymphocytes. It is a cell surface molecule that binds to the ligand CD80 (*B.7*) on antigen presenting cells. A *CTLA-4* gene polymorphism is described in several autoimmune diseases but in PSC this remains in question. The most recent and largest study was unable to demonstrate any effect in PSC<sup>[35]</sup>.

PSC progression is related to periportal and septal fibrosis and this is associated with excess production and reduced degradation of extracellular matrix. This is regulated by a series of metalloproteinases (MMPs) and their naturally occurring inhibitors. There is a common polymorphism in the promotor sequence of the *stromelysin (MMP3)* gene with either a 5A or 6A repeat. The 5A allele is associated with increased transcription of stromelysin compared to the 6A variant. Satsangi *et al* in Oxford have found an association between the carriage rate of the 5A allele and susceptibility to PSC. 5A homozygosity was associated with development of portal hypertension<sup>[36]</sup>. This may suggest the *MMP3* 5A allele as a marker for fibrosis.

Wienke *et al* could not confirm the association of the *MMP-3 5A* allele with PSC and also found no general associations of the *MMP-1* promotor polymorphism among Norwegian patients<sup>[37]</sup>. Patients with PSC who also had UC were found however to have an increased frequency of the *MMP-3* allele 5A compared with PSC patients without UC (60% compared to 45%). All patients with cholangiocarcinoma were found to be carriers of the *MMP-1* allele 1G compared with 72% of those with PSC who did not have cholangiocarcinoma.

*Intracellular adhesion molecule-1 (ICAM-1, CD54)* gene polymorphisms have been implicated in the susceptibility to a number of inflammatory conditions, including IBD. In PSC, studies have found that patients with advanced disease express ICAM on proliferating bile ductules and interlobular bile ducts. Increased soluble ICAM levels have been found in the serum of patients with PSC probably indicating activation of the immune system and inflammatory responses<sup>[38]</sup>. Yang *et al* have shown recently that, in British patients, the *ICAM-1* polymorphism K469E is associated with PSC and may be a protective allele. This association is independent of the coexistence of IBD. There is no relationship between the *ICAM-1* genotype and the rate of PSC progression<sup>[39]</sup>. These results were not confirmed in a Scandinavian population<sup>[40]</sup>.

## CELLULAR IMMUNE ABNORMALITIES IN PSC

There is a T cell predominant portal infiltrate in PSC

although the relative proportions and importance of the CD4 and CD8 cells are not known. CD4 cells are seen more commonly in the portal tracts and CD8 cells predominate in areas of interface hepatitis<sup>[41]</sup>. The cell infiltrate may change as the disease progresses. These cells are functional and are likely to be involved in the pathogenesis of disease. In the peripheral circulation there does appear to be a fall in CD8 cells as the disease progresses. This only occurs late in disease so is unlikely to be significant in disease pathogenesis<sup>[41-44]</sup>.

Bo and colleagues showed that cell proliferation and function of liver derived T lymphocytes is impaired in PSC patients compared with liver derived T cells obtained from normal controls or patients with other autoimmune liver diseases<sup>[45]</sup>. They believe this is due to exposure to high levels of TNF *in vivo* and this exposure may be chronic.

Previously relatively high levels of TNF- $\alpha$  have been seen in T cell lines from liver biopsies in patients with different stages of PSC while decreased levels were observed in PBC patients. Therefore increased levels of TNF- $\alpha$  are present in PSC patients whether the disease be early or late stage<sup>[45-46]</sup>.

### T cells in PSC

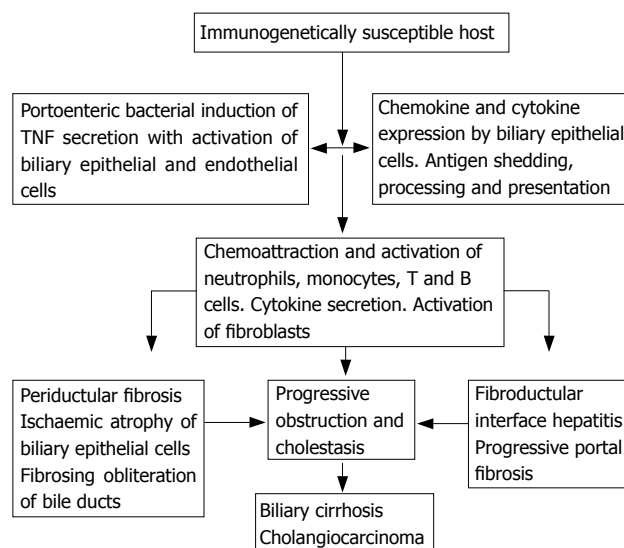

PSC is characterized by a prominent T cell infiltrate in areas of portal damage. The T cell receptor (TCR) determines the specificity of T cells. It consists of two disulphide linked polypeptides,  $\alpha$  and  $\beta$ . An alternative receptor, namely  $\gamma\delta$  has been identified. The predominant cell type is still  $\alpha\beta$  and the significance of T cells with  $\gamma\delta$  in PSC is not known<sup>[42]</sup>. TCR genes show genetic diversity but the *V $\alpha\beta$*  gene segment of the TCR can play a dominant role in recognition of certain peptide-MHC complexes. Expanded T cell populations using restricted sets of TCR *V* gene segments have been identified in areas of inflammation in the tissues affected in other immunopathic diseases such as RA and Sjogren's disease<sup>[47]</sup>. Broome reported the preferential expression in liver tissue of the V $\beta$ 3 region of the T cell receptor in PSC patients compared with liver tissue from PBC patients and healthy controls but no differences were seen in peripheral blood T cells<sup>[48]</sup>. This may indicate the presence of a specific antigen in the liver in PSC patients capable of driving the T cell production with this V $\beta$ 3 segment.

Oligoclonal T cell receptors that proliferate in culture with enterocytes and are cytotoxic to enterocyte cell lines were reported in PSC but this study is unconfirmed<sup>[49]</sup>. There are to date no studies of regulatory T cells (T regs) in PSC patients.

In summary, the available data do not as yet allow for any useful hypothesis on the T-cell contribution to the lesions of PSC.

### BEC

BEC appear to act as the target for the immune response in PSC and are also an active participant in the immune reaction. They express a number of cytokines, enzymes, intracellular adhesion molecules (ICAM-1) and HLA

**Figure 2** Vierling's hypothesis of the pathogenesis of primary sclerosing cholangitis<sup>[72]</sup>.

molecules. Normal BEC express only HLA class I and not class II whereas there is aberrant expression of class II molecules on BEC in PSC<sup>[50-52]</sup>, and also in PBC. Functionally important autoantibodies have been found to antigens on BEC in PSC. These induce BECs to produce IL-6 and increased expression of CD44. BEC however seem to lack the co stimulatory molecules necessary to activate T cells and unstimulated BEC inhibit T cell activation and this casts doubt upon the theory that BECs can act as antigen presenting cells<sup>[53,54]</sup>.

However, it has become clear that cholangiocytes rather than being passive targets may play primary roles in the pathogenesis of peribiliary inflammation and periductular fibrosis in PSC<sup>[54,55]</sup>. Stimulation by proinflammatory cytokines induces cholangiocyte secretion of multiple chemokines, cytokines, and growth factors that immunomodulate inflammation and fibrogenesis<sup>[55]</sup>. The chemoattracted T cells include a population of PSC-specific T cells primed in the gut.

### BACTERIA IN PSC

The association between PSC and IBD led to Vierling's hypothesis that colonic bacteria enter the portal circulation through a leaky mucosa in IBD thereby causing PSC (Figure 2)<sup>[55]</sup>.

Bacterial antigens may act as molecular mimics in genetically susceptible people and cause an immune reaction responsible for initiating PSC. The bacteria are able to get through gut walls made permeable by colitis or in theory by any infective episode of acute infective or inflammatory colitis. Chemokines and cytokines are then released from Kupffer cells in the liver attracting macrophages/monocytes, lymphocytes, activated neutrophils and fibroblasts to the portal tracts. Vierling further suggested that the concentric fibrosis resulting could cause atrophy of the BEC secondary to ischaemia. The bile duct loss would lead to progressive cholestasis, further fibrosis and secondary biliary

cirrhosis. This does not explain however why there are fewer PSC patients with Crohn's colitis as compared with UC and why there can be an associated stricturing of the pancreatic duct.

Portal bacteremia has been described in UC patients undergoing colectomy<sup>[56]</sup>. A study looking at explanted livers showed higher bacterial positivity rates in bile and bile ducts in PSC patients compared with PBC patients, and  $\alpha$ -haemolytic streptococci accounted for 46% of the bacterial strains found. Bile duct cannulation at endoscopic retrograde cholangiopancreatography (ERCP) could have accounted for this bacterial presence<sup>[57]</sup>. The study went on therefore to compare patients with PSC who had undergone ERCP to those who had not, in order to evaluate the potential role of these bacteria in the etiopathogenesis of PSC. Positive cultures were obtained from 3 of the naïve PSC patients and from 6 of the PSC patients with previous ERCP.  $\alpha$ -haemolytic streptococci were again the commonest bacteria seen. As most naïve PSC patients were found to have negative bacterial cultures this bacteria is unlikely to play a primary role in etiopathogenesis but may be involved in disease progression<sup>[58]</sup>.

Recent molecular studies have shown an increased prevalence of *H. pylori* and other non-gastric *Helicobacter* species in cholestatic liver diseases compared with healthy controls and noncholestatic liver disease. In PSC positivity was significantly but weakly associated with UC<sup>[59]</sup>.

Ponsioen *et al* have suggested an association between PSC and previous Chlamydia infection after the finding of an increase in seroprevalence of Chlamydia anti-lipopolysaccharide (LPS) antibodies in PSC patients, although no Chlamydia antibodies were found in liver tissue and thus the significance is unclear<sup>[60]</sup>.

Among animal models, none has yet have been developed showing all the features of PSC, although a rat model in which there is small bowel bacterial overgrowth has shown hepatic injury somewhat similar to that seen in human PSC<sup>[61,62]</sup>.

Abnormal accumulation of lipopolysaccharide (a bacterial endotoxin), presumably derived from portal blood, in the biliary epithelium has been shown in a rat model with a self-filling blind intestinal loop, and therefore may be involved in the pathogenesis of bile duct injury associated with intestinal injury<sup>[63]</sup>. Are these studies very persuasive?

## LYMPHOCYTE HOMING

PSC is strongly linked to IBD but it also runs a course independent from the bowel disease illustrated by the fact that the disease can develop many years after colectomy. Grant *et al* hypothesized that T lymphocytes generated in the gut during active inflammation persist as long-lived memory cells and undergo enterohepatic circulation and can then trigger an inflammatory response in the liver when activated by an appropriate stimulus. The nature of the stimulus remains unclear; possibilities include hepatic expression of the original priming antigen or possibly mediation solely by the

aberrant expression of gut specific adhesion molecules and chemokines<sup>[64]</sup>.

There is overlapping expression of many molecules between the gut and liver including the two potential addressins vascular adhesion protein-1 (VAP-1) and mucosal addressin cell adhesion molecule-1 (MAdCAM-1). VAP-1 expression on liver endothelium is normally far stronger than that seen on mucosal vessels. In IBD gut expression is greatly increased, suggesting that lymphocytes from the liver may be able to enter the inflamed gut using VAP-1. MAdCAM-1 endothelial expression was thought to be restricted to the gut but has been recently seen on portal endothelium in inflammatory liver disease (including PSC) associated with IBD. Mucosal lymphocytes express  $\alpha_4\beta_7$ , which allows adhesion to hepatic MAdCAM-1 suggesting it may play a role in lymphocyte recruitment<sup>[65-67]</sup>. They propose that memory lymphocyte cells recirculate between liver and gut using either/both MAdCAM-1 and VAP-1<sup>[65]</sup>.

The chemokine CCL21 activates lymphocyte adhesion to MAdCAM-1 dependent on  $\alpha_4\beta_7$ . CCL21, thought to only exist in secondary lymphoid tissue is upregulated in portal associated lymphoid tissue in PSC and plays an important role in recruiting lymphocytes. Expression of the gut-associated chemokine CCL25 (thymus-expressed chemokine (TECK)) has also been shown in PSC liver sinusoidal endothelium but was absent in liver in AIH/PBC. A significant population of CCR9+ mucosal lymphocytes (capable of binding CCL25) has been detected infiltrating PSC liver tissue compared with controls and matched peripheral blood, thus supporting the hypothesis of a T cell enterohepatic recirculation. CCR9 lymphocytes co-express the gut homing integrin  $\alpha_4\beta_7$ . Therefore CCL25 recruits CCR9+ lymphocytes to the liver in PSC by triggering adhesion to MAdCAM-1<sup>[66-67]</sup>. MAdCAM-1 and CCL25 are upregulated to the liver in inflammatory liver diseases whereas previously they were thought to be restricted to the gut. Conversely VAP-1, normally expressed in the liver, is up regulated in the gut in IBD<sup>[68]</sup>.

However this does not explain why PSC is associated more with UC than Crohn's disease, as it would be predicted that just as many memory T cells are produced in Crohn's disease as in UC.

## Hepatobiliary transporters in PSC

Defects in the hepatobiliary transport system have been shown to be the cause of a number hereditary cholestatic disorders eg progressive familial intrahepatic cholestasis and BSEP (bile salt export pump)<sup>[69]</sup>. This system is responsible for the hepatocellular uptake and excretion of bile salts into bile canaliculi. Defects in the transport system can result in bile duct injury.

Knockout mice for the *Mdr2 (Abcb4)* gene, which corresponds to human *MDR3/ABCB4*, spontaneously develop sclerosing cholangitis with features similar to human PSC<sup>[70]</sup>. A non-functional multidrug resistance 3 (MDR3) protein leads to the formation of a "toxic" bile with increased concentration of free, non-micellar bile acids which cause BEC injury, pericholangitis, periductal fibrosis and, eventually, sclerosing cholangitis. Studies in

Table 5 Comparison of PSC and AIP-SC

	PSC	AIP-SC
Gender	M:F = 2:1	Probably some male predominance <sup>[81,85,87]</sup>
Clinical presentation	Usually insidious. Sometimes with obstructive jaundice secondary to cholangiocarcinoma.	Mild abdo/Back pain Sometimes with short history of obstructive jaundice due to CBD stricture
Associated inflammatory bowel disease	Yes	No
Cholangiographic findings	Diffuse changes throughout intra- and extrahepatic bile ducts. Abnormalities in pancreatic duct common.	Pancreatic duct strictures or narrowing. Often stricture of distal 1/3 of common bile duct. Intrahepatic duct changes less common.
Blood chemistry data	Often cholestatic but bilirubin usually near normal.	May be cholestatic. Bilirubin often high
Autoantibodies	Atypical pANCA plus range of others	Antibodies to carbonic anhydrase II plus range of others <sup>[80,81,84]</sup>
Immunoglobulins	IgG4 levels normal	IgG4 levels usually elevated <sup>[82]</sup>
Histology	Absence of plasma cells positive for IgG4 on immunostaining	IgG4 positive plasma cells present in bile ducts and portal tracts <sup>[79]</sup>
Liver biopsy staging	Range of Ludwig staging including higher stages eg III or IV	Ludwig staging usually only I or II <sup>[86]</sup>
Treatment	Ursodeoxycholic acid ± biliary drainage for dominant strictures	Systemic steroid therapy usually leads to complete resolution of symptoms and signs of disease. Occasionally patients relapse and require longer courses of steroids

Table 6 Evidence for the influence of immune mechanisms on the aetiology of PSC

	Evidence for the influence of immune mechanisms
Humoral immunity	Increased circulating immune complexes Elevated immunoglobulin levels (IgG and IgM) Low titres of non-organ specific autoantibodies (ANA and SMA) High titres of antineutrophil nuclear antibody (ANNA)
Cell mediated immunity	Decreased levels of circulating peripheral CD8+ve T cells Portal T cell and NK cell infiltrate Increased activated and memory T cells Restricted T cell receptor repertoire (Vβ3) Aberrant expression of HLA-DR on BEC Coexpression of costimulatory molecules and HLA-DR on BECs Abnormal expression of adhesion molecules on biliary epithelial cells Abnormal expression of chemokine ligands on biliary epithelial cells
Immune effector mechanisms	Enhanced cytokine expression in the liver
Immunogenetic mechanisms	HLA associations

PSC patients, however, did not find MDR3 variations<sup>[71]</sup>. Similarly, the role of the cystic fibrosis transmembrane conductance regulator (CFTR) remains controversial<sup>[72-74]</sup>. The potential role of other hepatobiliary transporters eg BSEP, AE2 in the pathogenesis of PSC remains to be explored. As defects in these systems are known to cause bile duct injury and cholangitis, they are excellent candidates for further investigation.

The nuclear receptor SXR is a nuclear bile acid receptor which plays an important role in endogenous bile acid homeostasis and cholesterol synthesis. A recent study of PSC patients has shown that functional SXR gene variants modify the disease progression and affect survival<sup>[75]</sup>.

### Autoimmune pancreatitis (IgG4 associated sclerosing cholangitis)

Sarles *et al*<sup>[76]</sup> in 1961 provided the first description of what was later identified as autoimmune pancreatitis, an increasingly recognised benign inflammatory disease of the pancreas<sup>[77]</sup>. Abnormalities and sclerosing changes in both the intra- and extra hepatic bile ducts are well recognised in AIP (see pp this issue), and can cause diagnostic confusion with PSC. Correct diagnosis is important as AIP responds well to corticosteroid therapy and tends to have a significantly better outcome than PSC<sup>[71-81]</sup>. The association of AIP and sclerosing changes in the bile ducts has been termed AIP-SC<sup>[81-85]</sup>. Diagnostic criteria for AIP have been proposed and developed by the Japan Pancreas society<sup>[86]</sup>. These criteria consist of the finding of a diffuse narrowing of the pancreatic duct on imaging studies, and either a laboratory finding of an abnormally elevated serum gamma globulin, IgG, or more particularly IgG4 or the presence of autoantibodies or classical histopathological features of the disease ie fibrotic changes with a lymphocyte and, characteristically, plasma cell infiltration. The differences between the two conditions are summarised in Table 5.

## CONCLUSION

Immune mechanisms play an important role in the pathogenesis of PSC, although it remains unclear whether it is a classical autoimmune disease (Tables 2 and 6). There are strong MHC genetic associations including HLA molecules and the MIC molecules. HLA haplotypes however do not account for all the genetic susceptibility in the development of PSC and there is uncertainty about the importance of genes outside this region. Bacterial antigens may act as molecular mimics in hosts who are genetically susceptible and therefore cause an immune reaction leading to PSC initiation.

Lymphocytes may move from the inflamed gut in IBD *via* the enterohepatic circulation and cause inflammation of the liver when activated by a specific stimulus such as bacterially derived antigens.

## Abstract

Liver disorders with a likely autoimmune pathogenesis in childhood include autoimmune hepatitis (AIH), autoimmune sclerosing cholangitis (ASC), and *de novo* AIH after liver transplantation. AIH is divided into two subtypes according to seropositivity for smooth muscle and/or antinuclear antibody (SMA/ANA, type 1) or liver kidney microsomal antibody (LKM1, type 2). There is a female predominance in both. LKM1 positive patients tend to present more acutely, at a younger age, and commonly have partial IgA deficiency, while duration of symptoms before diagnosis, clinical signs, family history of autoimmunity, presence of associated autoimmune disorders, response to treatment, and long-term prognosis are similar in both groups. The most common type of paediatric sclerosing cholangitis is ASC. The clinical, biochemical, immunological, and histological presentation of ASC is often indistinguishable from that of AIH type 1. In both, there are high IgG, non-organ specific autoantibodies, and interface hepatitis. Diagnosis is made by cholangiography. Children with ASC respond to immunosuppression satisfactorily and similarly to AIH in respect to remission and relapse rates, times to normalization of biochemical parameters, and decreased inflammatory activity on follow up liver biopsies. However, the cholangiopathy can progress. There may be evolution from AIH to ASC over the years, despite treatment. *De novo* AIH after liver transplantation affects patients not transplanted for autoimmune disorders and is strikingly reminiscent of classical AIH, including elevated titres of serum antibodies, hypergammaglobulinaemia, and histological findings of interface hepatitis, bridging fibrosis, and collapse. Like classical AIH, it responds to treatment with prednisolone and azathioprine. *De novo* AIH post

liver transplantation may derive from interference by calcineurin inhibitors with the intrathymic physiological mechanisms of T-cell maturation and selection. Whether this condition is a distinct entity or a form of atypical rejection in individuals susceptible to the development of autoimmune phenomena is unclear. Whatever its etiology, the recognition of this potentially life-threatening syndrome is important since its management differs from that of standard anti-rejection therapy.

## INTRODUCTION

Autoimmune liver disorders of childhood are inflammatory liver diseases characterized histologically by a dense mononuclear cell infiltrate in the portal tract and serologically by the presence of non-organ and liver specific autoantibodies and increased levels of transaminases and IgG, in the absence of a known etiology. They usually respond to immunosuppressive treatment, which should be instituted as soon as diagnosis is made. In children, as well as in young adults, autoimmune hepatitis (AIH) often presents acutely and has a more aggressive course than in older patients. The previously accepted requirement of 6 mo duration of symptoms before diagnosis can be made has been abandoned. In children, there are two liver disorders in which the liver damage is likely to arise from an autoimmune attack: classical AIH and AIH/sclerosing cholangitis overlap syndrome (autoimmune sclerosing cholangitis, ASC). A possible autoimmune pathogenesis has also been postulated for the so called post liver transplantation "*de novo* AIH", a condition originally described in children and later confirmed in adults. According to data collected at the Kings College Hospital tertiary center, there is an increase in

the yearly prevalence of AIH and ASC in childhood, although referral bias may play a role. Thus, in the 1990s these conditions were diagnosed in 2.3% of about 400 children older than 4 mo referred during one year, while in the 2000s their incidence increased to 12%.

## AUTOIMMUNE HEPATITIS (AIH)

### Clinical features

Two types of childhood AIH are recognized: AIH type 1 is characterized by the presence of smooth muscle (SMA) and/or antinuclear (ANA) antibodies; AIH type 2 is positive for anti liver kidney microsomal type 1 (anti-LKM-1) antibody<sup>[1]</sup>. Type 1 AIH represents two thirds of the cases and is a disease of children and adults, while type 2 AIH is mainly described in children. Severity of disease is similar in the two types of AIH<sup>[1]</sup>. In both, there is a predominance of girls (75%-80%). Anti-LKM-1 positive patients are younger and have a greater tendency to present with acute liver failure, but the duration of symptoms before diagnosis and the frequency of hepatosplenomegaly are similar in both groups. Both have a high frequency of associated autoimmune disorders (about 20%) and a family history of autoimmune disease (40%). Associated autoimmune disorders include thyroiditis, inflammatory bowel disease, vitiligo, insulin-dependent diabetes, nephrotic syndrome in both types<sup>[1]</sup>. Type 2 AIH can be associated to autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED), an autosomal recessive genetic disorder in which the liver disease is reportedly present in about 20% of the cases<sup>[2]</sup>.

There are three clinical patterns of disease onset<sup>[1]</sup>: (1) in at least 40% of patients, the presentation is indistinguishable from that of an acute viral hepatitis (non-specific symptoms of malaise, nausea/vomiting, anorexia, and abdominal pain, followed by jaundice, dark urine, and pale stools), some children, particularly anti-LKM-1 positive, develop acute hepatic failure with grade II to IV encephalopathy 2-8 wk from onset of symptoms; (2) in 25%-40% of patients, the onset is insidious, with an illness characterized by progressive fatigue, relapsing jaundice, headache, anorexia, and weight loss, lasting from several months and even years before diagnosis; (3) in about 10% of patients, there is no history of jaundice, and the diagnosis follows presentation with complications of portal hypertension, such as splenomegaly, hematemesis from esophageal varices, bleeding diathesis, chronic diarrhea, and weight loss. The mode of presentation of AIH in childhood is therefore variable, and the disease should be suspected and excluded in all children presenting with symptoms and signs of prolonged or severe liver disease. The course of the disease can be fluctuating, with flares and spontaneous remissions, a pattern which may result in delayed referral and diagnosis. The majority of children, however, even those presenting with acute hepatitis, on physical examination reveal clinical signs of an underlying chronic liver disease, i.e. cutaneous stigmata (spider nevi, palmar erythema, leukonychia, striae),

**Figure 1** Portal and periportal lymphocyte and plasma cell infiltrate, extending to and disrupting the parenchymal limiting plate (interface hepatitis). Swollen hepatocytes, pyknotic necroses, and acinar inflammation are present. HE staining (Picture kindly provided by Dr. Alberto Quaglia).

firm liver and splenomegaly; at ultrasound the liver parenchyma is often nodular and heterogeneous.

### Diagnosis and laboratory findings

Diagnosis of AIH is based on a series of positive and negative criteria defined by the International AIH Group (IAIHG)<sup>[3,4]</sup>. Though these criteria have been produced mainly for research purposes, they have been validated also in the clinical practice. Liver biopsy is necessary to establish the diagnosis of AIH, the typical histological picture include: a dense mononuclear and plasma cell infiltration of the portal areas, which expands into the liver lobule; destruction of the hepatocytes at the periphery of the lobule with erosion of the limiting plate ("interface hepatitis"); connective tissue collapse resulting from hepatocyte death and expanding from the portal area into the lobule ("bridging collapse"); hepatic regeneration with "rosette" formation (Figure 1). In addition to the typical histology, other positive criteria include elevated serum transaminase and IgG/gammaglobulin levels, and presence of ANA, SMA, or anti-LKM-1. Negative criteria relevant to the paediatric age are evidence of infection with hepatitis B or C virus, Wilson disease, and drug or alcohol consumption.

**Autoantibodies:** A key criterion for the diagnosis of AIH is the detection of ANA, SMA, and anti-LKM-1 by indirect immunofluorescence. Autoantibody detection not only assists in the diagnosis but also allows, as mentioned above, differentiation of AIH in type 1 and type 2. ANA and SMA and anti-LKM-1 are practically mutually exclusive<sup>[5]</sup>; in those rare instances when they are present simultaneously, the child is classified as having AIH type 2. Recognition and interpretation of the immunofluorescence patterns is not always straightforward<sup>[5]</sup>. The operator dependency of the technique and the relative rarity of AIH explain the non-infrequent occurrence of errors in reporting, particularly of less frequent specificities such as anti-LKM-1. Problems do exist between laboratory reporting and clinical interpretation of the results that are partly dependent on clinicians' unfamiliarity with the disease spectrum of AIH, but also partly dependent on

insufficient standardization of the tests. This problem is being addressed by the autoimmune serology committee of the IAIHG<sup>[5]</sup>.

The basic technique for the routine testing of autoantibodies relevant to AIH is indirect immunofluorescence on a freshly prepared rodent substrate that should include kidney, liver, and stomach to allow the detection of ANA, SMA, anti-LKM-1 as well as anti liver cytosol type 1 (anti-LC-1, see below), but also of anti-mitochondrial antibody (AMA), the serological hallmark of primary biliary cirrhosis, a disease affecting almost exclusively adults. Since a high proportion of healthy adults may show ANA or SMA reactivity at the conventional starting serum dilution of 1/10, the arbitrary dilution of 1/40 is considered clinically significant by the IAIHG in the adult population. In contrast, in healthy children autoantibody reactivity is infrequent, so that titers of 1/20 for ANA and SMA and 1/10 for anti-LKM-1 are clinically relevant. Hence, the laboratory should report any level of positivity from 1/10, and the attending physician should interpret the result within the clinical context and the age of the patient.

ANA is detectable as a nuclear staining in kidney, stomach, and liver. Its pattern can be homogeneous, or coarsely or finely speckled. In most cases of AIH, but not in all, the pattern is homogeneous. For a clearer and easier definition of the nuclear pattern, HEp2 cells that have prominent nuclei can be used. These cells, however, should not be used for screening purposes, because nuclear reactivity to HEp2 cells is frequent at low serum dilution (1/40) in the normal population<sup>[6]</sup>. ANA reactivity is not specific to AIH, being detectable in chronic viral hepatitis B and especially C, though at lower titre, and in non-hepatic autoimmune disorders.

SMA is detected on kidney, stomach, and liver. On the renal substrate, it is possible to visualize a V (vessels), G (glomeruli), and T (tubules) staining<sup>[7]</sup>. VG and VGT patterns are the most frequently detected in AIH<sup>[8]</sup>. The VGT pattern corresponds to the so called "F actin" or microfilament (MF) pattern observed using cultured fibroblasts as substrate. Though "anti-actin" reactivity is present in the majority of patients with AIH type 1, some 20% of SMA positive AIH type 1 patients do not have the F-actin/VGT pattern<sup>[8]</sup>. The absence, therefore, of anti-actin SMA does not exclude the diagnosis of AIH<sup>[8]</sup>. As for ANA, SMA can be found in chronic viral hepatitis B or C and extrahepatic autoimmune disorders.

Anti-LKM-1 stains brightly the liver cell cytoplasm and the P3 portion of the renal tubules, but does not stain gastric parietal cells. Anti-LKM-1 is often confused with AMA, since both autoantibodies stain liver and kidney, though AMA stains the liver more faintly and the renal tubules more diffusely with an accentuation of the small distal ones and, in contrast to anti-LKM-1, it also stains the gastric parietal cells. In the context of childhood AIH, patients reported to be AMA positive are almost invariably positive for anti-LKM-1, since AMA positive AIH in children is extremely rare<sup>[9]</sup> and PBC even rarer, only two cases having been documented histologically and immunoserologically, both being

teenage girls<sup>[10]</sup>. The identification of the molecular targets of anti-LKM-1, i.e. cytochrome P4502D6, and of AMA, i.e. enzymes of the 2-oxo-acid dehydrogenase complexes, has led to the establishment of commercial immunoassays based on the use of the recombinant or purified antigens<sup>[11]</sup> that can resolve any doubts remaining after immunofluorescence examination. Anti-LKM-1 is highly specific for AIH type 2, being found outside this condition in a small proportion (~5%) of patients chronically infected by the hepatitis C virus, that usually possess the human leukocyte antigen (HLA) allele *DRB1\*07*.

Other autoantibodies less commonly tested but of diagnostic importance in paediatric AIH include those to liver cytosol type 1 (LC-1), anti-neutrophil cytoplasm (ANCA) and soluble liver antigen (SLA). Anti-LC-1, which can be present on its own, but frequently occurs in association with anti-LKM-1, is an additional marker for AIH type 2 and targets formimino-transferase cyclodeaminase (F<sub>1</sub>TCDF)<sup>[12]</sup>. In AIH type 1, as well as in inflammatory bowel disease and sclerosing cholangitis, ANCA is frequently found and targets a peripheral nuclear perinuclear antigen (hence the suggested name of pANNA, i.e. peripheral anti nuclear neutrophil antibody). pANNA is virtually absent in type 2 AIH<sup>[7]</sup>. Anti-SLA that was originally described as the hallmark of a third type of AIH<sup>[13]</sup>, is also found in some 50% of paediatric patients with type 1 and type 2 AIH, where it defines a more severe course<sup>[14]</sup>.

There are a small proportion of children with AIH without detectable autoantibodies. The prevalence and the clinical characteristics of this rare seronegative form of AIH, which responds to immunosuppression similarly to the seropositive forms, remain to be defined.

**Comparison between type 1 and type 2 AIH:** Clinical, laboratory and histological features of type 1 and 2 AIH are summarized in Table 1. In Northern Europe, type 1 AIH is associated with the presence of human leukocyte antigen (HLA) *DRB1\*03*<sup>[11,11]</sup>, while type 2 AIH is associated with the presence of *DRB1\*07* and, less frequently, with *DRB1\*03*<sup>[15]</sup>. In South America, the HLA *DRB1\*1301* allele is reported to predispose to paediatric AIH type 1 and is also associated with persistent infection with the endemic hepatitis A virus<sup>[16,17]</sup>. Interestingly, in Northern European children HLA *DRB1\*1301* is associated with autoimmune sclerosing cholangitis (see below). It is conceivable that some South American children diagnosed as having AIH type 1, but in whom routine cholangiograms were not performed, indeed had ASC.

Paediatric patients with AIH, whether anti-LKM-1 or ANA/SMA positive, have isolated partial deficiency of the HLA class III complement component C4, which is genetically determined<sup>[18]</sup>.

Anti-LKM-1-positive patients have higher levels of bilirubin and transaminases at presentation than those who are ANA/SMA positive and present significantly more frequently with fulminant hepatic failure<sup>[1]</sup>. Excluding children with the fulminant presentation, a

AIH: Autoimmune hepatitis; ASC: Autoimmune sclerosing cholangitis; ANA: Anti-nuclear antibodies; SMA: Anti-smooth muscle antibody; LKM1: Liver kidney microsomal type 1 antibody; pANCA: Perinuclear anti-neutrophil cytoplasmic antibody; SLA: Soluble liver antigen; C4: C4 component of complement; HLA: Human leukocyte antigen. <sup>1</sup>Measured by radioligand assay; <sup>2</sup>Increased in HLA DR\*0701 negative patients.

severely impaired hepatic synthetic function, as assessed by the presence of both prolonged prothrombin time and hypoalbuminemia, is more common in ANA/SMA-positive than in anti-LKM-1 positive patients. The vast majority of patients have increased levels of IgG, but some 20% do not<sup>[1]</sup>, indicating that normal IgG values do not exclude the diagnosis of AIH. Partial IgA deficiency is significantly more common in LKM1-positive than in ANA/SMA-positive patients<sup>[1,19]</sup>.

The severity of interface hepatitis at diagnosis is similar in both types, but cirrhosis on initial biopsy is more frequent in type 1 than in type 2 AIH, suggesting a more chronic course of disease in the former. Of note is that most patients already cirrhotic at diagnosis present with a clinical picture reminiscent of that of prolonged acute viral-like hepatitis. Multiacinar or panacinar collapse, which suggests an acute liver injury, is more frequently seen in type 2 AIH. The question as to whether the acute presentation in these patients represents a sudden deterioration of an underlying unrecognized chronic process or a genuinely acute liver damage remains open. Progression to cirrhosis during treatment is more frequent in type 1 AIH. As mentioned above, in both a more severe disease and a higher tendency to relapse is associated to the possession of antibodies to soluble liver antigen (SLA), which are

present in about half of the patients with AIH type 1 or 2 at diagnosis<sup>[11]</sup>.

**Differential diagnosis:** Since positive autoimmune serology can be present in conditions other than AIH, in particular ASC<sup>[20]</sup>, chronic hepatitis B<sup>[21]</sup> or C<sup>[22]</sup> virus infections, and Wilson disease<sup>[23]</sup>, all these disorders must be considered in the differential diagnosis and excluded. ASC, described below, shares the same serological profile as type 1 AIH, but has typical bile duct lesions on cholangiography. Up to 50% of children with hepatitis B and C are positive for ANA and/or SMA, usually at low titres<sup>[21,22]</sup>, and some 5% of patients with chronic hepatitis C have anti-LKM-1 antibodies. In these patients the histology can also mimic AIH, though usually the degree of inflammation is milder. Detection of the typical viral markers allows a correct diagnosis. ANA, and at times SMA, can be present in Wilson disease, in association with high IgG and an inflammatory liver histology, which can make the differential diagnosis with AIH type 1 difficult. Urinary, serum, and liver tissue copper studies and search for Kayser Fleischer rings should be performed in all cases.

**APECED:** APECED is a monogenic disorder<sup>[24,25]</sup> with a variable phenotype. About 20% of the cases develop AIH that resembles AIH type 2<sup>[2]</sup>. This condition, also known as autoimmune polyendocrine syndrome 1 is an autosomal recessive disorder caused by homozygous mutations in the *AIRE1* gene and characterized by a variety of organ-specific autoimmune diseases, the most common of which are hypoparathyroidism and primary adrenocortical failure, accompanied by chronic mucocutaneous candidiasis.

### Etiology and pathogenesis

The etiology of AIH is unknown, though both genetic and environmental factors are involved in its expression. Etiological hypotheses and possible mechanisms leading to the liver autoimmune attack are described under "Etiopathogenesis of AIH" in this issue.

### Management and prognosis

AIH is exquisitely responsive to immunosuppression. The rapidity and degree of response depends on the disease severity at presentation. All types of presentations, apart from fulminant hepatic failure with encephalopathy, respond to standard treatment with prednisolone with or without azathioprine.

Standard treatment for AIH consists of prednisolone 2 mg/kg per day (maximum 60 mg/d), which is gradually decreased over a period of 4 to 8 wk with progressive normalization of the transaminases, and then the patient is maintained on the minimal dose able to sustain normal transaminase levels, usually 2.5 mg/d or 5 mg/d depending on age<sup>[1,26]</sup>. During the first 6 to 8 wk of treatment, liver function tests should be checked weekly to allow a frequent fine-tuning, avoiding severe steroid side effects. If progressive normalization of the liver function tests is not obtained over this period of time

or if too high a dose of prednisolone is required to maintain normal transaminases, azathioprine is added at a starting dose of 0.5 mg/kg per day, which, in the absence of signs of toxicity, is increased up to a maximum of 2-2.5 mg/kg per day until biochemical control is achieved. Azathioprine is not recommended as first-line treatment because of its hepatotoxicity in severely jaundiced patients, but 85% of the patients will eventually require azathioprine addition. A preliminary report in a cohort of 30 children with AIH suggests that the measurements of the azathioprine metabolites 6-thioguanine and 6-methylmercaptopurine are useful in identifying drug toxicity and non-adherence and in achieving a level of 6-thioguanine considered therapeutic for inflammatory bowel disease<sup>[27]</sup>, though what is an ideal therapeutic level for AIH has not been determined. Although an 80% decrease of initial transaminase activity is obtained within 6 wk from starting treatment in most patients, complete normalization of liver function may take several months. In the King's series, normalization of serum transaminase activity occurred at median of 6 mo in ANA/SMA positive children and 9 mo in LKM-1 positive children<sup>[1]</sup>. Relapse while on treatment is common, occurring in about 40% of the patients and requiring a temporary increase of the steroid dose. An important role in relapse is played by non-adherence that is common, particularly in adolescents<sup>[28]</sup>. Moreover, the risk of relapse is higher if steroids are administered on an alternate-day schedule, often instituted in the belief that it has a less negative effect on the child's growth. Small daily doses are more effective in maintaining disease control and minimize the need for high-dose steroid pulses during relapses, with consequent more severe side effects<sup>[1]</sup>.

A question frequently asked by the parents of teenaged girls is whether treatment can be safely continued during pregnancy. Although the experience is limited, there does not appear to be adverse events for mother and baby<sup>[29]</sup>. In particular, no teratogenic effects have been described with azathioprine in humans, though for women concerned about its use, treatment with steroids alone can be used.

Cessation of treatment is considered if a liver biopsy shows minimal or no inflammatory changes after at least one year of normal liver function tests. However, it is advisable not to attempt to withdraw treatment within three years from diagnosis or during or immediately before puberty, when relapses are more common. The reasons for this are unclear, though an important role may be played by non-adherence, as mentioned above. In the Kings experience, successful long-term withdrawal of treatment was achieved in 20% of patients with AIH type 1, but in none with AIH type 2<sup>[1]</sup>.

In paediatrics, an important role in monitoring the response to treatment is the measurement of autoantibody titers and IgG levels, the fluctuation of which is correlated with disease activity<sup>[30]</sup>.

Despite the efficacy of standard immunosuppressive treatment, severe hepatic decompensation may develop even after many years of apparently good biochemical

control, leading to transplantation 10-15 years after diagnosis in 10% of the patients. In the Kings College Hospital series<sup>[1]</sup>, over 97% of the patients treated with standard immunosuppression were alive between 0.3 and 19 years (median 5 years) after diagnosis, including 8% after liver transplantation. Side effects of steroid treatment were mild, the only serious complication being psychosis during induction of remission in 4%, which resolved after prednisolone withdrawal. All patients developed a transient increase in appetite and mild cushingoid features during the first few weeks of treatment. After five years of treatment, 56% of the patients maintained the baseline centile for height or went up across a centile line, 38% dropped across one centile line, and only 6% dropped across two centile lines<sup>[31]</sup>. Moreover, it has recently been shown that long-term daily treatment with prednisolone in children with autoimmune liver disease does not affect their expected final adult height according to parental stature<sup>[32]</sup>.

Sustained remission, achieved with prednisolone and azathioprine, can be maintained with azathioprine alone in some children with AIH type 1, akin to the experience in adults<sup>[33]</sup>, but not in AIH type 2.

In those patients (up to 10%) in whom standard immunosuppression is unable to induce stable remission or who are intolerant to azathioprine, mycophenolate mofetil at a dose of 20 mg/kg twice daily can be successfully used<sup>[31]</sup>. In case of persistent no response or of intolerance to mycophenolate mofetil (headache, diarrhea, nausea, dizziness, hair loss, or neutropenia), the use of calcineurin inhibitors (cyclosporine A or tacrolimus) should be considered.

Children who present with acute hepatic failure pose a particularly difficult therapeutic problem. If not encephalopathic, they usually benefit from conventional immunosuppressive therapy, but only one of the six children with acute liver failure and encephalopathy in the Kings series responded to immunosuppression and survived without transplantation<sup>[1]</sup>.

## AUTOIMMUNE SCLEROSING CHOLANGITIS

ASC has the same prevalence as AIH type 1 in childhood<sup>[18]</sup>. This has been shown in a prospective study conducted over a period of 16 years, in which all children with serological (i.e. positive autoantibodies, high IgG levels) and histological (i.e. interface hepatitis) features of autoimmune liver disease underwent a cholangiogram at the time of presentation. Approximately 50% of these patients had alterations of the bile ducts characteristic of sclerosing cholangitis, though generally less advanced than those observed in adult primary sclerosing cholangitis (Figure 2). A quarter of the children with ASC, despite abnormal cholangiograms, had no histological features suggesting bile duct involvement and the diagnosis of sclerosing cholangitis was only possible because of the cholangiographic studies. Virtually all patients were seropositive for

**Figure 2** Retrograde cholangiogram of a child with autoimmune sclerosing cholangitis showing widespread bile duct strictures and dilatations (Picture kindly provided by Dr. Maria Sellars).

**Table 2** Laboratory parameters at presentation in children with autoimmune hepatitis and autoimmune sclerosing cholangitis<sup>[20]</sup>

	AIH	ASC
Bilirubin (nv < 20 micromol/L)	35 (4-306)	20 (4-179)
Albumin (nv > 35 g/L)	35 (25-47)	39 (27-54)
AST (nv < 50 IU/L)	333 (24-4830)	102 (18-1215)
INR (< 1.2)	1.2 (0.96-2.5)	1.1 (0.9-1.6)
GGT (nv < 50 IU/L)	76 (29-383)	129 (13-948)
AP (nv < 350 IU/L)	356 (131-878)	303 (104-1710)

AST: Aspartate aminotransferase; INR: International normalized prothrombin ratio; GGT: Gamma glutamyl transpeptidase; AP: Alkaline phosphatase; nv: Normal values.

ANA and/or SMA. Fifty-five percent were girls, and the mode of presentation was similar to that of typical AIH. Inflammatory bowel disease was present in about 45% of children with ASC compared to about 20% of those with AIH, and 90% of children with ASC had greatly increased serum IgG levels. At the time of presentation, standard liver function tests did not help in discriminating between AIH and ASC (Table 2), though the alkaline phosphatase/aspartate aminotransferase ratio was significantly higher in ASC. pANNA were present in 74% of patients with ASC compared to 45% of patients with AIH type 1 and 11% of those with AIH type 2. Susceptibility to ASC in children is conferred by the presence of HLA *DRB1\*1301*<sup>[32]</sup>. Clinical, laboratory, and histological features of type 1 and 2 AIH and ASC are compared in Table 1.

Children with ASC respond to the same immuno-suppressive schedule described above for AIH<sup>[18]</sup>, liver test abnormalities resolving within a few months after starting treatment in most patients. Steroids and azathioprine, however, though beneficial in abating the parenchymal inflammatory lesions, appear to be less effective in controlling the bile duct disease. Following favorable reports in adult primary sclerosing cholangitis<sup>[33,34]</sup>, ursodeoxycholic acid is added at the dose of 20-30 mg/kg per day, though there is no information as to whether it is helpful in arresting the progression of ASC. Akin to AIH, measurement of autoantibody titers and IgG levels is useful in monitoring disease activity and response to treatment<sup>[20]</sup>. The medium-term prognosis is good, with a reported 7-year survival of 100%, though 15% of the patients required liver transplantation during this period

of follow-up<sup>[18]</sup>. Evolution from AIH to ASC has been documented suggesting that AIH and ASC are part of the same pathogenic process<sup>[18]</sup>.

The prospective study conducted at Kings College Hospital shows that in childhood ASC and AIH have a similar prevalence<sup>[20]</sup>. It also shows that ASC is more frequent than sclerosing cholangitis without autoimmune features<sup>[20]</sup>, autoantibody negative sclerosing cholangitis having been observed in only 9 children referred over the 16-year study period<sup>[20]</sup>.

Whether childhood ASC and adult PSC belong to the same disease spectrum remains to be established, since no prospective study in a large patient cohort has investigated at the time of presentation the presence of bile duct damage in adults with features of autoimmune liver disease. Interestingly, in a retrospective study, a high proportion of adult patients originally diagnosed as having AIH type 1 were found to have sclerosing cholangitis on magnetic resonance cholangiography<sup>[34]</sup>. The long term follow up of the Kings paediatric ASC series will provide important information about the possible links between ASC and PSC.

## DE NOVO AIH AFTER LIVER TRANSPLANTATION

In the late 1990s, it was observed that AIH can arise *de novo* after liver transplantation in children who had not been transplanted for autoimmune liver disease<sup>[35]</sup>. Characteristic of this condition is a histological picture of interface hepatitis and multilobular collapse associated with increased IgG levels and positive autoantibodies. These include ANA, SMA, and classical anti-LKM-1, but also atypical anti-LKM-1, staining the renal tubules but not the liver. After this original report, *de novo* AIH after liver transplantation has been confirmed by several studies both in adult and paediatric patients<sup>[36,37]</sup>. Importantly, treatment with prednisolone and azathioprine using the same schedule for classical AIH, concomitant with reduction of the calcineurin inhibitor dose, is highly effective in *de novo* AIH, leading to excellent graft and patient survival. It is of interest that these patients do not respond satisfactorily to standard anti-rejection treatment, making it essential to reach an early diagnosis to avoid graft loss.

Whether the liver damage observed in these patients is a form of rejection or the consequence of an "auto-immune" injury, possibly triggered by drugs or viral infection, remains to be established. The administration of cyclosporin A or tacrolimus to rodents after bone marrow transplantation can result in a "paradoxical" autoimmune syndrome in which the immunosuppressive drugs interfere with maturation of T lymphocytes and favor the emergence of autoaggressive T-cell clones<sup>[35-37]</sup>. This experience in animals may explain, in part, the development of this disorder in immunosuppressed children after liver transplantation.

The manifestations of the autoimmune condition in rodents vary in different strains and depend on genetic

factors possibly encoded by the major histocompatibility complex<sup>[35]</sup>. Analysis of the HLA phenotypes of the recipients and donors in the original report did not show an association between the development of autoimmune features, the presence of either HLA *DRB1\*03* or *-DRB1\*04*, or the degree of donor-recipient HLA mismatch<sup>[28]</sup>. Five of the seven patients, however, had received livers from donors with HLA markers known to be associated with susceptibility to AIH, including two with *DRB1\*04*, one with *DRB1\*03*, and two with both *DRB1\*03* and *DRB1\*04*<sup>[38]</sup>.

## Abstract

The three major immune disorders of the liver are autoimmune hepatitis (AIH), primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC). Variant forms of these diseases are generally called overlap syndromes, although there has been no standardized definition. Patients with overlap syndromes present with both hepatitic and cholestatic serum liver tests and have histological features of AIH and PBC or PSC. The AIH-PBC overlap syndrome is the most common form, affecting almost 10% of adults with AIH or PBC. Single cases of AIH and autoimmune cholangitis (AMA-negative PBC) overlap syndrome have also been reported. The AIH-PSC overlap syndrome is predominantly found in children, adolescents and young adults with AIH or PSC. Interestingly, transitions from one autoimmune to another have also been reported in a minority of patients, especially transitions from PBC to AIH-PBC overlap syndrome. Overlap syndromes show a progressive course towards liver cirrhosis and liver failure without treatment. Therapy for overlap syndromes is empiric, since controlled trials are not available in these rare disorders. Anticholestatic therapy with ursodeoxycholic acid is usually combined with immunosuppressive therapy with corticosteroids and/or azathioprine in both AIH-PBC and AIH-PSC overlap syndromes. In end-stage disease, liver transplantation is the treatment of choice.

## INTRODUCTION

The term “overlap syndrome” is used to describe variant forms of autoimmune hepatitis (AIH) which present with characteristics of AIH and primary biliary cirrhosis (PBC) or primary sclerosing cholangitis (PSC). Standardization of diagnostic criteria for overlap syndromes has not been achieved so far, since these disorders are uncommon. It remains unclear whether these overlap syndromes form distinct disease entities or are only variants of the major immune hepatopathies<sup>[1,2]</sup>.

Overlap syndromes should always be considered once an autoimmune liver disease has been diagnosed<sup>[1]</sup>. Patients with overlap syndromes usually present with nonspecific symptoms, including fatigue, arthralgias, and myalgias. A hepatitic biochemical profile typically coexists with cholestatic laboratory changes<sup>[3,4]</sup>. Interestingly, transitions from one to another autoimmune hepatopathy have also been reported and are discussed together with the overlap syndromes<sup>[5,6]</sup>. Overlap of autoimmune cholangitis (AMA-negative PBC) and AIH has been described anecdotically and is discussed together with AIH-PBC overlap syndromes. Although combined features of both PBC and PSC have been reported in single cases<sup>[7]</sup>, there is no clear evidence for the existence of an overlap of PBC and PSC.

It appears inappropriate to use the term overlap syndrome for coexistence of AIH and other chronic liver diseases like chronic hepatitis C. Autoantibodies are detected in up to 65% of patients with chronic hepatitis C and LKM1 antibodies, the hallmark of AIH type 2 was also observed in 7% of the patients with chronic hepatitis C<sup>[8]</sup>. Conversely, in patients with AIH and hypergammaglobulinemia, anti-HCV tests in the past turned out to be false positive in many cases<sup>[9]</sup>. Thus, the term overlap syndrome should not be used for patients with AIH and concomitant chronic hepatitis C.

This article is an extension of a recent review<sup>[10]</sup> and discusses current views and controversies on overlap syndromes. A case report is included to exemplify the typical features of an AIH-PBC overlap syndrome.

## DIAGNOSIS OF AUTOIMMUNE LIVER DISEASES

The diagnostic criteria of AIH, PBC and PSC are discussed in detail in this issue of the *World Journal of Gastroenterology* and are therefore just summarized briefly, since they are the basis for the diagnosis of the respective overlap syndrome.

### AIH

The diagnosis of AIH depends on several descriptive criteria which were summarized and updated by the International AIH Group (IAIHG) in 1999<sup>[11]</sup>. A definite diagnosis requires exclusion of other major causes of liver damage, including alcoholic, viral, drug- and toxin-induced, and hereditary liver disease. The scoring system includes characteristic laboratory features (hepatic serum liver tests, the presence of elevated serum IgG or  $\gamma$ -globulins and of serum autoantibodies), histocompatibility leucocyte antigen (HLA) associations, a portal mononuclear cell infiltration and interface hepatitis in the liver tissue and a positive treatment response to corticosteroids<sup>[11]</sup>.

### PBC

The diagnosis of PBC is based on a cholestatic serum enzyme pattern, serum antimitochondrial antibodies (AMA) and/or PBC-specific AMA-M2, and a compatible histology. Although elevated serum IgM is characteristic for patients with PBC, it is not regarded mandatory to establish the diagnosis<sup>[12,13]</sup>. PBC is frequently associated with other autoimmune disorders, like Sjögren's syndrome, Hashimoto thyroiditis, and celiac disease.

### PSC

PSC is a rare chronic cholestatic disease of the liver and bile ducts that is generally progressive and leads to end-stage liver disease. In contrast to PBC, twice as many men as women are affected. PSC is diagnosed most frequently in patients aged between 25 and 40 years<sup>[14]</sup>. Criteria for the diagnosis of PSC include cholestatic serum enzyme pattern, typical cholangiographic findings of bile duct stenoses and dilatations and histologic findings compatible with PSC showing mild to moderate portal infiltration<sup>[14,15]</sup>. Concomitant inflammatory bowel disease is found in 70%-90% of the patients and atypical perinuclear antineutrophil cytoplasmatic antibodies (pANCA) are detected in more than 70% of the patients<sup>[16]</sup>.

## AIH-PBC OVERLAP SYNDROME

PBC and AIH are the most frequent autoimmune hepatopathies with a prevalence of 25-40/100 000<sup>[17,18]</sup> and 17/100 000<sup>[19]</sup>, respectively, in recent epidemiologic studies in Europe and the United States and female gender predominates in both AIH (80%) and PBC (90%-95%). Serum liver tests typically show a hepatic pattern in AIH and a cholestatic pattern with marked elevation of aP and  $\gamma$ -GT, but mild elevation of

**Table 1** Diagnostic criteria of AIH-PBC overlap syndrome proposed by Chazouillères *et al* in 1998<sup>[5]</sup>

AIH (2 out of 3 criteria)

- (1) Alanine aminotransferase (ALT) levels  $> 5 \times$  ULN
- (2) Serum immunoglobulin G (IgG) levels  $> 2 \times$  ULN or a positive test for smooth muscle antibodies (ASMA)
- (3) Liver biopsy showing moderate or severe periportal or periportal lymphocytic piecemeal necrosis

PBC (2 out of 3 criteria)

- (1) Alkaline phosphatase (AP) levels  $> 2 \times$  or  $\gamma$ -glutamyltranspeptidase (GGT) levels  $> 5 \times$  ULN
- (2) Positive test for antimitochondrial antibodies (AMA)
- (3) Liver biopsy specimen showing florid bile duct lesions

ULN: Upper limit of normal value.

serum transaminases in PBC. While serum IgG is the predominant immunoglobulin elevated in AIH, serum IgM is elevated in most patients with PBC.

Patients presenting with clinical, biochemical, serological and histological features of both diseases have been reported since the 1970s<sup>[20,21]</sup>. Later, the term "overlap syndrome" was used to describe these conditions, although there was no common definition or uniformly accepted diagnostic criteria for this<sup>[22,23]</sup>. Two extended analyses provided evidence for AIH-PBC overlap in 8% of 199 patients with AIH ( $n = 162$ ) or PBC ( $n = 37$ )<sup>[1]</sup> and in 9% of 130 patients with PBC<sup>[5]</sup>. In the latter study, an AIH-PBC overlap syndrome was accepted when 2 or 3 criteria for PBC and AIH were fulfilled<sup>[5]</sup> (Table 1). Although these diagnostic criteria for an AIH-PBC overlap syndrome are not validated and their sensitivity has not been established, they provide a diagnostic template that can be consistently applied<sup>[4]</sup>.

In a comparative study, patients with AIH-PBC overlap syndrome presented with typical features of PBC (AMA-M2 positive, bile duct damage compatible with PBC), but a more hepatic picture than a cohort of PBC patients<sup>[24]</sup>. Patients with AIH-PBC overlap syndrome showed a predominant HLA type B8, DR3, or DR4 similar to AIH and a good response to corticosteroid treatment, and this was, therefore, named "PBC, hepatic form"<sup>[24]</sup>. Autoantibodies are generally believed to present a hallmark for the diagnosis of AIH, but up to 20% of patients with AIH present without antinuclear antibodies (ANA), anti-smooth muscle antibodies (ASMA), or antibodies against liver-kidney-microsomes (LKM) 1<sup>[11]</sup>. ANA represent the least specific serum autoantibodies for the diagnosis of chronic liver diseases and are also found in 30% of elderly healthy controls, 10% of pregnant women, and 30% of patients with malignancies<sup>[25]</sup>. Serum ANA in patients with PBC are not a marker of AIH-PBC overlap syndrome, but often found in PBC patients without further signs of AIH<sup>[26]</sup>. In contrast, ANA with a specific immunofluorescence pattern of multiple nuclear dots directed against Sp100 (5-10 dots) or Coilin p80 (2-6 dots) are rather specific although less sensitive for PBC<sup>[25]</sup>. In 3.9% of 233 patients with PBC, the presence of soluble liver antigen (SLA) autoantibodies was found to be a marker of AIH-PBC overlap syndrome with a good

response to immunosuppressive therapy<sup>[27]</sup>.

In addition to AIH-PBC overlap syndrome, some patients presented with typical features of PBC or AIH<sup>[5,28]</sup>. A well-defined series of 12 patients with PBC followed by AIH was described in 282 PBC patients<sup>[29]</sup>. The time interval between the diagnosis of PBC and the diagnosis of AIH varied from 6 mo to 13 years. Of importance, patients with multiple flares of hepatitis at the time of diagnosis of AIH had already developed cirrhosis on liver biopsy<sup>[29]</sup>. Remission was achieved in 80% of the patients who received additional immunosuppressive therapy. This case series emphasizes the possible role of AIH in the deterioration of liver function in PBC patients unless diagnosis is made early and steroid therapy is administered. This study suggested that these patients may have two coincident autoimmune diseases rather than a variant of PBC or AIH<sup>[29]</sup>. A recent retrospective analysis indicated that patients with AIH-PBC overlap syndrome might have worse clinical outcomes compared to patients with PBC alone<sup>[30]</sup>. However, this conclusion is somewhat controversial, since the treatment was not standardized and no difference was found when the diagnostic criteria proposed by Chazouilleres *et al*<sup>[5]</sup> were applied in this cohort of patients.

### Therapy

Randomized controlled trials are the best method to address therapeutic issues. However, the low prevalence of AIH-PBC overlap syndrome has made controlled therapeutic trials in these patients impossible so far. Thus, therapeutic recommendations still rely on the experience in the treatment of either AIH or PBC, and on retrospective, non-randomized studies with inherent limitations. It remains controversial if patients with AIH-PBC overlap syndrome require immunosuppressive treatment in addition to ursodeoxycholic acid (UDCA). In a strictly defined cohort of 16 patients with AIH-PBC overlap syndrome, the response to UDCA therapy (13-15 mg/kg daily) and the survival of the patients were similar to patients with classical PBC<sup>[31]</sup>. However, other groups reported that a combined therapy of UDCA and corticosteroids is required in most patients to obtain a complete biochemical response<sup>[5,24]</sup>. This question was addressed again recently in a retrospective study of 17 patients with AIH-PBC overlap syndrome<sup>[32]</sup>. In this study, patients received UDCA alone or UDCA in combination with immunosuppressors and were followed up for 7.5 years. In the patients treated with UDCA alone, biochemical response was observed in only 3 patients whereas 8 patients were non-responders and 50% of them showed increased fibrosis. All but one of the non-responders subsequently received combined therapy, and 85% of the patients achieved biochemical remission<sup>[32]</sup>. In the second group of patients who received combined therapy throughout the study, fibrosis did not progress and 67% achieved biochemical remission. Thus, it appears appropriate to start treatment with UDCA (13-15 mg/kg daily). However, if this therapy does not induce an adequate biochemical response in an appropriate time span (e.g. 3 mo) or in patients with predominantly

hepatic serum liver tests, a glucocorticosteroid should be added. Prednisone has been used at an initial dose of 0.5 mg/kg daily and should be progressively tapered once ALT levels show a response<sup>[32]</sup>. The role of other immuno-suppressants, e.g. azathioprine (1-1.5 mg/kg daily) in the long-term management of patients with AIH-PBC overlap syndrome is unclear, but its successful use in AIH makes azathioprine an attractive alternative to corticosteroids for long-term immunosuppressive therapy<sup>[3,32]</sup>. Budesonide, a synthetic corticosteroid with a high first pass metabolism that reduces its systemic side effects, is a promising treatment option for patients with AIH and has also been used in patients with AIH-PBC overlap syndrome with success<sup>[33,34]</sup>. For corticosteroid-resistant patients with AIH-PBC overlap syndrome, intermediate treatment with other immunosuppressants such as cyclosporine A has been considered<sup>[23]</sup>. Liver transplantation is regarded as the treatment of choice for end-stage disease.

### A case report of AIH-PBC overlap syndrome

A 57-year-old woman presented to our outpatient clinic in May 2007 for evaluation of abnormal serum liver tests. She reported fatigue and slight pruritus, but was otherwise in good general health. In January 2007, elevated serum liver tests were detected for the first time when she went for a routine medical examination. At presentation, serum liver tests revealed elevated  $\gamma$ -GT ( $2 \times N$ ), elevated transaminases (AST  $2.5 \times N$ , ALT  $5.5 \times N$ ), and normal bilirubin. Serum AMA (1:3840) and AMA-M2, ASMA and SLA were positive, whereas ANA, LKM1 and ANCA were all negative. Her immunoglobulins showed elevated IgG (23.2 g/L) and IgM (3.3 g/L). Metabolic and viral liver diseases were ruled out. A liver biopsy disclosed an interface hepatitis and mild portal fibrosis without evidence of cirrhosis (Figure 1). AIH-PBC overlap syndrome was diagnosed and a combined therapy of UDCA (13-15 mg/kg daily) and budesonide (6 mg/d) was initiated. Two weeks later, her transaminases decreased by 50% and azathioprine (100 mg/d) was administered. After 3 mo of combined therapy, all serum liver tests were normal and budesonide was tapered to 3 mg/d. At the last follow-up visit in August 2007, the patient reported an improved general condition, and fatigue and pruritus disappeared.

## AUTOIMMUNE CHOLANGITIS (AIC)

### AIC-AIH OVERLAP SYNDROME

AIC shares many features with PBC and is therefore also called AMA-negative PBC. Like PBC, it is characterized by a female preponderance, a cholestatic serum enzyme pattern and florid bile duct lesions on histology and it slowly progresses to fibrosis and cirrhosis of the liver if left untreated<sup>[35]</sup>. Patients with AIC are AMA negative and often present with serum ANA and/or ASMA. Several studies support the view that AIC and PBC are variants of one single disease only differing in serum autoantibody pattern<sup>[36-38]</sup>. Twenty-two of 30 patients

**Figure 1** Overlap syndrome autoimmune hepatitis-primary biliary cirrhosis. A 57-year-old woman presented with elevated  $\gamma$ -GT ( $2 \times \text{ULN}$ ) and transaminases (AST  $2.5 \times \text{ULN}$ , ALT  $5.5 \times \text{ULN}$ ), and normal bilirubin. Serum AMA (1:3840), AMA-M2, ASMA and SLA were positive. Her immunoglobulins showed elevated IgG (23.2 g/L) and IgM (3.3 g/L). A liver biopsy disclosed an interface hepatitis and mild portal fibrosis without evidence of cirrhosis. **A:** HE,  $\times 20$ ; **B:** HE,  $\times 40$  (Courtesy of Prof. Dr. Müller-Höcker, Munich).

with AIC (AMA-negative PBC), but none of the 316 controls, were positive in a new AMA-M2 recombinant assay which detected autoantibodies directed against human E2 members of the 2-oxo acid dehydrogenase complex family<sup>[36]</sup>. In addition, immunohistochemical studies showed that PDC-E2 immunoreactivity was expressed on apical membranes of biliary epithelial cells not only in patients with PBC, but also in 7 of 9 patients with AIC<sup>[37]</sup>. Treatment response to UDCA (13-15 mg/kg daily) and outcome of liver transplantation in end-stage disease were also similar in patients with AIC and those with PBC<sup>[39,40]</sup>. Thus, these data indicate that a majority of AIC patients (when defined as AMA-negative PBC) suffer from “true” PBC.

Concomitant features of AIH and AIC have been reported in single cases. An AMA-negative woman presented with features of an AIH-AIC overlap syndrome based on the presence of hepatitic and cholestatic biochemical changes and interface hepatitis as well as bile duct lesions on histology. In analogy to the therapy of AIH-PBC overlap syndrome, this patient responded to a combined treatment with UDCA and immunosuppressors<sup>[41]</sup>.

## AIH-PSC OVERLAP SYNDROME

While AIH-PBC overlap syndrome is predominantly found among adults, AIH-PSC overlap syndromes have

mainly been described in children, adolescents and young adults<sup>[42-44]</sup>. Use of the modified AIH score led to the diagnosis of an overlap syndrome in 8% of 113 PSC patients and 1.4% of 211 PSC patients, respectively, when evaluated retrospectively<sup>[45,46]</sup>. However, diagnostic criteria are not defined for AIH-PSC overlap syndrome which makes comparability of these studies difficult. In a recently published prospective study, 41 consecutive patients who were diagnosed with PSC were evaluated for an AIH-PSC overlap syndrome<sup>[47]</sup>. The diagnosis of AIH-PSC overlap syndrome was established when the following criteria were met: (1) revised AIH score  $> 15$ ; (2) ANA or ASMA antibodies present in a titre of at least 1:40; and (3) liver histology with piecemeal necrosis, lymphocyte rosetting, moderate or severe periportal or periseptal inflammation<sup>[47]</sup>. By applying these criteria, 17% of the PSC patients were diagnosed with AIH-PSC overlap syndrome. Patients with AIH-PSC overlap syndrome were treated with UDCA (15-20 mg/kg daily), prednisolone (0.5 mg/kg daily, tapered to 10-15 mg/d) and 50-75 mg azathioprine with good biochemical response<sup>[47]</sup>. Of interest, the survival probability of the patients with AIH-PSC overlap syndrome was better than those with classical PSC as assessed by the Mayo score, a prognostic index.

The largest case series of AIH-PSC overlap syndromes in children and adolescents was published by colleagues from the Kings' College in London<sup>[44]</sup>. In this prospective study, a group of 55 children was followed up for 16 years who showed clinical, biochemical, and histological signs of AIH. In 27 of the 55 children, cholangiographic findings were typical of sclerosing cholangitis, whereas other signs and symptoms were characteristic of AIH. Therefore, the term “autoimmune sclerosing cholangitis” (ASC) was proposed for this AIH-PSC overlap syndrome. Patients with ASC more commonly suffered from inflammatory bowel disease and more often were positive for ANCA in serum than those with AIH. Serum transaminases tended to be higher in AIH, but serum alkaline phosphatase although mostly elevated in PSC was normal at several occasions in both diseases. Thus, AIH and ASC may belong to the same disease process and may overlap with PSC.

Increasing awareness for the AIH-PSC overlap syndrome has led to the observation that AIH and PSC may be sequential in their occurrence, and this has first been described in children<sup>[44]</sup>. More recently, a similar observation has been reported in a small case series of 6 adults (mean age 31 years; 4 male; 3 with ulcerative colitis) who developed biochemical and cholangiographic features of PSC after an average of 4.6 years of a diagnosis of AIH and became resistant to immunosuppressive therapy<sup>[6]</sup>. Thus, in patients with AIH who become cholestatic and/or resistant to immunosuppression, PSC should be considered and ruled out.

## Therapy

Ursodeoxycholic acid (UDCA) is widely administered in PSC due to its beneficial effects on serum liver tests,

histological features, prognostic surrogate markers, and development of colonic dysplasia associated with accompanying ulcerative colitis, although long-term efficacy of UDCA still remains unproven<sup>[48-52]</sup>. UDCA at higher doses (> 20 mg/kg daily) may be superior to standard doses for patients with PSC<sup>[53]</sup> and has also been used in the treatment of AIH-PSC overlap syndrome<sup>[47,52]</sup>. UDCA has been used in combination with immunosuppressive drugs in AIH-PSC overlap syndrome, and the long-term course was considered favorable<sup>[44,47]</sup>. Thus, UDCA in combination with an immunosuppressive regimen may be an adequate medical treatment for most patients with AIH-PSC overlap syndrome although data from controlled trials are lacking. Liver transplantation should be considered in late-stage diseases.

## Abstract

Liver-related autoantibodies are crucial for the correct diagnosis and classification of autoimmune liver diseases (AiLD), namely autoimmune hepatitis types 1 and 2 (AIH-1 and 2), primary biliary cirrhosis (PBC), and the sclerosing cholangitis variants in adults and children. AIH-1 is specified by anti-nuclear antibody (ANA) and smooth muscle antibody (SMA). AIH-2 is specified by antibody to liver kidney microsomal antigen type-1 (anti-LKM1) and anti-liver cytosol type 1 (anti-LC1). SMA, ANA and anti-LKM antibodies can be present in de-novo AIH following liver transplantation. PBC is specified by antimitochondrial antibodies (AMA) reacting with enzymes of the 2-oxo-acid dehydrogenase complexes (chiefly pyruvate dehydrogenase complex E2 subunit) and disease-specific ANA mainly reacting with nuclear pore gp210 and nuclear body sp100. Sclerosing cholangitis presents as at least two variants, first the classical primary sclerosing cholangitis (PSC) mostly affecting adult men wherein the only (and non-specific) reactivity is an atypical perinuclear antineutrophil cytoplasmic antibody (p-ANCA), also termed perinuclear anti-neutrophil nuclear antibodies (p-ANNA) and second the childhood disease called autoimmune sclerosing cholangitis (ASC) with serological features resembling those of type 1 AIH. Liver diagnostic serology is a fast-expanding area of investigation as new purified and recombinant autoantigens, and automated

## INTRODUCTION

The presence of autoantibodies plays a central role in the diagnosis and classification of autoimmune liver diseases (AiLD)<sup>[1,2]</sup>, but their nature and significance remain challenging in regard to pathogenesis. Such antibodies discriminate between distinct subtypes of the AiLD and facilitate diagnosis of the overlap syndromes<sup>[3]</sup>. AiLD represent a broad range of disorders that can affect one or the other of the two cellular components, namely hepatocytes in autoimmune hepatitis (AIH), and cholangiocytes in primary biliary cirrhosis (PBC), primary sclerosing cholangitis (PSC) and the autoimmune hepatitis/sclerosing cholangitis overlap syndrome of childhood, designated as autoimmune sclerosing cholangitis (ASC)<sup>[4]</sup>, and discussed elsewhere in this issue.

Antibody to nuclei (ANA) and/or to smooth muscle (SMA) characterizes type 1 AIH (AIH-1) and antibody to a liver kidney microsomal constituent (anti-LKM) defines patients with type 2 AIH (AIH-2)<sup>[5]</sup>. Usually the two patterns of serology are mutually exclusive, but in the rare cases in which they coexist, the disease features resemble those of AIH-2<sup>[6]</sup>. ASC is a third form of AiLD

which is similar clinically, histologically and serologically to AIH-1, but is associated with radiological changes of sclerosing cholangitis<sup>[7]</sup>. SMA, ANA and to a lesser extent anti-LKM can be found in post-transplantation *de novo* AIH<sup>[8]</sup>. The presence of anti-mitochondrial antibodies (AMA) with a specificity for the E2 subunit of the pyruvate complex (PDC-E2), and certain PBC-specific ANA, characterise PBC<sup>[1,9]</sup>. Perinuclear anti-neutrophil cytoplasmic antibody (p-ANCA) is the most frequent antibody reactivity in primary sclerosing cholangitis (PSC)<sup>[1,3]</sup>, but *per se* has low specificity for diagnosis.

## HISTORICAL NOTES ON AUTOIMMUNE LIVER SEROLOGY

The evolution of knowledge on AIH is discussed in another article in this issue. Here we provide a brief historical survey of the serological tests currently used by diagnostic laboratories.

### Anti-nuclear antibody (ANA)

Serum antibodies with specificity for cell nuclear antigens were first described by Miescher *et al* in 1954<sup>[10]</sup> following the discovery of the lupus erythematosus (LE) cell by Hargraves and colleagues<sup>[11]</sup> and the recognition that the LE cell phenomenon was related to a serum factor reacting with nuclear antigens, subsequently termed “antinuclear factor” (ANF), and later antinuclear antibody (ANA). Deoxyribonucleic acid (DNA) and deoxyribonucleoprotein (DNAP) were identified in 1957 as “ANF” target antigens<sup>[11,12]</sup> and it was further shown that antibodies responsible for the LE-cell phenomenon reacted with DNA and gave a “homogenous” pattern of nuclear staining by immunofluorescence<sup>[13]</sup>. In 1956 a positive test for LE cells in blood was reported in young women with a chronic liver disease then called chronic active hepatitis (CAH), leading to the designation of “lupoid hepatitis”, an early label for what is now known as AIH-1<sup>[14,15]</sup>. Testing for ANF/ANA by immunofluorescence (IFL) supplanted the cumbersome LE cell test in the early 1960s.

### Smooth-muscle autoantibody (SMA)

Antibodies binding to smooth muscle of rat stomach were initially detected in serum samples of patients with liver diseases by Johnson *et al*, in 1965<sup>[16]</sup>. The presence of SMA in patients with AiLD was confirmed by Whittingham *et al*<sup>[17]</sup>. Patients with non-AiLDs were reported as seronegative for SMA and, notably, also negative were patients with SLE. The antibody was often found in association with ANA, which was already a known marker of AIH, and tended to fade with steroid induced remission. Bottazzo *et al*<sup>[18]</sup> reported that the SMA staining arterial vessels (V), glomerular mesangium (G) and fibers surrounding the kidney tubules (T), responsible for the VGT pattern, was confined to an aggressive form of hepatitis now known to be AIH-1. The antigenic moiety mainly but not exclusively responsible for SMA activity in what in the 1970s was called CAH was identified as filamentous (F) actin<sup>[19-21]</sup>.

### Liver kidney microsomal antibody (anti-LKM)

Cytoplasmic antibodies in “CAH” were described in the laboratory of Deborah Doniach<sup>[22,23]</sup> whose group first used the expression anti-liver kidney microsomal (anti-LKM) antibodies<sup>[24]</sup>. “Microsomal” is something of a misnomer as “microsomes” are the *in vitro* equivalent of particles of the endoplasmic reticulum wherein the antigen is located. Other nosological entities in which anti-microsomal antibodies were evident included drug induced hepatitis, leading to the use of LKM1, LKM2, LKM3 to designate the different immunofluorescent patterns, which reflect the different targeted autoantigens<sup>[25]</sup>. The ability of anti-LKM1 antibodies to define a second serological type of AIH, i.e. AIH type 2, was proposed by Homberg *et al*<sup>[26]</sup>. Three groups independently identified cytochrome P450 IID6 (CYP2D6) as the molecular target of anti-LKM1 antibodies<sup>[27-29]</sup>; the group of Alvarez<sup>[27]</sup> was the first to publish its data in the form of a full-length paper.

As mentioned, other LKM antibody patterns were subsequently described. LKM2 antibodies were recognised in patients with hepatitis induced by tienilic acid<sup>[24]</sup>, a uricosuric diuretic withdrawn from clinical use in 1980 and Rizzetto’s group described LKM3 antibodies in a proportion of cases of chronic hepatitis D infected patients<sup>[30]</sup>. In contrast to anti-LKM1 and LKM2 antibodies, anti-LKM3 stained human exocrine pancreas and thyroid. Anti-LKM2 reacted with CYP2C9 and anti-LKM3 with uridine diphosphate glucuronosyl transferases (UGT)<sup>[25]</sup>. A fourth type of LKM antibodies recognising CYP1A2 and CYP2A6 has been described in patients with AIH associated with autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED)<sup>[31]</sup>. The IFL pattern of the antibody is indistinguishable from that of anti-LKM1. An anti-liver microsomal antibody (anti-LM) staining the centrolobular hepatocytes but not the kidney and which recognises CYP1A2 has been described in dihydralazine-induced hepatitis and in a few cases of AIH<sup>[32-34]</sup>.

### Liver cytosol antibody (anti-LC1)

Anti-LC1 were originally described in association with anti-LKM1, or in isolation, by Martini *et al* in patients with AIH-2<sup>[35]</sup>. Lenzi *et al* have also found anti-LC1 antibodies in 14% anti-LKM-1 antibody positive patients suffering from chronic hepatitis C virus infection<sup>[36]</sup>. The enzyme formiminotransferase cyclodeaminase (FTCD) has been identified as the molecular target of anti-LC1 antibodies<sup>[37,38]</sup>.

### Mitochondrial antibody (AMA)

The first indication that PBC could be an autoimmune disease was obtained in 1958 when the serum of a woman with PBC was found to contain high titres of complement-fixing antibodies directed to tissue homogenates<sup>[39]</sup>, that later, by absorption studies, were shown to be absorbed by a rat liver mitochondrial fraction<sup>[40]</sup>. A breakthrough for the clinical hepatologist was the observation in 1965 by Walker, Doniach,

Roitt and Sherlock that human tissue sections rich in mitochondria give a characteristic immunofluorescence pattern when they are incubated with sera from patients with PBC but not with controls which, in that study, included patients with extra-hepatic bile duct obstruction, drug induced cholestasis and viral hepatitis<sup>[41]</sup>. In 1967, Berg *et al*<sup>[42]</sup> demonstrated that PBC sera reacted *in vitro* with a trypsin-sensitive mitochondrial antigen that was named M2 antigen, in contrast to M1, the target of anti-cardiolipin antibody. Subsequently Berg developed a nomenclature based on the types of anti-mitochondrial reactivity that spanned M3-M9, but this is no longer used. The M2 antigen was located at the inner surface of the inner mitochondrial membrane of all mitochondria tested<sup>[42-45]</sup>. The target antigens of M2 were identified in the 1980s as components of the 2-oxo-acid dehydrogenase complexes, the predominant target being the E2 subunit of pyruvate dehydrogenase complex, as judged by molecular cloning<sup>[46,47]</sup>. PBC-specific AMA were later shown to recognise other enzymes of the 2-OADC, including the E2 subunits of branched chain oxoacid dehydrogenase complex (BCOADC), the oxoglutarate dehydrogenase complex (OGDC) and the PDC-E3 binding protein<sup>[1,48]</sup>.

#### **Antibodies against soluble liver antigen/liver-pancreas antigen**

Two autoantibodies, anti-soluble liver antigen (SLA) and anti-liver-pancreas (LP), both described in AIH by two independent German groups, have been shown to target the same antigen, hence the current name of anti-SLA/LP antibodies<sup>[49-51]</sup>. The LP antigen has first been reported by Berg's group in the supernatant of liver and pancreas homogenates<sup>[50]</sup>. The SLA antigen was described by Manns and colleagues in 1987 as a component of the supernatant of liver and kidney homogenates<sup>[49]</sup>. Anti-SLA antibodies detected by a competitive ELISA were then proposed as markers of a third type of severe AIH seronegative for the conventional AIH-1 autoantibodies<sup>[49]</sup>.

#### **Anti-asialoglycoprotein receptor antibodies**

Attempts to identify antigens specifically expressed on the hepatocyte surface which could serve as self targets in AiLD have led to the description of a crude liver extract preparation known as the liver specific protein (LSP) and its major component, the asialoglycoprotein receptor (ASGPR)<sup>[52,53]</sup>. ASGPR, also designated as hepatic lectin, is a type II transmembrane glycoprotein. It is the only known liver-specific autoantigen, and is constitutively expressed on the hepatocellular membrane.

### **RECOMMENDATIONS FOR AUTOANTIBODY DETECTION BY IMMUNOFLUORESCENCE (IFL)**

IFL is the main technique for the screening of autoantibodies diagnostically relevant to liver disease. The methodology is practically unchanged from that

introduced by Weller and Coons in 1954<sup>[54]</sup>. It uses unfixed, air-dried, tissue sections which are incubated with a test serum potentially containing an antibody. After removing unbound serum by washing, a fluorochrome labelled second antibody, raised in animal and specific for human immunoglobulins, is applied to detect the first tissue-bound antibody<sup>[55]</sup>. Specific patterns can then be recognised using an ultraviolet microscope. A consensus statement in 2004 from the Committee for Autoimmune Serology of the International Autoimmune Hepatitis Group (IAIHG) provided guidelines on how to test for autoantibodies relevant to AIH and concluded that indirect IFL on fresh sections of multi-organ (liver, kidney, stomach) from rodents (usually rat) should be the first line screening<sup>[55]</sup>. The recommendations of the Committee include detailed guidelines for the preparation of substrate, application of the test serum samples, optimal dilution of samples and fluorochrome-labelled revealing agents, selection of controls and identification of diagnostically relevant staining patterns<sup>[55]</sup>. The use of the three tissues enables the simultaneous detection of virtually all the autoantibodies relevant to liver disease, namely SMA, ANA, anti-LKM1, AMA and anti-LC1<sup>[55]</sup>. The first serum dilution recommended for autoantibody detection (before titration) is for adults 1:40, and for children 1:20 for ANA and SMA and 1:10 for anti-LKM1 in children<sup>[55]</sup>.

#### **Autoantibodies detected by IFL and their reactants**

**ANA:** This autoantibody is readily detectable as nuclear staining in all the three tissues of the composite substrate. On the liver it is also possible to identify different patterns, the homogenous being typical of AIH-1<sup>[55]</sup>. A clearer definition of the different ANA patterns seen in PBC is best achieved by the use of the human larynx epithelioma cancer cell line (HEp-2) because these cells have large nuclei, and the mitotic phase of these cells permits the easy detection of anti-centromere antibodies (ACA) because they stain the chromosomes of cells in mitosis<sup>[56,57]</sup>. HEp-2 permit ready detection of the IFL patterns called multiple nuclear dot (MND) and rim-like membranous (RLM) typical of PBC<sup>[58,59]</sup>. Anti-MND stains 5-20 dots of variable size, distributed all over the nucleus but sparing the nucleoli<sup>[58]</sup>. The pattern can be confused with that of ACA but anti-MND do not stain the chromosomes of cells in mitosis whereas ACA do so<sup>[58]</sup>. Moreover, the dots of ACA are all of the same size while those of MND vary in size and number between individual cells<sup>[58]</sup>. In addition to homogenous ANA, speckled and nucleolar patterns are seen in AIH, and to a lesser extent in PBC, but are not disease-specific.

**SMA:** SMA of the VGT pattern is considered specific for AIH-1, though some 20%-40% of patients with AIH-1 do not have it<sup>[55]</sup>. SMA can also be detected, always by IFL, using fibroblasts or HEp-2 cells. The VGT pattern corresponds to the microfilament staining of isolated fibroblasts and represents a cable pattern across the cell<sup>[18]</sup>. Both patterns have been termed "anti-

**Figure 1** Immunofluorescence of anti-mitochondrial (A and B), and anti-liver kidney microsomal antibody (anti-LKM1) (C and D). AMA stain (A) stronger the smaller, distal tubules while anti-LKM1 the proximal tubules of the rat kidney (C). These specificities are frequently misdiagnosed, especially when only the kidney substrate is used and the sections do not contain both proximal and distal tubules. Thus, the use of rat stomach (B) and liver (D) is strongly recommended to prevent misinterpretation; AMA characteristically stain the gastric parietal cells while anti-LKM1 stain the rat liver but not the stomach.

actin” though there is no molecular proof as yet that actin is indeed the only or indeed the main target of VGT SMA.

**Anti-LKM1:** Anti-LKM1 brightly stains the third portion of the proximal renal tubules and the cytoplasm of the hepatocytes but it spares cells of the gastric mucosa<sup>[55]</sup>. Anti-LKM1 is a frequently undiagnosed autoantibody, being commonly misinterpreted as AMA<sup>[1,60]</sup>. AMA is extremely rare in pediatric patients and PBC is extremely rare in childhood<sup>[61,62]</sup>. So, when AMA is reported in a child with clinical and histological characteristics of AIH, the serological report is almost certainly incorrect.

**AMA:** The confusion between AMA and anti-LKM1 occurs because both autoantibodies stain the renal tubules, though with a pattern different to a trained eye and readily appreciated when the kidney tissue section contains both distal and proximal tubules (Figure 1). AMA stains strongly the mitochondria-rich distal tubules which are smaller than the proximal tubules stained by anti-LKM1 antibodies. AMA also stains the gastric parietal cells within the stomach, which are spared by anti LKM1, whereas AMA stains hepatocytes much less brightly than does anti-LKM1. The analysis therefore of the three-tissue substrate should allow a correct serological interpretation. Some serodiagnosticians claim

a utility of HEp-2 cells for recognition of AMA which gives a “string of pearls” pattern of cytoplasmic staining. Unfortunately interpretative problems are still frequent especially in those laboratories where only kidney is used as substrate, and particularly when the tissue is poorly oriented. Advice on how to orient and cut the kidney has been issued by the Autoimmune Serology Committee of IAIHG<sup>[55]</sup>.

**Anti-LC1:** This antibody stains the cytoplasm of hepatocytes with a zonal distribution within the liver, being particularly abundant on perivenous hepatocytes and the renal tubules. In most cases, however, anti-LC1 is obscured by the simultaneous presence of anti-LKM1<sup>[35,36]</sup>. Anti-LC1 can be also detected by gel diffusion techniques such as double dimension immunodiffusion and counter immunoelectrophoresis, techniques in which the cytosol of liver homogenate is used as antigen and the test serum is run with a positive control<sup>[63]</sup>.

**ANCA:** ANCA is detected by indirect IFL using neutrophils as substrate and can give a cytoplasmic (c-ANCA) or perinuclear (p-ANCA) pattern<sup>[64,65]</sup>. The pattern of p-ANCA is an artifact caused by the ethanol fixation of the neutrophils which leads to the migration of some positively charged cytoplasmic antigens to the negatively charged nuclear envelope, so giving the characteristic perinuclear fluorescence staining. An atypical p-ANCA staining, unaffected by ethanol fixation, gives a perinuclear staining subtly different from the classical p-ANCA. It recognizes components of the nuclear envelope and has been described, especially in patients with PSC<sup>[66]</sup>. In view of the location of the antigen, some groups are now describing these antibodies as perinuclear anti-neutrophil nuclear antibodies (p-ANNA)<sup>[67,68]</sup>.

## AUTOANTIGENS OF LIVER-RELATED AUTOANTIBODIES

### Nuclear antigens

No single AIH-1-specific nuclear antigen has been identified so far. A number of nuclear molecular targets has been detected, including centromere, histones, double-stranded DNA, chromatin, and ribonucleoprotein complexes with no single pattern or combination thereof being characteristic of AIH<sup>[3]</sup>, although most typical is a homogenous pattern attributable to anti-chromatin.

### Smooth muscle antigens

SMA giving the “anti-actin” IFL pattern has long been considered highly diagnostic for AIH type 1, its target deemed to be F-actin (noting that purified actin is a monomer G-actin, which is polymerized in the presence of ATP)<sup>[3,20,55,69]</sup>. The advent of commercial kits using highly purified F-actin as target has provided the opportunity both to test the molecular specificity of the SMA giving the IFL actin pattern and to assess the diagnostic performance of antibodies directed to molecularly pure F-actin (anti-FA)<sup>[70-75]</sup>. In Granito and

Villalta's studies, the IFL anti-actin pattern was strongly associated with AIH-1 and so was anti-FA, this latter being marginally more sensitive<sup>[70,74,75]</sup>. When disease specificity of the two reactivities was analysed the IFL pattern was found to be highly specific, being absent or extremely rare in diseases other than AIH-1. In sharp contrast, anti-FA was detectable in patients with viral hepatitis, PBC, primary sclerosing cholangitis, AIH-2 and celiac disease<sup>[70,74,75]</sup>. In a paper by Frenzel, positivity for anti-FA was found in some 75% of patients subsequently diagnosed as having AIH-1 but also in 24% non-AIH patients<sup>[71]</sup>. In an attempt to address the relatively high non-specificity of the molecular assay, Villalta *et al* performed a receiver operating curve (ROC) analysis, from which they deduced for this assay a cut off point giving a specificity similar to IFL: the cut off point had to be increased from the 30 arbitrary units (AU) suggested by the manufacturer to 53 AU<sup>[75]</sup>. At this cut-off point the specificity of the molecular assay was indeed comparable to that of IFL, but the sensitivity dropped by more than 10% below that of IFL.

The results obtained with the IFL and molecular assays overlap considerably, but by no means completely, with several instances of positivity with one test and not with the other<sup>[72,73,75]</sup>. With the availability of highly purified F-actin the question as to whether the antibody responsible for the anti-actin IFL pattern is directed against actin could be tested directly<sup>[70-75]</sup>. Three anti-SMA positive sera containing both reactivities were absorbed with solid phase F-actin: the reactivity against F-actin was abolished (absorbed out) but that giving the fluorescent pattern was unaltered in two of the 3 sera and reduced, but not abolished, in the third<sup>[72]</sup>. In summary, detection of the IFL anti-actin pattern continues to provide to date the best specificity/sensitivity compromise<sup>[55]</sup>. The antibody responsible for the IFL "actin" pattern targets, in addition to actin, molecules other than actin<sup>[3,72]</sup>. The question arises as to whether to maintain the tradition, and with it the term of "anti-actin" for the antibody recognised in IFL, or whether to call it anti-micro filament (MF) pattern as suggested by the Serology committee of the IAIHG<sup>[55]</sup>.

### **LKM1 antigen**

While the target antigens of ANA and SMA certainly need better molecular definition, that of anti-LKM1 in AIH-2 has been clearly identified as the microsomal enzyme cytochrome P450IID6 (CYP2D6)<sup>[5,26-28]</sup>. Its identification has enabled the establishment of assays based on the use of recombinant antigens which have proven useful in solving diagnostic uncertainties between AMA and anti-LKM1<sup>[1,60,76]</sup>. Such ELISAs, however, are not always able to detect anti-LKM1 antibodies in patients with chronic hepatitis C virus infection whereas IFL and radioligand assays can do so possibly because of their ability to identify conformational epitopes undetectable by ELISA<sup>[77-80]</sup>. Short CYP2D6 peptides used as antigenic preparations perform less well than those using full-length CYP2D6 and their diagnostic use is limited.

### **LC1 antigen**

ELISAs for detection of antibodies to FTCD, the target of anti-LC1, have been developed and used in diagnostic laboratories and their diagnostic and clinical relevance is under investigation<sup>[37,38]</sup>.

### **SLA/LP and ASGPR**

Progress has been made in the definition of other autoantibodies frequently present in AIH but undetectable by IFL including antibodies against SLA/LP<sup>[51,81-85]</sup> and ASGPR. Most of anti-SLA/LP positive patients are also positive for ANA, SMA or anti-LKM1, but occasionally anti-SLA is present in isolation and, in this case, its detection is of diagnostic importance<sup>[81,86]</sup>. The identification of the molecular target of anti-SLA/LP antibodies as the UGA serine tRNA-associated protein has led to the development of ELISA or dot-blot assays increasingly replacing the conventional inhibition ELISA originally used for anti-SLA antibody detection<sup>[51,83]</sup>. Recent studies investigating the exact role of this protein have shown that SLA/LP is a selenocysteine synthase but how the biosynthesis of selenocysteine may relate to the pathogenesis of AIH is not known<sup>[87]</sup>.

Anti-ASGPR antibody detection requires either purified or recombinant antigen. The lack of disease-specificity and the difficulty in developing a reliable molecular based assay for the detection of anti-ASGPR has limited its wider applicability in diagnostic practice.

### **Mitochondrial antigens**

The most recent advance in the immunodiagnosis of AMA is the availability of an ELISA using the triple MIT3 hybrid antigen preparation, developed in the Gershwin laboratory. This preparation contains all three immunodominant mitochondrial antigenic epitopes, namely PDC-E2, BCOADC-E2 and OGDC-E2<sup>[88]</sup>. Although assays based on MIT3 are reported to give positive results for PBC sera that test negative for AMA by conventional IFL techniques<sup>[89,90]</sup>, IFL testing for AMA should remain the screening procedure.

### **PBC-specific nuclear antigens**

As mentioned above, major target antigens of PBC-specific ANA have been identified. These include the nuclear body speckled 100 kDa (sp100), promyelocytic leukaemia (PML), and small ubiquitin-like modifier (SUMO) proteins corresponding to the MND pattern, and proteins within the nuclear pore complex (anti-NPC) including the 210 kDa glycoprotein (gp210) and the 62 kDa nucleoporin (NUP62), the major target antigens of anti-RLM antibodies and responsible for the RLM pattern<sup>[58,59,91]</sup>. New immunoassays testing autoantibodies to sp100, PML, gp210 and NUP62 have been developed using short peptides, polypeptides or full-length proteins as targets, but they have not been fully evaluated nor standardized<sup>[91-98]</sup>. They may be of diagnostic assistance, especially in those cases where it is difficult to interpret the IFL staining patterns due to concurrent autoantibody reactivities or in true AMA-negative PBC cases<sup>[1,92,99,100]</sup>. We note also the presence

of ACA reactivity in the combined PBC/CREST disease. Assays to detect multiple reactivities (multiplex) and to provide a full autoimmune serological profile of relevance to PBC are being developed<sup>[89]</sup>. At present, a lack of guidelines for the detection of PBC-specific autoantibodies by scientific bodies responsible for the standardization of autoimmune serological tests is a significant handicap and perpetuates uncertainties on which are the clinically relevant tests (see below).

### Atypical p-ANCA (pANNA) antigens

These are under current investigation<sup>[66-68]</sup>. The original description of a 50 kDa neutrophil-specific nuclear protein of the nuclear pore complex as the target antigen recognised by 90% of atypical p-ANCA from patients with PSC was followed by a study from the same group suggesting that the identity of the antigen is tubulin beta chain 5 (TBB5)<sup>[101]</sup>. However, when using the molecular target for their detection anti-TTB5 antibodies were found not only in PSC but also in other AiLDs.

## DIAGNOSTIC RELEVANCE OF LIVER-RELATED AUTOANTIBODIES

ANA, SMA, anti-LKM1, AMA and p-ANCA should be determined in all patients with biochemical, clinical and/or histological features suggestive of AiLD<sup>[3,5]</sup>. Autoantibody titres usually vary during the course of the disease. Hence seronegativity or low autoantibody titres on a single test cannot exclude the diagnosis of AiLD and repeat tests may allow autoantibody detection and correct disease classification. Conversely, the presence of autoantibodies even at high titres in the absence of any other clinical and laboratory features suggestive of AiLD is insufficient to make a diagnosis though a patient with high titre autoantibodies needs to be seen at regular intervals. Titres of ANA, SMA and LKM1 antibodies contribute in calculating the IAIHG diagnostic score for patients with a probable or definite diagnosis of AIH<sup>[5]</sup>. IFL titres of > 1:80 attract a +3 score; 1:80 a +2 score and 1:40 +1 score. A negative score of -4 is given to cases with hepatic features but detectable AMA at a titre of  $\geq$  1:40; such mixed serology points to “overlap syndrome”, discussed in another article in this issue. In children, titres of 1:20 for ANA or SMA and 1:10 for anti-LKM1 are sufficient to support the diagnosis of AIH if accompanied by other suggestive features<sup>[5,55]</sup>.

In AIH-1, ANA alone are present in 15% of patients, SMA alone in 35%, and ANA and SMA co-occur in 60%<sup>[3]</sup>. In the 5% or so of cases negative for these reactivities, anti-SLA/LP may be positive. In AIH-2 at presentation anti-LKM1 and/or anti-LC1 antibodies are positive in more than 90% of patients<sup>[25,35,36,63]</sup>. In PBC, AMA are detectable in more than 95% of patients and disease-specific ANA occur in 30%-70% of PBC patients according to different reports<sup>[9,58,59,100]</sup>. In PSC, atypical p-ANCA are present in up to 90% of patients but this reactivity also occurs in AIH (up to 70%) and PBC (5%),

as well as frequently in patients with inflammatory bowel disease<sup>[66-68,102,103]</sup>. In what is termed “*de novo*” AIH and in post-liver transplant patients, ANA, SMA, AMA and anti-LKM have been reported, at varying frequencies<sup>[85,94]</sup>. A diagnosis of AIH-2 is strongly supported by seropositivity for anti-LKM1 and/or anti-LC1, particularly in the absence of viral hepatitis C<sup>[5]</sup>. For PBC, the presence of AMA is one of the three widely accepted diagnostic criteria<sup>[9]</sup>.

Autoantibody positivity is part of the criteria used for the diagnosis of AiLD, though it is not diagnostic on its own. Elevated titres and certain patterns carry significant diagnostic connotations.

We are aware of various reports that, at first sight, might appear prejudicial to the diagnostic utility of liver-related autoantibodies<sup>[104]</sup>. Thus ANA and/or SMA are reported in PBC, PSC, *de novo* AIH, chronic viral hepatitis B, C and D, acute liver failure, drug-induced hepatitis, non-alcoholic steatohepatitis, alcohol-induced liver disease, hepatocellular carcinoma, and also in a variety of non-liver related diseases. Hence, the diagnostic significance of antibody positivity depends on the associated clinical features<sup>[3]</sup>, as well as the level of reactivity. Anti-LKM1 and anti-LC1 are reported in a proportion of adult (0%-6%) or pediatric (0%-11%) cases with chronic hepatitis C infection<sup>[36,105-107]</sup>. AMA are present (expectedly) in patients with AIH/PBC overlap syndrome, and also in chronic hepatitis C virus infected patients<sup>[1]</sup>, and most recently were described in patients with acute liver failure<sup>[108]</sup>; AMA occur also in various rheumatological disorders which may co-exist with PBC notably Sjögren's syndrome and systemic sclerosis<sup>[1,48,108-111]</sup> and are described in non-liver related conditions with asymptomatic recurrent bacteriuria in women, pulmonary tuberculosis and leprosy<sup>[112-114]</sup>. However we would submit that in the index disease (AIH or PBC) the frequency and titre of the relevant liver-related autoantibody is substantially higher than for the contrast disease.

Anti-ASGPR antibodies are found particularly in AIH-1 (approximately 90%) but are also present in patients with PBC (14%), chronic hepatitis B and C (7%) and alcoholic hepatitis (8%)<sup>[3,52,115]</sup>. Anti-SLA antibodies can be found in occasional seronegative AIH patients i.e. those who are negative for ANA, SMA or anti-LKM-1. Anti-SLA antibodies are also frequently present (up to 50%, depending on the sensitivity of the method used) in typical cases of AIH-1 and AIH-2, and also in ASC<sup>[86]</sup>. Their high specificity for AiLD has been questioned by reports of anti-SLA being present in some 10% of chronically infected HCV patients<sup>[115]</sup>. More recently, anti-SLA antibodies have been described in 22% of patients with acute liver failure (ALF)<sup>[111]</sup>. Since in most cases of ALF we do not know the cause, the presence of anti-SLA can either detract from their disease specificity or, alternatively, suggest an autoimmune pathogenesis (or an autoimmune component to the pathogenesis) of ALF. Monitoring of autoantibodies may be useful in the case of AIH as disappearance or sharp decrease of ANA, SMA and anti-LKM1 can be an indicator of response to

immunosuppressive treatment<sup>[3,6]</sup>. AMA titres do not relate to the stage of PBC and their fluctuation over time does not seem to have pathogenic significance<sup>[1,9,116]</sup>, although “activity” of the PBC process is not as readily measurable as that of AIH. Practically AMA are only tested at presentation to help establish the diagnosis and repeat tests are normally requested only in cases seronegative for AMA at presentation but with clinical or laboratory findings compatible with PBC<sup>[1,2,117]</sup>.

## PROGNOSTIC SIGNIFICANCE AND UTILITY OF LIVER-RELATED AUTOANTIBODIES

### AIH

Both SMA and ANA tend to lower in titre and even disappear during immunosuppressive therapy in most patients with AIH-1 although neither their titre at diagnosis nor their fluctuations during the disease are thought to predict disease course and outcome<sup>[3]</sup>. However, in 2002 Gregorio *et al* found a positive correlation between SMA titre and AST levels over time in pediatric AIH-1 cases, suggesting a potential use of these antibodies, together with IgG levels, to monitor disease activity<sup>[118]</sup>. There are no comparable adult sequential studies; this may be a reason why no correlation has been ascertained. Nevertheless, Czaja and colleagues have suggested that adult AIH-1 patients with antibodies to anti-actin have a disease onset earlier in life, respond less well to corticosteroids and progress to liver failure or require liver transplantation more frequently compared to those without anti-actin antibodies<sup>[69]</sup>. The presence of antibodies to double stranded DNA (dsDNA) has been associated with higher levels of immunoglobulin G and higher relapse rates during immunosuppressive treatment compared to seronegative cases<sup>[119]</sup>. Seropositivity for anti-ASGPR in patients with AIH correlates with histological activity with persistence indicating unresponsiveness to immunosuppressive treatment, and re-appearance being highly suggestive of relapse especially after corticosteroid withdrawal<sup>[3,52,115,120]</sup>. Anti-SLA antibodies denote patients with a more severe course of AIH and a propensity for relapse after corticosteroid withdrawal compared to their negative counterparts<sup>[49,81,121,122]</sup>. AIH-2 patients with anti-LC1 antibodies have histologically more severe disease compared to those without anti-LC1 antibodies<sup>[35,123,124]</sup>.

### PBC

AMA titres do not seem to be associated with disease severity but those of the IgG3 subclass may identify patients prone to develop more severe disease compared to those without AMA-IgG3<sup>[116,125]</sup>. PBC-specific ANA have been found more frequently in patients with advanced disease in a number of cross-sectional studies. Anti-NPC seropositivity is associated with accelerated progression to advanced disease and death<sup>[94,96,100,126-129]</sup> and also, ACA may identify patients with more severe PBC according to studies from USA and Japan<sup>[96,130]</sup>. These data

have obvious implications for the clinical management of PBC given that the only accepted index for estimating survival has been obtained and validated in patients with advanced PBC and hence is of limited use in early disease. Thus, anti-NPC and ACA testing may be important for identifying asymptomatic patients with a likely unfavourable disease course. Once PBC has progressed to advanced histological stages, and serum bilirubin levels have become abnormal, anti-NPC determinations do not appear to offer any additional advantage over other prognostic models such as the Mayo risk score.

## PATHOGENIC RELEVANCE OF LIVER-RELATED AUTOANTIBODIES

Despite their undoubted clinical relevance in diagnosis and classification of AiLD, the pathogenic role of autoantibodies and the mechanisms through which they may cause liver damage remains a topic for further research, mainly because of the difficulty in discriminating those actively involved in the immunopathogenic cascade, from those secondary to liver cell damage. The mechanism(s) responsible for the induction of liver-related autoantibodies is currently unknown; several possibilities including molecular mimicry and immunological cross-reactivity have been suggested<sup>[78,93,106,131-145]</sup>. Most liver-related autoantibodies have limited organ specificity and this notion militates against a direct pathogenic role in highly organ-specific autoimmune injury. For antibodies with a pathogenic potential, complement-dependent and/or antibody-dependent cell-mediated cytotoxicity (ADCC) are the likely effectors of damage<sup>[131,146]</sup>.

## EMERGING ISSUES: DIAGNOSTIC ACCURACY, QUALITY ASSURANCE AND STANDARDIZATION PROGRAMMES FOR LIVER AUTOIMMUNE SEROLOGY

There are a number of open issues on serum autoantibodies in AiLD. Their diagnostic significance is unquestioned, but problems concerning autoantibody detection and interpretation have not yet been resolved and are not being addressed with sufficient vigour. Several laboratories ignore, for example, the IFL cut-off points recommended by the Committee for Autoimmune Serology of the IAIHG and use their own, thus undermining comparability between different laboratories/centres. Worryingly, the cost per test seems a major reason for arbitrary elevation of cut-off points in routine practice: selecting 1:80 or even 1:160 as a screening dilution expands the number of “negatives” albeit reducing or eliminating the need for re-testing. In patients with AiLD and relatively low autoantibody titres, such as children with AIH, a report that is inaccurately indicative of negativity for autoantibodies can delay diagnosis and, harmfully, defer treatment<sup>[76,147]</sup>. Hence rigorously performed autoantibody testing may in fact

provide a more economical report than a “false negative” one if such leads the clinician to order additional costly diagnostic procedures.

Additional problems for autoantibody testing especially with IFL are intrinsic to the methodology itself. First, availability of tissue substrate comprised of freshly cut sections from cryostat blocks of unfixed liver, kidney stomach tissue is limited to relatively few specialised laboratories. Second, sections of commercial origin are of variable quality because, to lengthen shelf-life, they are treated with fixatives, which readily result in enhanced background staining<sup>[55]</sup>. Third, IFL requires highly-trained and experienced personnel, is time-consuming and cannot be automated, resulting in a low throughput and increased personnel costs leading to a significant shift from IFL towards ELISAs or blot assays based on liver-autoantibody profiles; these compared to IFL are less-time consuming, easy to perform and amenable to automation. However, the authors of this review reiterate the recommendations of the Committee for Autoimmune Serology of the IAIHG stating that the current ELISAs should complement but not replace IFL. Either technique has their *pros* and *cons*, and gives answers to different questions, such that results are not directly comparable<sup>[148-150]</sup>. Most liver-related autoantibodies can be detected by IFL when using a triple rodent tissue. HEP-2 cells can help to differentiate ANA patterns and ethanol-fixed neutrophils can be used for the detection of ANCA. In contrast, ELISAs give answers for (usually) pre-selected individual autoantibody specificities. While the analytical sensitivity of ELISAs is satisfactory, their specificity varies according to the manufacturer<sup>[150]</sup> whereas such problems are rather infrequent by IFL testing based on a triple rodent tissue substrate<sup>[151]</sup>.

Over the last decade there has been a steady increase in the use of the liver-related autoantibody tests to assist both diagnosis and clinical research into ALD<sup>[55]</sup>. This increase has been attributed mainly to the introduction of molecularly based assays for the testing of antibodies to F-actin<sup>[70-75]</sup>, CYP2D6<sup>[152]</sup> and SLA<sup>[83,122,153]</sup> in AIH, and for evaluating antibodies to sp100 and gp210 in PBC<sup>[92,94-96,154]</sup>. Of concern, results for these antibody specificities may be promulgated by laboratories without authentication from externally or independently monitored quality assurance programmes (QAP).

Quality assurance (QA) can occur at three levels. The first is at the level of commercial providers of assay kits, reagents etc who would establish QA “in house” before marketing but who often elect to participate also in QAPs for routine laboratories. The second are the formalised QAPs, run by semi-governmental agencies or other organizations, as described below. The third level, which scarcely exists, involves the end-user, the responsible clinician, who must order tests advisedly with good clinical data and interpret these in the light of the clinical information to make wise evidence-based decisions. Thus it behoves the clinician to become fully aware of the many contributions (and shortcomings) of contemporary diagnostic immunoserology.

## REPRESENTATIVE QUALITY ASSURANCE PROGRAMMES FOR DIAGNOSTIC SEROLOGY IN LIVER DISEASE

### USA

The College of American Pathologists (CAP, [www.cap.org](http://www.cap.org)) runs survey programmes which allow laboratories to evaluate regularly their autoantibody testing performance. Of relevance to liver, CAP circulates coded anti-M2 AMA, anti-LKM1 and SMA samples for testing. The participating laboratories analyse the sera and return their results for evaluation. In return, each laboratory receives an anonymised report of the performance of all participating laboratories.

### UK

A National External Quality Assessment Service (UK NEQAS) ([www.ukneqas.org.uk](http://www.ukneqas.org.uk)) is responsible for the objective assessment of the performance of autoantibody testing. The UK NEQAS for General Autoimmune Serology incorporates one sample in each of six distributions annually for AMA, anti-LKM1 and SMA. The performance reports of the participating laboratories also provide information on kit suppliers. Participation is not limited to UK but is open to non-UK Countries (Table 1).

### Germany

There are currently two regulatory and quality assurance agencies, namely INSTAND (Institut für Standardisierung, [www.instandev.de](http://www.instandev.de)) and DGKL (Deutsche Gesellschaft für Klinische Chemie und Laboratoriumsmedizin, [www.dgkl.de](http://www.dgkl.de)). INSTAND circulates twice per year two samples to be tested for AMA, SMA and anti-LKM1 antibody testing. Participants (150) report results quantitatively and semi-quantitatively (from 0-4 to evaluate antibody titre; 0 = negative; 1 = borderline; 2 = low; 3 = middle; and 4 =

high). There is no reference to specific manufacturers but only to test methods and overall percentage of consistent results. DGKL has a similar approach but evaluations are divided on the basis of the methods used and they provide also information in relation to the kits manufacturers. Target values are determined in two reference laboratories.

### France

Quality autoantibody assessment in France is organised by the French Health Products Safety Agency (AFSSAPS, Agence Française de Sécurité Sanitaire des Produits de Santé, <http://agmed.sante.gouv.fr/>). This Agency has the executive responsibility for proposing relevant QAPs to clinical laboratories, whether in the private or in the public sector. An autoantibody detection survey has been running on an annual basis since 1998.

### Italy

In Italy there are no formal regulatory and quality assurance programmes with several laboratories participating in the surveys by UK NEQAS or CAP. Recently, a study group has been formed (Forum Interdisciplinare per la Ricerca nelle Malattie Autoimmuni-FIRMA-[www.gruppofirma.com](http://www.gruppofirma.com)). FIRMA aims to provide guidelines for autotibody testing and to identify and collect sera of different autoantibody specificities that will be available for all of its member institutions.

### Finland

Labquality at Helsinki offers twice per year three samples for SMA, AMA and anti-LKM1 assessment. Qualitative target values are determined in a reference laboratory and results are listed according to manufacturer and method. Evaluation reports are confidential.

### Australia and New Zealand

QAPs have been established under the auspices of the Royal College of Pathologists of Australasia (RCPA) based on the selection by RCPA of expert organizing groups which distribute batches of sera to diagnostic laboratories that voluntarily elect to participate ([www.rcpaqap.com.au](http://www.rcpaqap.com.au)). Diagnostic laboratories from Australia, New Zealand, and several South East Asian countries together with manufacturers and purveyors of kits participate in this programme. The Tissue Antibodies module includes AMA, SMA and anti-LKM1 antibodies. Feedback to the laboratories is by a report to all participants in which any single laboratory can identify its own performance versus that of all other participants. The RCPA issues certification of participation in this QAP. The reports sent back to laboratories are inspected by the National Association of Testing Authorities (NATA) during laboratory assessment visits. In order to be accredited, laboratories must participate and perform satisfactorily in the relevant proficiency testing programmes. There is a 'regulatory' element here in that NATA certification is required for access to fees under the Medicare rebate scheme.

As expected, quality assurance programmes have highlighted difficulties encountered by peripheral laboratories. In mid-2007, UK NEQAS distributed a serum with a typical anti-LKM1 antibody staining; a substantial proportion (53 out of 356, 15%) of the laboratories reported negativity for anti-LKM1 antibody test and, among these 53 laboratories, 43 incorrectly reported positivity for AMA instead (Peter White, UK NEQAS, personal communication). Also, rather worryingly, several additional laboratories did not return reports on anti-LKM1 either because they themselves do not offer this test or because they ignore its significance (Peter White, UK NEQAS, personal communication).

It is clear that exchange of calibrated reference sera and rigorous standardization programmes on liver-related autoantibody serology are urgently needed. Such initiatives will need to involve initially researchers and laboratories with a special interest in the respective antibody specificities and subsequently clinical laboratories performing routine screening tests. To this end, efforts have been made recently by the IAIHG to arrange an exchange of sera at international level but whether such an initiative will take off depends on securing financial support. Administrative sponsorship should initially come from the International Association for the Study of Liver (IASL), the American Association for the Study of Liver Diseases (AASLD) or the European Association for the Study of Liver (EASL) or from Clinical Immunology Societies of developed countries.

In conclusion, practice guidelines on liver autoimmune serology based on consensus of experts in the field have been issued and need to be steadily updated<sup>[55]</sup>. The more the clinician is aware of these guidelines, the greater the chance of correct and clinically relevant autoantibody diagnosis. It is in the best interest of the patient to obtain eventually the highest possible commitment and coordination of all organizations, agencies, industrial partners and networks working in the field.

## Abstract

Liver transplantation remains an effective treatment for those with end-stage disease and with intractable liver-related symptoms. The shortage of organs for transplantation has resulted in the need for rationing. A variety of approaches to selection and allocation have been developed and vary from country to country. The shortage of donors has meant that new approaches have to be adopted to make maximal use of the available organs; these include splitting grafts, use of extended criteria livers, livers from non-heart-beating donors and from living donors. Post transplantation, most patients will need life-long immunosuppression, although a small proportion can have immunosuppression successfully withdrawn. Newer immunosuppressive drugs and different strategies may allow a more targeted approach with a reduction in side-effects and so improve the patient and graft survival. For autoimmune diseases, transplantation is associated with significant improvement in the quality and length of life. Disease may recur after transplantation and may affect patient and graft survival.

## INTRODUCTION

The three major autoimmune liver diseases that may

require liver transplantation are primary biliary cirrhosis (PBC), primary sclerosing cholangitis (PSC) and autoimmune hepatitis (AIH). In this review, we will discuss the role, timing and outcome of transplantation for these indications.

Criteria for liver transplantation for patients with autoimmune diseases are relatively well defined<sup>[1]</sup>. As with other indications, liver transplantation is indicated either to relieve intractable symptoms of liver disease (such as pruritus or encephalopathy which do not respond to conventional therapy) or to prolong life. Life after transplantation is normally excellent but is never normal. Furthermore, survival is reduced when compared to an age and sex-matched population<sup>[2]</sup>. Reasons for the reduction in survival include the mortality of the procedure itself, the risks of recurrent disease and the consequences of immunosuppression which may be class related (such as an increased risk of sepsis and some malignancies) or more-specifically related to the individual drugs used (such as renal failure and cerebro- and cardio-vascular death). Thus, for most patients with chronic liver disease, timing of transplantation has to be done with consideration of the risks and balance of remaining with the native liver and of the procedure.

Some guidance is given by prognostic models, of which the most commonly used is the model for end-stage liver disease (MELD) formula<sup>[3]</sup>. MELD, initially used to predict short-term survival after stent insertion has been shown to be accurate in prediction of most patients with chronic liver disease. The score, which is derived from serum bilirubin, creatinine and prothrombin time, is useful; for the average patient, there is a survival benefit when transplanted with a score of 16 or more. Addition of other analytes to the formula, such as serum sodium, may increase the accuracy<sup>[4]</sup>. In some situations, the model does not predict outcome. For example, in those with a liver cell cancer where the prognosis without transplant is dependent on the cancer rather than parenchymal function. Other exceptions occur with hepatopulmonary syndromes, for example. There are several recent reviews of the general indications and contra-indications (see for example<sup>[5,6]</sup>).

There is an increasing gap between the number of patients who would benefit from a transplant and the availability of suitable organs for transplantation. In order to fulfil demand, differing strategies have been utilized: this includes use of split livers, non-heart beating donors, marginal donors and to a lesser extent,

living donor programmes. These strategies have, to some extent, masked the shortage of organs. Extended criteria or marginal livers are being utilized in greater numbers, (these are grafts where there is concerns that their use might impact on the outcome of the patient). These include those grafts where there is a greater risk of non-function (characterized by steatosis in the graft, older donors and prolonged cold ischemia times), technical problems (such as the use of split, partial or reduced grafts) or those grafts that carry a risk of transmission of viral infection or malignancy.

Living donor transplantation accounts for around 2%-5% of transplants in Europe and North America but for almost all transplants carried out in Asia, where donation rates from deceased donors are very low. Limitations on living donation focus on the risk to the donor: too much liver volume removed from donor may induce liver failure in the donor, too little may cause recipient graft failure. The mortality for the donor in left lobe is 0.05% rising to 0.4%-0.5% in right lobe transplants and donor morbidity is 20% with long-term outcomes unknown<sup>[7]</sup>.

The shortage of grafts means that rationing must occur: the competing interests of equity, justice and utility have to be recognised. Thus, criteria for selection (that is admission to the list) and allocation (identification of the recipient for a graft) need to be agreed. Different health care systems have adopted different principles. Conflict may exist where transplantation is considered for some indications, such as liver disease from alcohol where the medical views are not in accordance with those of the public<sup>[8]</sup>. The immunological processes that operate in an allografted liver are complex, since the immune system of the host can react against alloantigens, human leucocyte antigen (HLA) molecules and "minor" transplantation antigens of the donor. Concurrently, passenger leucocytes of the donor may react against HLA or other antigens of the host, resulting in "two-way" immune responsiveness. The liver above all other organs has a propensity to generate a state of intra-hepatic immune tolerance that limits harmful immune reactivities, sometimes to the degree that immunosuppressant drugs become dispensable after a liver transplant. The immunological issues involved, which are beyond the scope of this article, are discussed informatively in several reviews<sup>[9,10]</sup>.

Post transplant, most patients will need life-long immunosuppression. However, in the last decade there have been developments in the management of immunosuppression. In the early days of liver transplantation, the principles of immunosuppression after liver transplant were extrapolated from renal transplant programmes. However, there are some major differences: early acute rejection after liver transplantation is not associated with an adverse outcome; the requirement of immunosuppression is less and sometimes, as mentioned, it is even possible to withdraw immunosuppression completely. It is not possible reliably to identify those patients in whom immunosuppression can be safely withdrawn: however, those with good graft

function at 5 years and with minimal inflammation on histology and were not transplanted for autoimmune diseases are most likely to benefit from a planned withdrawal of immunosuppression<sup>[11,12]</sup>.

Tailoring immunosuppression to the individual is a much discussed but little practiced approach. For instance, those grafted for hepatitis C virus infection need to be protected against rejection since major changes in corticosteroids will increase the consequences of viral re-infection. The advent of newer biological agents including humanized monoclonal antibodies such as Campath-1H (alemtuzumab), antibodies to interleukin-2 receptor (IL-2R), and CTLA-4Ig, may permit more selective approaches to immunosuppression. Campath-1H is a humanized monoclonal antibody against CD52, a molecule expressed on the surface of human B and T lymphocytes. Antibodies to the IL2Ra chain target the CD25 molecule on activated T lymphocytes. Cytolytic T-lymphocyte-associated antigen 4 (CTLA-4) Ig is an immunoglobulin fusion protein with CTLA-4, a natural down-regulatory molecule expressed by T lymphocytes. There are other biologicals under investigation. Induction of full tolerance has long been the goal of solid organ transplantation but, despite advances in the laboratory, this goal has so far remained elusive in the human. The adoption of approaches allowing for early immunological engagement (the Window of Opportunity for Immunological Engagement) as suggested by Calne<sup>[13]</sup> or use of Campath-1 or other biologicals may offer a new and effective approach<sup>[14]</sup>.

## AIH

AIH is a relatively uncommon indication for liver transplantation, currently accounting for no more than 5% of cases<sup>[15]</sup>. As with cirrhosis from other causes, liver transplantation is indicated in those with end-stage disease characterized by a MELD score > 16, signs of decompensation on treatment such as hepatic encephalopathy, ascites or variceal haemorrhage or, rarely, with hepatocellular carcinoma development. In those who present with acute or fulminant liver failure, liver transplantation should be considered early in the course. Outcomes are good with 1 year and 5 years patient survival rates of about 87% and 80%-90%. Graft survival rates at 1 year and 5 years are 84% and 74%-76%<sup>[16-18]</sup>.

### **Recurrence after transplantation**

Diagnostic criteria for recurrent AIH (rAIH) have been developed and are summarised in Table 1. The reported recurrence rate of AIH following transplantation is variable 17%-42% at 5 years<sup>[19,20]</sup>. Table 2 shows the reports of recurrent AIH. Gautam's systematic review of 13 papers concluded disease recurrence occurred in 22% of recipients at a median interval of 26.4 mo<sup>[21]</sup>. Czaja suggested that a loss of self-tolerance and molecular mimicry would explain the repopulation of the allograft with recipient antigen-presenting cells and that the already primed promiscuous recipient cytotoxic

Table 1 Criteria for the diagnosis of recurrent AIH

Criteria
Liver transplant for autoimmune hepatitis
Auto-antibodies in significant titre (> 1:40)
Sustained rise in serum aminotransferase activity (> 2 times normal)
Elevated serum immunoglobulins
Compatible liver histology (infiltration of portal tracts by plasma cells, piecemeal necrosis and bridging necrosis <sup>[21]</sup> )
Corticosteroid dependency
Exclusion of other causes of graft dysfunction (such as rejection and HCV infection)

T cells are likely factors for recurrent disease<sup>[22]</sup>.

Many studies have been published in the literature, but most include relatively small numbers, use different criteria for the diagnosis and are retrospective. Reich retrospectively reviewed 24 AIH transplant recipients; 6 patients developed biopsy proven recurrence at 15 mo, 3 proceeded to regrafting and 2 of these patients developed recurrent AIH in the second graft. No patient transplanted for fulminant hepatic failure developed recurrence compared to 1/3 of those with chronic disease<sup>[15]</sup>. Duclos-Vallee performed protocol biopsies and demonstrated histological recurrence preceded biochemical abnormality by 1-5 years in 23.5%<sup>[25]</sup>. There was no difference in survival or recurrence between the three sub-types of AIH. Rates of rejection were high both in the control and AIH groups but greater in those grafted for AIH. (50% and 88%)<sup>[27]</sup>. No patient required re-transplant because of recurrent disease and there was no difference in patient survival or graft survival<sup>[18]</sup>.

There are no consistent risk factors for recurrence identified. Pre-transplant disease duration, donor/recipient gender distribution, HLA studies, and rejection episodes did not correlate with AIH recurrence but the degree of necro-inflammation in the native liver was significantly greater in those with recurrence in one study<sup>[24]</sup>. The choice of immunosuppression is controversial but a recent systematic review by Gautam found no difference in recurrence rates between recipients on tacrolimus (31%) or cyclosporin<sup>[21]</sup>.

Khalaf reported a histological recurrence in 18.7% (median follow up of 530 d) which was successfully treated by optimizing immunosuppression. Steroid withdrawal failed in all recipients and was always accompanied by almost immediate elevation of liver enzymes<sup>[28]</sup>. A case of AIH recurrence 6 years after a living donor related liver transplant, in the absence of autoantibodies was reported. The patient had steroids discontinued 1 year post orthotopic liver transplant (OLT) whilst maintained on tacrolimus but became antinuclear antibody (ANA) positive again 3 years later, 2 years prior to the histological diagnosis but in the absence of abnormal LFTs<sup>[29]</sup>.

### De novo AIH

De novo AIH has features of a steroid responsive AIH in patients transplanted for other non-immune indications and is characterized by a biochemical

Table 2 Reports of recurrent autoimmune hepatitis

Author	Follow up (mo)	n	Recurrence	Period recurrence occurred	Re-OLT/Cirrhosis
Milkiewicz 1999 <sup>[23]</sup>	29	47	13/47	29 mo	3/47
Ayata 2000 <sup>[24]</sup>	67	12	5/12	35-280 d	2/12
Reich 2000 <sup>[15]</sup>	27	24	6/12	At 15 mo	3/24
Molmenti 2002 <sup>[18]</sup>	29	55	11/55	At end	
Duclos-Vallee 2003 <sup>[25]</sup>	120	17	7/17	2.5 yr <sup>1</sup>	2/17
Núñez-Martínez 2003 <sup>[26]</sup>	38	15	1/15	At end	
Vogel 2004 <sup>[27]</sup>	24	28	9/28	5 yr	4/28
Gautam 2006 <sup>[21]</sup>			23%	2.4 mo <sup>2</sup>	

<sup>1</sup>Mean; <sup>2</sup>Median.

hepatitis, circulating auto-antibodies, elevated immunoglobulins and an inflammatory infiltration with interface hepatitis. The first report of de novo AIH was in 7 children at a median of 2 years post-transplant<sup>[30]</sup>. Children are more at risk than adults but the condition is still relatively uncommon with an incidence of around 3%. There is usually a good response to additional immunosuppression with corticosteroids, but in some cases there is progression to cirrhosis and subsequent graft failure<sup>[31]</sup>. Whether this is truly a de novo autoimmune phenomenon or merely a form of rejection is not certain: early studies suggesting an immune response to graft antigens are controversial<sup>[32]</sup> and studies suggesting an immune response to graft isoforms of glutathione-S transferase remain unconfirmed.

### Conclusion

The outcome for OLT in AIH is good and is merited in those with chronic disease and a much smaller cohort will have an acute or fulminating course the prognosis of which is relatively unaffected by corticosteroids. Recurrence of disease is relatively common in the allograft and may be detected on protocol biopsy at an asymptomatic stage before biochemical or clinical clues. Generally recurrent AIH responds well to increases in immunosuppression or addition of corticosteroids. This should be taken into account when considering long term immunosuppression and especially on reduction should be in conjunction with immunoglobulins, autoantibody profile and histology. Most data are retrospective with relatively small numbers and studies are lacking in long term reduction and withdrawal of immunosuppression and further controlled studies are required.

### PBC

#### Indications

Indications for transplantation are listed in Table 3. Unlike pruritus, which is rapidly reversed after transplantation, lethargy is not an indication since often

**Table 3** Indications for transplantation in PBC

Indications
Symptom based
Intractable pruritus refractory to medical therapy
Hepatic encephalopathy
End-stage liver disease
Recurrent variceal haemorrhage
Episode of spontaneous bacterial peritonitis
Pulmonary hypertension
Hepato-pulmonary syndrome
Diuretic resistant ascites
Progressive osteopaenia
Muscle-wasting
Hepatoma (Milan criteria)
Biochemistry
Serum bilirubin > 150 µmol/L
Serum albumin < 25 g/L

it does not improve with transplantation<sup>[33]</sup>. The need for transplantation for PBC is falling (United Network for Organ Sharing (UNOS) data shows, of 2391 cadaveric liver transplants in 1991, 18% were for cholestatic liver disease compared with 10% of 4579 in 2000 and was the second most common indication for transplantation) and the impact of ursodeoxycholic acid (UDCA) is a tempting but controversial explanation.

### Timing of transplantation

A variety of disease-specific prognostic models have been developed but for short term survival a MELD score is effective and a score > 16 indicates a survival benefit from transplantation. Serum bilirubin > 100 µmol/L<sup>[34]</sup> as well as significant poor liver function with length of life attributed to disease limited to 1 year are indicators for transplantation assessment<sup>[35]</sup>. A Mayo risk score > 7.8 has also been validated to indicate survival in the absence of transplantation<sup>[36,37]</sup>.

### Survival after OLT

The 1, 3 and 5 year actuarial patient and graft survival was 94%, 91%, and 82%, and 89%, 83%, and 75%, respectively in a series of 301 PBC transplant recipients in the UK<sup>[38]</sup> which is comparable to European transplant registry data. The commonest indication for re-transplantation in the first year is chronic rejection<sup>[39]</sup>. Survival rates remain consistently better than other indications, even after adjusting for case-mix and other risk factors. Immunosuppression is usually a standard triple regimen of calcineurin inhibitor (tacrolimus or cyclosporin), corticosteroids (withdrawn over 3 mo) and azathioprine or mycophenolate mofetil.

### Recurrent disease

Recurrent disease (Table 4) is diagnosed by characteristic histology and absence of other causes of graft damage. The histology of recurrence is comparable to pre-transplant PBC<sup>[40]</sup>. Patients with anti-mitochondrial antibodies and normal liver function tests in the presence of normal histology may develop recurrence with hallmark granulomatous cholangitis<sup>[41]</sup>. Elevated serum

**Table 4** Criteria for the diagnosis of recurrent PBC

Criteria
Transplantation for PBC
Characteristic histological features of PBC
Mononuclear inflammatory infiltrates
Lymphoid aggregates
Epithelioid granulomas
Bile duct damage
Persistence of anti-mitochondrial antibodies
Elevated immunoglobulins
Exclusion of other causes of graft damage

Definite recurrent PBC is made when all 4 of these criteria are present, and in the presence of at least 3 of the 4 histological features. Probable recurrence when only 2 histological features are present<sup>[40]</sup>.

immunoglobulins and persisting anti-mitochondrial antibodies do not in themselves indicate recurrent disease. Recurrent PBC is seen in 17% of patients at a mean of 36 mo<sup>[42]</sup> rising to 30% at 10 years. Recurrence rates on biopsy as high as 35% at 1 year have been reported<sup>[43]</sup>. The reported median time to recurrence is between 3.7 and 5 years<sup>[44,45]</sup>. Recurrence may not be diagnosed unless a protocol biopsy is taken as the liver tests may be normal<sup>[42]</sup>; indeed only half will have biochemical abnormality<sup>[44]</sup>. Liver tests may remain normal for 5 years after histological diagnosis<sup>[45]</sup>.

The role of UDCA in the treatment or prevention of recurrent PBC remains uncertain. A retrospective review of 154 PBC liver transplant recipients followed at the Mayo Clinic for least 1 year reported that recurrent PBC was not associated with death or liver re-transplantation. 38 patients with recurrent PBC received UDCA at an average dose of 12 mg/kg per day for a mean duration of 55 mo. Over a 36-mo period, an estimated 52% of UDCA-treated patients experienced normalization of serum alkaline phosphatase and alanine aminotransferase compared to 22% of untreated patients but no significant difference in the rate of histological progression was noted between subgroups. UDCA did not influence patient and graft survival<sup>[46]</sup>. It should be noted that this experience does not concord with our own unpublished data where graft loss from recurrent PBC is 4%.

Should all those transplanted for PBC be offered UDCA? The agent is safe and improves all serological parameters and may retard progression so, even in the absence of clear evidence, we would advocate its routine use.

### Risk factors for recurrence

Many studies have evaluated risk factors for recurrence. The literature is mixed concerning donor and recipient age as well as cold and warm ischaemia time<sup>[42,43,47,48]</sup>. The type of immunosuppression used is also controversial<sup>[45,49]</sup>. In a study of 485 recipients followed up over 79 mo, the recurrence rate with tacrolimus was 23% with OR 2.73 and time to recurrence 62 mo compared to 123 mo on cyclosporin ( $P < 0.001$ )<sup>[47]</sup>. Guy found similar results with OR 2.5 for tacrolimus<sup>[43]</sup>. No differences between cyclosporin and tacrolimus were

seen in other trials, though protocol liver biopsies were not performed or were only done in the context of graft dysfunction<sup>[50,51]</sup>. Sanchez reported a 156 patient cohort using protocol biopsies at 1, 2, 5, 10 and 15 year intervals with recurrence in 8.4% of recipients taking cyclosporin, azathioprine and steroids, compared with 12.2% of those receiving cyclosporin and steroids alone and 16.7% of patients taking tacrolimus and steroids ( $P = 0.11$ )<sup>[52]</sup>. Thus the evidence does suggest that cyclosporin is, compared with tacrolimus, associated with a slower rate of progression of recurrent disease. Whether this indicates that those grafted for PBC should be offered cyclosporin-based immunosuppression rather than that based on tacrolimus, and whether those with recurrent PBC should be switched from tacrolimus to cyclosporin is uncertain.

### Implications of recurrence

The consequences of recurrent disease appear to be relatively small<sup>[53]</sup>. In our series of 486 PBC transplant recipients, 3 were re-grafted as a consequence of recurrent disease, all of whom have recurrence in the re-graft<sup>[54]</sup>.

### Quality of life issues

Pruritus may resolve within days of transplantation. Fatigue persists and does not appear to improve post liver transplant<sup>[33]</sup> although there is a great improvement in quality of life<sup>[55]</sup>. Gross studied 157 adult patients with PBC or PSC before and 1 year after liver transplantation. The quality of life following transplantation was significantly better than before transplantation in all aspects but at 1-year follow-up, was not predictable by the pre-transplant subjective health status or clinical factors<sup>[56]</sup>.

## PSC

### Survival after transplantation

Indications for transplantation are as for other end-stage liver disease complications. European data show patient survival at 1, 3, 5 and 10 years was 86%, 79%, 76% and 66% respectively from Jan 1988-June 2006 (www.eltr.org).

### PSC recurrence

Recurrent PSC (Table 5) must be distinguished from secondary sclerosing cholangitis; Characteristic histological features are not always present so the diagnosis may be made on imaging the biliary tree. PSC recurrence is relatively common with figures of 37% at 36 mo and 60 % at 5 years<sup>[57,58]</sup>. Gautam's systematic review of 14 reports revealed a recurrence rate of 17% but was unable to comment upon possible risk factors<sup>[21]</sup>. Sheng studied the prevalence of stricturing disease in 100 patients who underwent transplantation for PSC and 543 controls without PSC. 27% PSC liver recipients compared to 13% of controls showed intra-hepatic strictures by cholangiography. Intra-hepatic and non-anastomotic extra-hepatic strictures were significantly more frequent in the PSC group<sup>[59]</sup>. In a small cohort who underwent living donor liver transplantation with a median follow up of 3.5 years, half developed recurrent

**Table 5** Criteria for the diagnosis of recurrent primary sclerosing cholangitis<sup>[72]</sup>

#### Criteria

Transplant for PSC

Multiple non-anastomotic strictures, headings and irregularity more than 90 d post OLT

Characteristic liver histology (fibrous cholangitis and/or fibro-obliterative lesions) with or without ductopenia, biliary fibrosis or biliary cirrhosis may be seen (but absence of characteristic features does not exclude the diagnosis).

Exclusion of other causes of secondary sclerosing cholangitis & stricturing (due to surgery, trauma, ischaemia, hepatic artery stenosis/thrombosis, established ductopaenic rejection, blood type ABO incompatibility and infections)

Cholestatic liver tests

PSC with the mean time to recurrence 3.3 years (1.1-5.4 years). There was no direct comparison to their cadaveric cohort<sup>[60]</sup>. Khettry retrospectively analysed 51 PSC patients with a follow-up of 2 to 14 years. Of the remaining 42 patients, 6 had recurrent PSC with typical histological and cholangiographic findings, 12 had autoimmune liver disease that was not otherwise specified with histology of AIH/overlap syndrome, 3 had chronic rejection, 4 had ischemic cholangiopathy, and 17 had no recurrence. Post-transplant malignancies were significantly more common in the non-recurrent cases compared with all others combined ( $P = 0.031$ ) and caused death in four. The majority of deaths (11/13) in other groups were due to sepsis. In conclusion, allograft autoimmune liver disease was seen in 18 (43%) of 42 long-term post-LT PSC patients, with progression in 5 of 18 patients. Features of PSC were seen in 6 (33%) of 18<sup>[61]</sup>.

Many factors have been associated with recurrence including steroid-resistant rejection, OKT3 use, preservation injury, ABO incompatibility, cytomegalovirus infection, male sex, donor-recipient gender mismatch and steroid resistant rejection but not specific calcineurin inhibitor use or frequency of rejection<sup>[61-67]</sup>.

Although there is some controversy as to the effect of pre-transplant colectomy on the recurrence rate, our own data consistently show that colectomy either before or during transplant is not associated with recurrent disease whereas the incidence of recurrence in those who had a colectomy post transplant is no different to those with an intact colon. Overall, recurrence of PSC leads to patient and graft loss.

### Colitis and colonic neoplasia after transplantation

Evidence linking immunosuppression with inflammatory bowel disease-free survival is mixed<sup>[68,69]</sup>. Colitis is variable and may present *de novo* after transplantation, with an incidence of 6% at 1 year and 20% at 5 years<sup>[70]</sup>. In a study of 20 PSC transplant recipients with coexisting ulcerative colitis followed over a median period of 11.9 years before OLT and 4.4 years after OLT, there was a significantly higher relapse rate after OLT than pre-transplant. 35% of recipients went onto colectomy after OLT (3 for disease severity and 4 for neoplasia/

dysplasia)<sup>[71]</sup>. These results were mirrored in a study from Birmingham which looked at 152 patients with PSC (100 with coexisting IBD). The incidence of colorectal cancer after transplant was 5.3% compared with 0.6% in non-PSC cases. All cancers in the PSC group were in patients with IBD and an intact colon. The cumulative risk of developing cancer in the 83 patients with an intact colon and IBD was 14% and 17% after 5 and 10 years, respectively. The multivariate analysis identified colonic dysplasia after transplant ( $P < 0.0003$ ), duration of colitis more than 10 years ( $P < 0.002$ ), and pancolitis ( $P < 0.004$ ) as risk factors<sup>[69]</sup>. Colonoscopy is thus recommended annually following transplant.

## FUTURE PROSPECTS

Over the last three decades, liver transplantation has evolved from an experimental, high risk procedure to a routine operation with a high success rate. Indications have widened and contra-indications decreased. Currently, the major limitation remains the shortage of organs so that not everyone who might benefit from the procedure can receive a graft and surgeons have to use extended criteria organs. The use of stem cell therapy and liver cell transplants, remain in their infancy. There still remain considerable challenges ahead: major causes of graft loss include recurrent disease, especially Hepatitis C but also autoimmune diseases, and the side-effects and complications of immunosuppression. The goal of achieving tolerance remains elusive but the development of new agents, especially biologicals, may allow for more effective strategies. The stimulus and challenges of liver transplantation have advanced our understanding of the mechanisms of alloantigen immune recognition and target cell damage and helped introduce new immune-modifying agents and strategies. They have also helped our understanding of the anatomy, physiology and pathophysiology of the liver. However, the long-term goal of clinical research must be the treatment of disease in the native liver so that transplantation becomes redundant.

## Abstract

Chronic viral hepatitis is a common disease in the general population. During chronic hepatitis, the prognosis and clinical management are highly dependent on the extent of liver fibrosis. The fibrosis evaluation can be performed by FibroTest (using serological markers), by Elastography or FibroScan (a noninvasive percutaneous technique using the elastic properties of the hepatic tissue) and by liver biopsy (LB), considered to be the "gold standard". Currently, there are three techniques for performing LB: percutaneous, transjugular and laparoscopic. The percutaneous LB can be performed blind, ultrasound (US) guided or US assisted. There are two main categories of specialists who perform LB: gastroenterologists (hepatologists) and radiologists, and the specialty of the individual who performs the LB determines if the LB is performed under ultrasound guidance or not. There are two types of biopsy needles used for LB: cutting needles (Tru-Cut, Vim-Silverman) and suction needles (Menghini, Klatzkin, Jamshidi). The rate of major complications after percutaneous LB ranges from 0.09% to 2.3%, but the echo-guided percutaneous liver biopsy is a safe method for the diagnosis of chronic diffuse hepatitis (cost-effective as compared to blind biopsy) and the rate of complications seems to be related to the experience of the physician and the type of the needle used (Menghini type needle seems to be safer). Maybe, in a few years we will use non-invasive markers of fibrosis, but at this time, most authorities in the field consider that the LB is useful and necessary for the evaluation of chronic hepatopathies, despite the fact that it is not a perfect test.

## INTRODUCTION

Chronic viral hepatitis is a common disease in the general population. Chronic hepatitis B virus (HBV) infection affects 350 million individuals globally, and approximately 15%-40% may develop serious complications, including end-stage liver disease and hepatocellular carcinoma<sup>[1]</sup>. Chronic hepatitis C virus (HCV) infection is also an important cause of chronic hepatitis, data from World Health Organization (WHO) suggesting that 170 million people are infected world-wide with HCV, 10 million of them in Western Europe<sup>[2]</sup>. It is estimated that at least 3.9 million persons (1.8% of the population) in the United States are anti-HCV seropositive, and that 2.7 million are chronically viremic<sup>[3]</sup>.

At the same time, alcoholic steatohepatitis (ASH) and non-alcoholic steatohepatitis (NASH) are frequent in the developed countries. Regarding NASH, long-term follow up studies on obese patients showed increased cirrhosis-related morbidity and mortality<sup>[4]</sup>. Also, studies on cohorts of diabetic patients showed increased incidence of non-alcoholic chronic liver disease and hepatocellular carcinoma<sup>[5]</sup>.

The complete evaluation of a patient with diffuse liver diseases requires: clinical evaluation, biological evaluation and morphopathological exam-liver biopsy (LB), for the grading and staging of the liver disease. The clinical evaluation is often irrelevant, only the presence of spider naevi on the anterior thorax or an enlarged and firmer liver could suggest that the patient already has liver cirrhosis (suspicion that has to be confirmed or infirmed by further tests). The biological evaluation by means of

the usual tests is also often irrelevant, especially in chronic hepatitis C, known to induce sometimes severe hepatic lesions, while the aminotransferases are normal or only slightly elevated. Thus, it is considered that the liver biopsy has a key role for the diagnosis and follow-up of chronic diffuse hepatopathies, especially for the staging of chronic hepatitis C<sup>[6-9]</sup>.

So, what is the utility of LB in chronic liver disease? Fontollet<sup>[6]</sup> stated that LB has the following roles: to confirm the diagnosis of chronic hepatitis; to assess the necro-inflammatory activity (grading) and the severity of fibrosis (staging); to exclude another hepatopathy or an associated disease; to certify the diagnosis of cirrhosis (when present).

A review of the short history of LB shows us that: Paul Ehrlich is credited with performing the first percutaneous LB in 1883 in Germany; Sheila Sherlock described the percutaneous LB technique in 1945 and after Menghini reported a technique for the “one-second needle biopsy of the liver” in 1958, the procedure became more widely used<sup>[10]</sup>.

But did the LB become a method of diagnosis unanimously accepted by the patients and the doctors? To answer this question we will present the results of a French study, performed on 1177 general practitioners that showed that 59% of the patients infected with HCV refused the LB, opinion shared by 22% of the general practitioners<sup>[11]</sup>.

All these being said, we would like to discuss in this paper several aspects concerning the LB, trying to answer the following questions: (1) Why? (2) Who? (3) How to perform the LB?

## WHY TO PERFORM A LB IN CHRONIC LIVER DISEASE?

During chronic hepatitis, the prognosis and clinical management are highly dependent on the extent of liver fibrosis<sup>[12]</sup>. The fibrosis evaluation can be performed by means of: FibroTest-using serological markers; Elastography or FibroScan-a noninvasive percutaneous technique using the elastic property of the hepatic tissue; liver biopsy-that seems to be the “gold standard”.

### FibroTest

The non-invasive tests for the assessment of the severity of chronic liver diseases are an interesting alternative, more and more evaluated in the last years, aimed to replace, maybe, the LB. After 2000, the non-invasive tests predictive of liver damage were studied more and more, especially in chronic hepatitis C<sup>[13]</sup> and, more recently, also in chronic hepatitis B<sup>[14]</sup> and NASH<sup>[15-17]</sup>.

FibroTest-ActiTest (FT-AT) was developed using biochemical markers and repeatedly demonstrated a high predictive value for fibrosis and necroinflammatory histological activity, in patients with chronic hepatitis C<sup>[18-21]</sup>. In two separate studies the FT-AT has been proven valuable also in patients with chronic hepatitis B<sup>[14, 22]</sup>.

FT-AT is a noninvasive blood test that combines the

quantitative results of six serum biochemical markers (alfa2-macroglobulin, haptoglobin, gamma glutamyl transpeptidase, total bilirubin, apolipoprotein A1 and ALT) with patients' age and gender in a patented artificial intelligence algorithm (USPTO 6631330) in order to generate a measure of fibrosis and necroinflammatory activity in the liver<sup>[14]</sup>. Previously validated FT-AT are used (Biopredictive, Paris, France; Fibro-SURE LabCorp, Burlington, NC), that provide an accurate measurement of bridging fibrosis and/or moderate necroinflammatory activity with AUROC (Area Under Receiver-Operating Characteristic Curve) predictive value between 0.70 and 0.80, when compared to the liver biopsy<sup>[23]</sup>.

It is recommended that FibroTest-ActiTest should not be performed during Ribavirin therapy, because it can induce hemolysis and low haptoglobin levels, nor in patients with Gilbert's syndrome, with acute hepatitis or extra hepatic cholestasis<sup>[23]</sup>, cases in which falsely elevated fibrosis and activity scores can be obtained.

In a recently published editorial in the American Journal of Gastroenterology, Paul Thuluvath<sup>[24]</sup> discusses the FibroTest, stating that it was extensively studied only by Poynard *et al* and that there are only few independent studies. It is also considered that there are significant inter-laboratory variations, thus some studies demonstrated that significant fibrosis can be over-looked or over-rated in approximately 15%-20% of the cases. As a conclusion of this editorial, Paul Thuluvath considers that “we may be approaching a time when serum biomarkers may become an integral part of the assessment of patients with chronic liver disease, but published evidence suggests that these markers are not yet ready for prime time”.

### Elastography or FibroScan

Another non-invasive method of assessment of liver fibrosis is transient elastography. This technique enables the assessment the liver's stiffness and it is performed by a device called FibroScan (Echosens). The main component of the FibroScan is an ultrasound probe mounted on a vibrating device (piston). The patient to be examined lies down on his back and the ultrasound probe is applied to the skin surface between the ribs, thus examining the right liver lobe. The piston induces elastic vibrations, with low frequency and small amplitude that propagate through the liver. The reflected waves are captured by the transducer, their velocity being directly related to the elasticity (stiffness) of the liver. After several elastographic measurements are performed, the mean value must be calculated, thus enabling a correct assessment of the fibrosis.

This method of evaluation is totally painless and lasts only a few minutes. The stiffness of the liver is measured up to 2 cm in depth and on a surface with the diameter of approximately 1 cm (thus enabling the evaluation of a portion of the liver 500 times bigger than by LB)<sup>[25]</sup>. In the study performed by Foucher *et al*<sup>[26]</sup> the stiffness of the liver was measured up to a depth of 4 cm and on a surface with the diameter of 1 cm, so that 1/500 of the liver was evaluated. However the FibroScan device is ex-

ceedingly expensive rising to more than 60 000 Euros.

The value of the FibroScan method for the assessment of the severity of fibrosis in chronic hepatitis is under evaluation, but in the last 2 years several papers were published that demonstrate that this non-invasive method is precise enough to be compared to LB<sup>[12,25-28]</sup>.

In the study performed by Castera *et al*, the elasticity of the liver, measured with the FibroScan device, varied between 2.4 and 75.4 kilopascals (kPa), with a median of 7.4 kPa<sup>[27]</sup>. When comparing the FibroScan to the LB in patients with chronic hepatitis C, the cut-off values were 7.1 kPa for  $F \leq 2$ ; 9.5 kPa for  $F \leq 3$  and 12.5 kPa for  $F = 4$ <sup>[27]</sup>. The area under the receiver operating characteristic curve (AUROC) of FibroScan was 0.83 for  $F \leq 2$ ; 0.90 for  $F \leq 3$  and 0.95 for  $F = 4$ <sup>[27]</sup>. The same authors demonstrated that, when combined with FibroTest, FibroScan was more precise than the LB, the AUROC values reaching 0.88, 0.95 and 0.95 respectively, for fibrosis  $\leq 2$ ,  $\leq 3$  or 4.

In a study performed by Ziolkowski *et al*<sup>[12]</sup> the AUROC value of FibroScan as compared to the LB was 0.79 for  $F \leq 2$ ; 0.91 for  $F \leq 3$  and 0.97 for  $F = 4$ . Thus, the authors concluded that transient elastography appears reliable to detect significant fibrosis or cirrhosis in patients with chronic hepatitis C.

The majority of studies that compared the FibroScan to the FibroTest and to the LB showed a slight superiority of FibroScan *vs* FibroTest<sup>[27,28]</sup>.

Starting from the encouraging results of FibroScan in patients with chronic hepatitis C, this method was also used to evaluate the severity of fibrosis in patients with chronic hepatitis B and in patients with primary biliary cirrhosis (PBC)<sup>[29,30]</sup>.

It is probable that in a not too far future, the combination of FibroScan with FibroTest could avoid biopsy in most patients with chronic hepatopathies<sup>[27]</sup>.

FibroTest and Elastography have a good value for the cases with no fibrosis or with important fibrosis (cirrhosis), but for the intermediate stages the value is low. This is the reason why LB is still the most used method of assessment of the severity of liver lesions in chronic hepatitis, several guidelines recommending that the decision to treat should be made after liver biopsy<sup>[31-32]</sup>.

### Liver biopsy

At this moment LB is still the "gold standard" for the evaluation of chronic hepatitis<sup>[33]</sup>, but the method is not perfect. There are some problems regarding the diagnosis of cirrhosis by LB<sup>[33]</sup> and regarding the differences of the severity of fibrosis when twin LB are performed in both liver lobes<sup>[34]</sup>. This is why we consider appropriate a review of the advantages of LB, of its limits, of the best techniques to perform LB and also of the possible complications.

How representative can be a needle biopsy? The size of a biopsy specimen, which varies between 1 cm and 4 cm in length and between 1.2 mm and 1.8 mm in diameter, represents 1/50 000 of the total mass of the

**Figure 1** Liver biopsies performed in our department in the last years (1996-2005).

liver<sup>[31]</sup>. The British guideline about LB<sup>[31]</sup> considers that most hepatologists are satisfied with a biopsy specimen containing at least six to eight portal triads. A critical review of the literature reveals that biopsy samples 2 cm or more in length, containing at least 11 complete portal tracts, should be reliable for grading and staging chronic viral hepatitis<sup>[35]</sup>. Another study, concerning the dimensions of the biopsy specimen needed in order to perform an accurate pathological diagnosis, demonstrated that a fragment of at least 10 mm is enough for a correct staging and grading<sup>[36]</sup>.

But which is the main reason to perform liver biopsy? The answer is: chronic hepatitis C. In our Department of Gastroenterology, the last 1500 LB were performed to evaluate: chronic C viral infection in 56.0% of the cases; chronic B viral infection in 34.2% of the cases; chronic viral coinfection in 3.2% of the cases; NASH and ASH in 4.5% of the cases and other liver diseases in 1.7% of the cases<sup>[37]</sup>.

In France, in a nationwide survey, Cadranet *et al*<sup>[38]</sup> showed that 54% of the LB were performed for chronic C viral infection. The total number of LB performed each year in France is approximately 16 000<sup>[39]</sup>.

The number of LB performed in every department increased in the last 15 years, mainly due to the increasing number of cases with chronic hepatitis C discovered in the last period, but we do not know the future trend, in connection to the introduction of non-invasive tests of fibrosis. The evolution of the number of ultrasound guided LB in our department in the last 10 years is shown in Figure 1.

### WHO SHOULD PERFORM THE LIVER BIOPSY?

There are two main categories of specialists who perform LB: gastroenterologists/hepatologists and the radiologists. The specialty of the individual who performs the LB determines if the LB is performed under ultrasound (US) guidance or not.

In many countries the ultrasound examination is performed both by radiologists and by clinicians (Germany, Italy, Austria, Switzerland and Romania). In other countries, the ultrasound examination is performed only by radiologists (USA, UK, The Netherlands and Denmark).

Currently it is estimated that in the USA, 50% of the LB are performed by radiologists<sup>[40]</sup>. In the same country, a questionnaire regarding the LB practice, answered by 112 gastroenterologists/hepatologists,

showed that 30% of them do not perform LB (due to concern about risks, low reimbursement and logistical issues)<sup>[41]</sup>. Another important fact is that in countries in which gastroenterologists do not perform US examinations, the LB performed by the clinician are “blind”, or done by the radiologist. It was suggested in USA that, by installing a US machine in the endoscopy unit, the cost of LB would decrease because a previous US examination in the Radiology Department would not be necessary before the LB, but that would require the gastroenterologist and hepatologist to become proficient in US technique and interpretation<sup>[40]</sup>.

The European Diploma of Gastroenterology stipulates that, in order to become specialists, all the gastroenterologists should perform at least 300 US examinations<sup>[42]</sup>. In the opinion of Vautier's team, issued years ago, “the ideal liver biopsy may be one that is performed in the ward by a gastroenterologist using ultrasonographic guidance”<sup>[43]</sup>.

## HOW TO PERFORM LB?

Currently, there are 3 techniques for performing a liver biopsy<sup>[31]</sup>: percutaneous, transjugular and laparoscopic. The percutaneous liver biopsy (PLB) can be performed: blind, US guided or US assisted.

The most important question regarding the percutaneous liver biopsy that should be addressed is: *blind or echo-guided techniques?* The answer depends on the skills of the gastroenterologist (hepatologist) and on the technical possibilities (accessibility to the ultrasound machine).

However, it is still debatable whether ultrasound-guided LB has an advantage over the blind one or not<sup>[43,44]</sup>. In a prospective study in France, Cadranet *et al.*<sup>[38]</sup> showed that from 2084 liver biopsies, only 56% were echo-guided. Also, many studies showed that the complications of LB seem to be related to the type of the technique, blind or echo-guided, respectively: (1) Younossi *et al.*<sup>[45]</sup> showed that the complications appeared in 4% of the cases with “blind” biopsies and in 2% of the cases with “ultrasound-guided” biopsies (the study revealed the cost-effectiveness of echo-guided biopsy); (2) Farrell *et al.*<sup>[46]</sup> showed complications in 1.8% of the cases with “ultrasound-guided” biopsies and in 7.7% of the cases with “blind” biopsies ( $P < 0.05$ ); (3) Pasha *et al.*<sup>[44]</sup> showed that severe complications occurred in 0.5% of the cases with “ultrasound-guided” biopsies and in 2.2% of the cases with “blind” biopsies ( $P < 0.05$ ). The same author revealed that the pain appeared more often (50% of the cases) in the “blind” biopsy group as compared to the “ultrasound-guided” biopsy group (37% of the cases,  $P = 0.003$ ).

But how often does the ultrasound guidance change the liver biopsy site? In a prospective study, Riley<sup>[47]</sup> showed that by ultrasound examination the site of biopsy was changed in 15.1% of the cases (21/165 patients). The reasons for changing the place of biopsy were the interposition of: lung, gall bladder, large central

vessel, ascites, colonic loop, and slim liver edge.

Considering all these facts, it is reasonable and cost-efficient to perform the LB under US guidance<sup>[40,45]</sup>, recent data suggesting a decrease in severe postbiopsy complications by up to 30% and less postbiopsy pain<sup>[40]</sup>.

## Type of needle

There are two types of biopsy needles used to perform a LB: “cutting needles” (Tru-Cut, Vim-Silverman) and “suction needles” (Menghini needle, Klatzkin needle, Jamshidi needle). Regarding how we use the needle, we can perform the LB manually or automatic, using spring-loaded devices (the so called “gun system”).

Data from literature showed that there is a correlation between the rate of complications and the type of the needle used for biopsy: 3.5‰ for the Tru-Cut needle and 1‰ for the Menghini type needle<sup>[48]</sup>.

Usually the choice of the biopsy instrument/needle is based on operator preference, instrument availability and clinical scenario<sup>[40]</sup>. The choice between the automatic biopsy gun *vs* manual activated needle depends on the experience of the center (operator). In a Dutch study<sup>[49]</sup> that compared standard Tru-Cut needle with a new automatic biopsy gun (Acecut), the performance of the automatic needle was superior and more consistent with respect to tissue yield, but post-biopsy pain and post-biopsy use of analgesics was superior after automatic biopsy gun. Thus, the authors<sup>[49]</sup> conclude that the automatic Tru-Cut needle offers an advantage, particularly for physicians with no or limited experience in liver biopsy.

Another group<sup>[50]</sup> did not find either type of needle to offer more safety when comparing the Tru-Cut needle with an automatic biopsy needle.

In a personal prospective study<sup>[37]</sup>, we compared the number of portal spaces obtained after PLB performed with a modified Menghini needle (manual activated needle) to the number of portal spaces obtained by PLB performed with an automatic needle (Auto Vac). The mean number of portal spaces obtained by Menghini needle biopsy was  $14.03 \pm 7.48$ , and by automatic needle biopsy was  $8.81 \pm 4.35$  ( $P < 0.0001$ ).

## The size of the needle

Usually the size of the biopsy needle used for LB in chronic hepatopathies varies between 1.2 and 1.8 mm. Gazelle's group<sup>[51]</sup> showed that larger needles produce more bleeding after LB in anaesthetized pigs (by comparing 2.1 mm with 1.6 mm needles and also by comparing 1.6 mm with 1.2 mm needles). Another study performed by Plecha *et al.*<sup>[52]</sup>, using cutting needles of 14, 18 and 22 gauge on porcine models, showed that the larger is the caliber of the needle, the greater is the absolute blood loss, but the conclusion of the study was that the use of larger-caliber needles is more efficient, despite the greater amount of blood loss, because more tissue can be recovered and because fewer passes are necessary, thus reducing the chance of complications.

However, other studies concerning the size of the

needle in connection with the rate of hemorrhagic complications, performed in humans, did not show any difference<sup>[46]</sup>.

### The number of passes of the needle into the liver

It has been demonstrated that taking more than one biopsy can increase the diagnostic value, but may have an effect on morbidity<sup>[38,39,47,53,54]</sup>. In a study performed by Riley<sup>[47]</sup> on 165 patients, only in 1.8% of cases multiple passes were necessary (noting that a low multiple pass rate was observed when applying ultrasound guidance), but in another study<sup>[55]</sup>, two needle passes were required in 20% of the patients and 3 needle passes in 0.2% of the cases.

From our point of view, after a long experience in performing PLB, we consider that the visual inspection of the hepatic fragment obtained by LB represents the guarantee that enough histological material was obtained. If we are unhappy with the size of the specimen, we perform another hepatic pass in the same session, rather than make a new biopsy later.

### The experience of the operator

There are controversial results regarding this issue. In one study, Gilmore *et al*<sup>[55]</sup> showed that the rate of complications in PLB was 3.2% if the operator had performed less than 20 biopsies and only 1.1% if the operator had performed more than 100 biopsies. In the study of Chevalier's group<sup>[56]</sup> the operator's experience did not influence either the final histological diagnosis or the degree of pain suffered by the patients.

### The safety of PLB

In a very large multicentric retrospective study concerning 98 445 liver biopsies, Poynard *et al*<sup>[57]</sup> showed that the LB was followed by severe adverse events in 3.1% of the cases and by mortality in 0.3% of the cases. In another large study the mortality rate from fatal hemorrhage after PLB was 0.11%<sup>[58]</sup>. In the well-known retrospective study performed by Piccinino *et al*<sup>[48]</sup> on 68 276 PLB, death was infrequent (0.09/1000 biopsies). The rate of major complications after PLB ranges from 0.09% to 2.3%<sup>[40]</sup>, while in a French study, severe complications appeared in 0.57% of cases<sup>[38]</sup>.

Another important question is: when did the post biopsy complications appear? From the retrospective multicentric study of Piccinino<sup>[48]</sup> we found that 61% of the complications appeared in the first 2 hours after the biopsy, 82% in the first 10 hours and 96% in the first 24 hours after biopsy. Some studies showed that the rate of complications is similar in out or inpatients<sup>[58,59]</sup>.

## CONCLUSION

Percutaneous echo-guided liver biopsy is a safe method for the diagnosis of chronic diffuse liver diseases (cost-effective in comparison with blind biopsy) and the rate of complications seems to be related to the experience of the physician and the type of the needle used (the Menghini type needle seems to be safer).

Perhaps the use of non-invasive markers will be

used in the future. For now, liver biopsy is useful and necessary for the evaluation of chronic hepatopathies, despite the fact that it is not a perfect test.

## INTRODUCTION

Magnetic resonance imaging (MRI) of the small bowel has been an unexplored field of application for years. Since 1998 the number of the publications has started to increase<sup>[1-6]</sup>. The reason was not lack of interest, but the technical inadequacy of the MR scanners to perform motion-free examinations. With the development of hardware (gradients, multi-channel coils) and software (fast and ultrafast sequences), which enabled breath-held studies, freezing voluntary (respiratory) and involuntary (peristaltic) motion artifacts, it opened the access to modern abdominal MRI.

High soft tissue contrast resolution, acquisition of multi-planar images and the possibility to obtain functional information make MR an interesting imaging technique to evaluate the small bowel disease. The absence of ionizing radiation is an important feature of MRI examinations because inflammatory diseases such as Crohn's disease (CD) are studied most frequently, which are prevalent among children and young adults<sup>[7-9]</sup>.

The major advantage of MRI, compared with conventional barium radiographic studies, is direct visualization of small bowel wall. This feature dramatically changes the image interpretation process. Radiologists must shift their attention from analysis of mucosal profile and lumen caliber to direct evaluation of bowel wall thickness and parietal inflammatory changes.

## IMAGING PROTOCOLS

### Small bowel distension

Bowel distension is a most important requisite for any method of the small bowel. A collapsed bowel loop can hide lesions or simulate pathologic wall thickening. The presence of the lesion that generates small bowel obstruction creates a natural distention of lumen and the possibility of examining the patient without any preparation<sup>[6,10-11]</sup>. In contrast, the relative collapse of bowel loops under standard conditions has led researchers to study a variety of methods of luminal distension.

## Abstract

High soft tissue contrast resolution, acquisition of multi-planar images and the possibility to obtain functional information make magnetic resonance an interesting imaging technique to evaluate the small bowel disease. The absence of ionizing radiation is an important feature of magnetic resonance imaging (MRI) examinations because inflammatory diseases such as Crohn's disease (CD) are studied most frequently, which are prevalent among children and young adults. MRI, using modern equipment and a rigorous technical approach, can offer detailed morphologic information and functional data on the small bowel. This article discusses the MRI protocols for small bowel and the MR imaging findings of small bowel diseases, such as CD and small bowel neoplasms.

Zhu J, Xu JR, Gong HX, Zhou Y. Updating magnetic resonance imaging of small bowel: Imaging protocols and clinical indications. *World J Gastroenterol* 2008; 14(21): 3403-3409 Available

There are two main approaches for MRI of the small bowel: (1) study following oral administration of contrast material; and (2) study with distension of lumen obtained with contrast material that is introduced through a naso-jejunal tube (MR enteroclysis).

### **Oral contrast agents for small bowel MRI**

Oral contrast agents can be classified into positive, negative and biphasic categories according to their action on the signal intensity of bowel lumen.

A positive agent is a paramagnetic substance that produces a high signal intensity on T1-weighted sequences. It reduces T1 relaxation time without, or only minimally, influencing T2 relaxation time. Because of the water content of the contrast solution, it also results in high signal intensity on T2-weighted images. Positive contrast agents include paramagnetic substances, such as gadolinium chelates, ferrous and manganic ions and manganese ions<sup>[12-16]</sup>. The use of positive oral contrast agents has been abandoned almost completely because a hyperintense lumen does not enable a clear differentiation with inflammatory parietal enhancement.

A negative agent is a substance that produces a low signal intensity on T1- and T2-weighted sequences. These substances induce local inhomogeneity in the magnetic field that affects T1 and T2 relaxation time. T2 effects predominate and are caused by spin dephasing with a consequent loss of signal intensity. Negative contrast agents include perfluorooctyl bromide<sup>[17]</sup>, iron oxides<sup>[15,18]</sup>, and oral magnetic particles<sup>[14,15]</sup>. Barium sulfate, if used at high concentrations, can be considered a negative contrast agent<sup>[19]</sup>. Negative contrast agents are more favorable if hyperintense signal of the bowel wall and the surrounding fat tissue signs of acute inflammation have to be detected on T2-weighted sequences<sup>[15]</sup>. However, magnetic susceptibility on gradient echo sequences may alter image quality on breath-held T1-weighted images.

The term “biphasic” recently was introduced to define those substances that show different signal intensities depending on different sequences<sup>[20]</sup>. The first group (hyperintense signal on T1-weighted images and hypointense signal on T2-weighted images) included manganese and substances that contain manganese, and gadolinium chelates, which can act as biphasic contrast agents if administered at high concentrations<sup>[15]</sup>. The second group (hypointense signal on T1-weighted images and hyperintense signal on T2-weighted images) included water, hyperosmolar and isosmolar watery solutions, and barium sulfate<sup>[15]</sup>. Although water is the safest and cheapest agent, it has the limitation of intestinal absorption, which compromises an adequate distension of distal ileum in many patients<sup>[21]</sup>. To obviate this problem, hyperosmolar solutions, such as mannitol-based solutions, have been used. Mannitol reduces water absorption and distends the distal ileal loops well. Major drawbacks are undesirable side effects, such as diarrhea, meteorism and abdominal cramps<sup>[21-25]</sup>.

In an attempt to reduce undesirable side effects and to obtain better distension of the distal ileum, some new oral mixtures, such as Polyethylene glycol, a water

solution combined with low concentration sorbitol and locus bean gum (LBG), were used as the oral contrast agents<sup>[19,26,27]</sup>. They are all hyperosmolar. Some of them can reduce the side effect and ensure optimal intestinal distension with appropriate concentration and reasonable transit time.

### **Magnetic resonance enteroclysis**

MR enteroclysis (MRE) is an emerging technique for the evaluation of small intestinal diseases. Administration of an iso-osmotic water solution through a nasojejunal catheter can guarantee adequate luminal distention, and in combination with ultrafast sequences, such as single shot TSE, true FISP, HASTE and 3D FLASH, resulting in excellent anatomic demonstration of the small intestine. MR fluoroscopy can be performed during MRE examination to monitor the filling process and might be useful in studying low-grade stenosis or motility related disorders. MRE is a very promising technique for the detection and characterization of involved small bowel segments in patients with Crohn's disease while its diagnostic performance in disclosing lumen narrowing and extramural manifestations and complications of the disease is outstanding. Initial experience shows that MRE is very efficient in the diagnosis of small bowel tumors and can be used in the evaluation of small bowel obstruction<sup>[20,28,29]</sup>.

### **Sequences**

Fast sequences that are able to acquire T1- and T2-weighted images within a single breath-hold are essential requisites for MRI evaluation of small bowel. In T2-weighted images, several studies<sup>[11,5,6,28,29]</sup> support the validity of single-shot sequences, including half-Fourier single-shot turbo spin-echo (HASTE) and single-shot fast spin-echo. Because these sequences, based on the half-Fourier reconstruction technique, have extremely fast acquisition time (approximately 1 second per image), they are able to freeze motion artifacts. Single-shot sequences differ from each other depending on echo time (TE). Using long TE (e.g. about 600 m) can obtain selective images of fluids with cancellation of surrounding organs (similar to magnetic resonance cholangiopancreatography). Using shorter TE (60-90 m) can obtain simultaneous evaluation of fluids, bowel wall and surrounding structures. The use of fat saturation pulses is a useful complement to the acquisition of T2-weighted sequences<sup>[2,13,14,29-31]</sup>. Fat saturation causes an increase in contrast between bowel wall and the surrounding fat tissue. This can help assess the bowel wall inflammation and identify the inflammatory changes in peritoneal fat tissue.

The “balanced” or “hybrid” gradient-echo sequence has been introduced in clinical practice. This sequence, known as true fast imaging with steady-state precession (true-FISP), presents with an intermediate contrast between T1- and T2-weighted images<sup>[29,31-33]</sup>. Shorter repetition times (TR) are used (< 3 m) and the acquisition time is short. The true FISP sequence provides motion-free, high-resolution images similar to T2-weighted images of the intestine, mesentery and

**Figure 1** A 36-year-old man with Crohn's disease, the small bowel thickness exceeds 4-5 mm on T2W image, and stratified appearance (so-called "target" or "double halo" appearance) can be seen.

**Figure 2** A 25-year-old man with Crohn's disease and inflammation of ileocecal junction. T2W image shows "double halo" appearance (arrows) of thickened (8 mm) bowel wall.

vasculature in 1.5 s. However, this sequence is prone to susceptibility artifacts from intraluminal air and from "black boundary" artifact due to the chemical shift phenomenon, which may obscure the subtle bowel wall thickening. The black boundary artifact can be eliminated with use of fat suppression.

T1-weighted images are obtained with fast spoiled-gradient-echo sequences, using 2-D or 3-D acquisition. The acquisition time ranges from 15 to 20 seconds. T1-weighted sequences generally are used following intravenous injection of contrast material to evaluate enhancement, a useful parameter to assess disease activity, especially the inflammatory activity. T1-weighted images also benefit from the use of fat saturation. The gadolinium-enhanced fat-suppressed spoiled gradient-echo sequence provides T1-weighted images with excellent visualization of the enhanced bowel wall, which contrasts well with the low-signal-intensity mesenteric fat and negative intraluminal contrast material<sup>[34,35]</sup>.

The latest technical development to speed up the acquisition process is parallel imaging, based on simultaneous acquisition of spatial harmonics, or sensitivity encoding techniques. Marked improvement in spatial resolution can be achieved in shorter acquisition times<sup>[36]</sup>. Parallel imaging can reduce the number of phase encodings to be acquired per TR. Consequently, the spatial resolution can be increased while maintaining an acquisition time that is compatible with a single breath-hold, or the number of scans to be acquired, which allows a larger volume coverage. Alternatively,

**Figure 3** A 42-year-old man with Crohn's disease, T2W image shows skip lesions of ileum with thickened (7 mm) bowel wall.

**Figure 4** A 36-year-old woman with Crohn's disease, the bowel wall of the involved segment has a homogeneous enhancement at CE-T1W image. And the "comb sign" also can be seen.

the acquisition time can be reduced drastically. The drawback in the use of parallel imaging is the reduction of signal-to-noise ratio (SNR) and the need to perform a calibration of equipment immediately before image acquisition<sup>[37]</sup>.

## CLINICAL INDICATIONS

### **Inflammatory bowel disease (CD) (Figures 1-4)**

Chronic inflammatory disease, and in particular, CD, represents the most common application of MRI of small bowel<sup>[1-5,8,9,15,28-35,38]</sup>.

### **Imaging findings**

With MRI, both inflammatory changes of the bowel wall and extramural complications of Crohn's disease can be assessed. The non-invasiveness of this technique, as well as its lack of ionizing radiation, has prompted many radiologists to perform systematic studies of MRI for evaluation of Crohn's disease.

In patients having proved suspected CD, cross-sectional images, including CT and MRI, should be analyzed specifically for the presence and character of a pathologically altered bowel segment (wall thickness, pattern of attenuation, degree of enhancement, length of involvement), stenosis and prestenotic dilatation, skip lesions, fistulas, abscess, fibrofatty proliferation, increased vascularity of the vasa recta (comb sign), mesenteric adenopathy, and other extraintestinal disease involvement.

The normal small bowel wall thickness is between 1 mm and 3 mm when the lumen is well distended. Any portion of the bowel wall that exceeds 4-5 mm is

considered abnormal<sup>[19,12,17,19,26,29,39,40]</sup>. An adequate intestinal distension is mandatory because collapsed loops or spastic intestinal segments may mimic wall thickening. Most optimal distension is obtained with MR enteroclysis with instillation of contrast medium after nasojejunal intubation under fluoroscopic guidance. Although many authors reporting on MR enteroclysis administer antiperistaltic drugs to reduce motion artifacts, reflex atony is induced by high flow rates, theoretically allowing images (almost) free of motion artifacts<sup>[41,42]</sup>. Drawbacks are that this technique is uncomfortable for patients and exposes them to a considerable dose of ionizing radiation of up to 8 mSv during intubation<sup>[43]</sup>. To avoid such disadvantages, MRI has been performed by many researchers using oral contrast media. Many contrast media have been proposed, but no oral contrast medium has yet been accepted universally as optimal for use<sup>[2,3,7,14-19,22-26]</sup>.

Small bowel wall thickening is a sensitive, but not pathognomonic, sign of CD. It is observed in several other intestinal diseases, such as ischemic disorders and infections.

Although superficial mucosal lesions are missed easily as a result of inadequate spatial resolution, MR imaging can detect early inflammatory changes of the bowel wall, based on enhancement after intravenous injection of contrast medium. The bowel wall of the involved segment may have a homogeneous or stratified appearance at MR imaging after enhancement. The homogeneous enhancement is diffuse and transmural with no recognition of different bowel layers. The stratified appearance (so-called "target" or "double halo" appearance) is related to alternating layers of higher or lower attenuation or signal intensity. The stratified appearance also can be seen on T2-weighted imaging. "Target" or "double halo" appearance is often seen in active lesions, particularly after the intravenous administration of contrast medium, and related to submucosal edema. The intensity of enhancement correlates with the degree of inflammatory lesion activity. Inactive disease is characterized by no abnormalities or bowel wall thickening with relative low signal intensity representing fibrosis with limited, homogeneous contrast enhancement. Absence of stratification on T2-weighted images with stratified enhancement on T1-weighted images is often due to fibrosis, which is a typical long-standing CD<sup>[29,33,35,44]</sup>. This sign (stratified enhancement) also can be seen on MSCT (multi-slice CT) images<sup>[45,46]</sup>.

Increased vascularity of the vasa recta (comb sign) is a sign of active inflammation. It arises from the combination of vascular engorgement of vasa recta and fibro-fatty proliferation and is demonstrated as multiple tubular, tortuous opacities on mesenteric side of ileum, aligned as the teeth of a comb<sup>[29]</sup>. "Comb sign" is frequently seen on enhanced MSCT images<sup>[46,47]</sup>. Abscess and phlegmon can occur in the small bowel mesentery, abdominal wall, or psoas muscle or around the anus. Abscesses and phlegmon are well demonstrated at fat-saturated T2-weighted MR imaging and can be distinguished reliably, which aids in management planning. Fistulas and sinus tracts are also depicted, however, the

reported sensitivity of MR imaging for depicting sinus tracts is 50%-75% when a conventional enteroclysis study is used as a reference<sup>[32,39,45]</sup>. Mesenteric lymphadenopathy ranging from 3 to 8 mm in size is depicted at MR imaging with a true fast imaging with steady state precession (FISP) or T2-weighted turbo spin-echo sequence<sup>[32,41]</sup>. If these sequences are not available, axial T1- or T2-weighted spin-echo imaging should be added. When lymph nodes are larger than 10 mm, lymphoma and carcinoma must be excluded.

### Assessment of disease activity

Imaging techniques form a very important part of the evaluation of CD. However, several clinical scoring systems have been developed as well to assess disease activity and response to therapy, especially in trials. The Crohn's disease activity index (CDAI) is currently the gold standard for clinical evaluation of disease activity<sup>[47,48]</sup>. This index is relatively subjective since an important part of the total score is derived from items that reflect the patient's perception of disease (general well being and "intensity of abdominal pain"). However, in many studies, this index has been used as gold standard for disease activity since it is a validated and extensively used clinical index. Scores ranging from 0 to approximately 600 with values below 150 are considered as remission and values over 150 as active disease. MR imaging was used to evaluate disease activity<sup>[9,30-35,38,41,44,48,49]</sup>. Based on different experiences, contrast-enhanced (CE) fat-suppressed T1-weighted images offer the best correlation between MR findings and CDAI, although a correlation that used fat-suppressed T2-weighted images is also demonstrated. MRI can clearly distinct pathologic from normal bowel wall in CD, as it detects significant variations in bowel wall thickness with clinical improvement and is able to reflect pathologic inflammatory changes at the bowel wall based on variations in the CE. In most patients with active disease, abnormal bowel identified on MR imaging was isointense or slightly hypointense to the psoas muscles on T1-weighted imaging. On T2-weighted imaging, the abnormal bowel segments were usually isointense or slightly hyperintense compared with the psoas muscle. MR imaging can correctly identify active disease, the enhancement pattern of abnormal bowel is diffuse and layered. The layered pattern is seen only in patients with active disease. Consequently, this technique is reliably applicable to the follow-up of patients with CD. MRI is able to detect significant variations in bowel wall thickness and contrast enhancement (CE), reflecting favorable clinical response to medical treatment of CD's relapse<sup>[30,34,49]</sup>.

## NEOPLASMS (Figure 5)

### Benign masses

Benign and malignant small intestinal tumors are uncommon. Adenomas, leiomyomas and lipomas constitute the three most common primary benign small intestinal tumors<sup>[50]</sup>. In general, benign tumors occur less commonly in the duodenum and increase in frequency

**Figure 5** A: A 68-year-old man with adenocarcinomas, T2W image shows the tumor with similar signal intensity, the proximate jejunum dilating conspicuously; B: The same patient, tumor shows heterogeneous enhancement greater than adjacent bowel on gadolinium-enhanced image.

in the ileum. The term “polyp” is a clinical term for any tumorous mass that projects above the surrounding normal mucosa. Hamartomatous, hyperplastic and inflammatory polyps are benign, non-neoplastic lesions and adenomatous polyps are true neoplastic tumors containing dysplastic epithelium and are precursors of carcinoma. Polyps are infrequently symptomatic and are usually incidental findings at autopsy. Current convention is that leiomyomas should be classified as gastrointestinal stromal tumors (GIST), and benignancy can never be determined with absolute certainty. Small bowel GIST accounts for 25% of these tumors. As in the stomach, these may be large and ulcerating.

### Malignant masses

Adenocarcinomas account for 50% of all small bowel malignancies, but only account for less than 1% of all gastrointestinal malignancies<sup>[51]</sup>. The most common site for small bowel adenocarcinoma is the duodenum. This tumor frequently occurs in close proximity to the ampulla and as a result may cause obstructive jaundice<sup>[52]</sup>. Adenocarcinoma and metastases can be seen rarely in the jejunum.

Most primary gastrointestinal non-Hodgkin lymphomas are of B-cell type, and appear to arise from B cells of mucosa-associated lymphoid tissue (MALT). In the small intestine, the terminal ileum is the most common site affected, which may reflect the relatively greater amount of lymphoid tissue present in this segment compared with the duodenum and jejunum.

Carcinoids are the most common primary neoplasm of the small bowel. They are well-differentiated neuroendocrine neoplasms that occur primarily in the distal ileum. Men and women are affected with equal frequency. Most patients present with tumor-related symptoms of bleeding and bowel obstruction or intussusception. Ileal carcinoids are regional mesenteric metastases and vascular sclerosis. The primary tumor may be quite small with the accompanying lymphadenopathy and desmoplastic reaction in the root of the mesentery presenting as the only visible manifestation of disease. Liver metastases are responsible for the “carcinoid syndrome”,

which is characterized by vasomotor instability, intestinal hypomotility and bronchoconstriction<sup>[53]</sup>.

### Imaging findings

Tumors had similar signal intensity to normal small bowel on precontrast images. Tumors showed heterogeneous enhancement greater than adjacent bowel on gadolinium-enhanced images. Tumor local extent was best shown on precontrast-spoiled gradient-echo images and postgadolinium T1-weighted fat-suppressed images. Image quality was most consistent on breath-hold images. Precontrast breath-hold T1-weighted spoiled gradient-echo images and gadolinium-enhanced fat suppressed images demonstrate tumor extent most reliably. The accuracy of the technique in cases of non-occlusive tumors of the lumen is not known, given the lack of large case series<sup>[28,54]</sup>.

## CONCLUSION

MR imaging, using modern equipment and a rigorous technical approach, can offer detailed morphologic information and functional data on the small bowel. The optimal study technique is debatable, although the oral administration of contrast material as a first-line approach is less expensive, faster, easier to perform and better tolerated by patients. MR enteroclysis might be reserved for selected cases as a second-line study.

The major clinical indication is the evaluation of patients who have suspected or known CD. The absence of ionizing radiation, in view of the young age of most of the patients and the frequency of the examinations, is an important advantage over other techniques (radiography and CT enteroclysis).

also different between these groups. Sham and honey groups had similar incidence of bacterial translocation ( $P > 0.05$ ). BDL group had significantly higher rates of bacterial translocation as compared with sham and honey groups. Bacterial translocation was predominantly detected in mesenteric lymph nodes.

**CONCLUSION:** Supplementation of honey in presence of obstructive jaundice ameliorates bacterial translocation and improves ileal morphology.

### Abstract

**AIM:** To evaluate the effects of honey on bacterial translocation and intestinal villus histopathology in experimental obstructive jaundice.

**METHODS:** Thirty Wistar-Albino rats were randomly divided into three groups each including 10 animals: group I, sham-operated; group II, ligation and section of the common bile duct (BDL); group III, bile duct ligation followed by oral supplementation of honey (BDL + honey) 10 g/kg per day. Liver, blood, spleen, mesenteric lymph nodes, and ileal samples were taken for microbiological, light and transmission electron microscopic examination.

**RESULTS:** Although the number of villi per centimeter and the height of the mucosa were higher in sham group, there was no statistically significant difference between sham and BDL + honey groups ( $P > 0.05$ ). On the other hand, there was a statistically significant difference between BDL group and other groups ( $P < 0.05$ ). The electron microscopic changes were

### INTRODUCTION

Obstructive jaundice is a common clinical entity complicated by intestinal failure and endotoxemia, leading to high postoperative morbidity and mortality rates. The gastrointestinal tract performs a variety of functions in digestion, selective absorption, and secretion. However, its barrier function, which prevents spread of intraluminal bacteria and endotoxins to the organs and tissues, plays a key role<sup>[1-2]</sup>. Intestinal barrier failure is associated with an increased incidence of bacteria and toxin translocation from the intestinal lumen to the systemic circulation, causing systemic infection and multiple organ failure in the critically ill or injured patient<sup>[3]</sup>. Gut barrier failure may result from one or more of the three basic pathophysiologic conditions; disruption of the normal ecologic balance of the indigenous gut microflora, impaired host immune defenses, and physical disruption of the gut mucosal barrier<sup>[4]</sup>.

Bacterial translocation is the passage of bacteria or endotoxins from the gastrointestinal tract to extraintestinal sites, such as mesenteric lymph nodes, liver, spleen, and/or bloodstream. In a normal, healthy individual, gut-originated bacteremia and sepsis do not occur because the host has multiple defense mechanisms to prevent the bacteria and their products from crossing the mucosal barrier and spreading to systemic tissues. Under certain experimental and clinical circumstances, this intestinal barrier function becomes overwhelmed or impaired, resulting in bacterial translocation<sup>[4]</sup>. Current advances in the pathophysiology of intestinal failure in obstructive jaundice have showed that the breakage of gut barrier is multifactorial, involving disruption of the immunologic, biological, mechanical, and biochemical barrier<sup>[1]</sup>.

Honey is a supersaturated sugar solution produced by honey bees from nectar of different plants. It has a long tradition of use for wound healing since ancient times. Honey has bactericidal, bacteriostatic, antifungal, antiviral, scolical, antioxidant, antitumoral, and anti-inflammatory effects<sup>[5-12]</sup>.

In this study, we investigated the effects of honey on bacterial translocation and intestinal morphology in experimental obstructive jaundice.

## MATERIALS AND METHODS

### Animals

Thirty Wistar-Albino male rats, weighing  $250 \pm 25$  g, were housed under constant temperature ( $21 \pm 2^\circ\text{C}$ ) individually in wire cages with 12 h light-dark cycle. Twelve hours before anesthesia, animals were deprived of food, but had free access to water 2 h before anesthesia. No enteral or parenteral antibiotics were administered at any time. The rats that died during the experiment were excluded from the experiment and no new rat was included. The procedures in this experimental study were performed in accordance with the National Guidelines for The Use and Care of Laboratory Animals and approved by Animal Ethics Committee of Ankara Research and Training Hospital.

### Study groups

Rats were randomly divided into three groups each including 10 animals: group I, sham-operated; group II, ligation and section of the common bile duct (BDL); group III, BDL followed by oral supplementation of honey 10 g/kg per day (Balpamak LTD, Istanbul, Turkey), once a day, with nasogastric tube (7 Gauge feeding tube) that was inserted daily and taken off after honey supplementation. Animals were sacrificed by high-dose diethyl ether inhalation on postoperative day 7. Liver, blood, spleen, mesenteric lymph nodes, and ileal samples were taken for microbiological, light and TEM (transmission electron microscopic) examination.

There isn't a standard dose for honey in experimental studies. The dose used in previous studies ranges between 0.078 g/kg to 5 g honey/rat per day<sup>[12-15]</sup>. We gave 10 g/kg per day to each rat.

### Operative procedure

Animals were anesthetized by intramuscular injection of 30 mg/kg ketamine hydrochloride (Ketalar®; Parke-Davis, Istanbul, Turkey) and 5 mg/kg xylazine (Rompun®, Bayer, Istanbul, Turkey). Midline laparotomy was performed under sterile conditions. In the sham-operated group (group I) the common bile duct (CBD) was freed from the surrounding soft tissue and was manipulated without ligation and transection. In group II and III, CBDs of the rats were identified, double ligated with 5-0 silk, and sectioned between the ligatures. The same surgeon performed all procedures. The abdominal incisions were closed in two layers with continuous 3-0 silk sutures. Animals were allowed to feed after the operation.

### Microbiological and biochemical examination

The mesenteric lymph nodes (MNLs), spleen and liver were chopped with sterile instruments under aseptic conditions. Then the tissue samples were weighed and placed in tubes containing 1.5 mL broth (thioglycolate, Oxoid, UK) and homogenized. After that 0.01 mL tissue samples were inoculated on blood agar (Oxoid, UK) and Levine Eosine Methylene Blue (EMB) agar (Oxoid, UK). Plates were incubated at  $37^\circ\text{C}$  for examination of bacterial growth. The growth of bacteria in quantitative culture was observed at 24 h and 48 h.

Blood samples taken from inferior vena cava of rats were inoculated on the medium of aerobic and anaerobic blood culture. The aerobic and anaerobic blood cultures were observed by incubation in BACTEC 9240 blood culture system (Becton Dickinson, USA) at  $37^\circ\text{C}$  for seven days. Samples taken from the blood culture bottle giving positive alarm were subcultured by inoculating on blood agar and EMB agar. The subcultures were inoculated at  $37^\circ\text{C}$  under aerobic and anaerobic condition and examined at 24 h and 48 h.

Total bilirubin, aspartate aminotransferase (AST), and alanine aminotransferase (ALT) levels were measured as parameters indicative of hepatic function by an autoanalyser (Olympus AU640, Japan).

### Histopathological examination

For light microscope analyses, tissue samples from the terminal ileum were obtained from all animals. In order to avoid mucosal suffering, the intestinal lumen was carefully cannulated and gently washed with normal saline solution before the sampling. The ileal samples were fixed in 10% neutral buffered formalin, embedded in paraffin, sectioned at  $5\ \mu\text{m}$  by Leica RM 2125 RT, and stained with hematoxylin and eosin (HE) for routine light microscopic examination. Histopathological examinations were performed by a pathologist who was blinded to the study design and photographs were taken with Nikon Eclipse E 600. The number of villi per centimeter (V/cm) and the total mucosal thickness were assessed in all groups. The mucosal thickness was measured in a minimum of 20 well-preserved villi in each randomly selected sample from each tissue block.

For TEM (transmission electron microscopic)

**Figure 1** The micrographs of light microscope stained with haematoxylin and eosin. Micrograph (A) illustrates the typical structure of villi; (B) blunting of the villi (arrow head) and subepithelial edema (asterisk); (C) existing subepithelial edema (asterisk) and the total mucosal thickness (arrow).

analyses, samples were fixed with phosphate buffered (pH 7.3) 2.5% glutaraldehyde and 2% PFA mixture solution for 2 h at room temperature. They were washed with phosphate buffered saline solution (PBS, pH 7.3) and were fixed with 1% osmium tetroxide for 2 h as secondary fixation. After washing, they were embedded in Araldite 6005 and were cut with Leica EM FCS (Wien, Austria) ultramicrotome. One  $\mu\text{m}$  semi-thin sections were stained with Toluidin blue-Azur II to select the region of interest for the following procedures. Sixty to 70 nm thin sections were stained with uranyl acetate and lead citrate. They were examined and photographed using a LEO 906 E TEM (80 Kv, Oberkochen, Germany). The pathologist was blinded about the groups.

### Statistical analysis

Differences between the numbers of positive cultures of the groups were evaluated by chi-square test. Scores of total mucosal thickness and number of villi per centimeter were presented as mean  $\pm$  SD and compared by One-Way ANOVA or Kruskal-Wallis variance analysis. If the *P* values of the variance analyses were statistically significant, differences between groups were analyzed with the Mann-Whitney *U* test. Statistical analyses were performed with the Statistical Package for the Social Sciences (SPSS), version 13.0 for Windows (SPSS Inc., Chicago, USA). *P* < 0.05 was considered to be statistically significant.

## RESULTS

### General

All rats were sacrificed on postoperative day 7. Two rats from group II (BDL group) and one from group III (BDL + honey group), totally 3 rats, died during the early postoperative period probably due to anesthesia. The liver function tests and bilirubin levels were normal in sham group and high in BDL and BDL + honey groups.

### Intestinal morphology

In all specimens of the sham group, the histological

**Table 1** Mean number of villi per cm and mean height of mucosa ( $\mu\text{m}$ )

Groups	Mean number of villi per cm	Mean height of mucosa
Sham (Group I)	84.40 $\pm$ 3.75 <sup>b</sup>	640.02 $\pm$ 43.72
BDL (Group II)	73.01 $\pm$ 2.83	567.50 $\pm$ 34.54
BDL + Honey (Group III)	81.33 $\pm$ 3.46 <sup>b</sup>	625.56 $\pm$ 38.77

<sup>b</sup>*P* < 0.01 vs II, *P* values for mean height of mucosa: 0.002, I vs II; 0.005, II vs III.

features showed regular appearance of ileal tissue. When we evaluated the specimens systematically, including assessment of villous architecture, surface and crypt epithelia, lamina propria constituents and submucosal structures, no alteration was found in sham group (Figure 1A). The specimens of the BDL group presented villous blunting associated with reduced mucosal thickness. We identified subepithelial edema mostly located at the tip of the villi, but also extended throughout the villus, with epithelial layer moderately lifted from the lamina propria. We observed that the crypts were generally preserved. The number of villi per centimeter (V/cm) (villus density) was decreased in BDL group (Figure 1B). In group III, the subepithelial edema still existed, but villous blunting was not evident. Farther, the crypts generally appeared to be preserved (Figure 1C). Although the number of villi per centimeter and the height of the mucosa were higher in sham group, there was no statistically significant difference between sham and BDL + honey groups (*P* > 0.05). On the other hand, there was a statistically significant difference between BDL group and other groups (*P* < 0.05). Mean number of villi per centimeter and mean mucosal height of the groups are given in Table 1.

The ultrastructure of intestinal epithelial junctional complexes was observed by electron microscopy. In the sham group, enterocytes were tightly bound to the luminal surface by junctional complexes. Zonulae occludens, zonulae adherentes and maculae adherentes appeared normal in the sham group. The luminal surface was covered with microvilli (Figure 2A). When we evaluated the BDL group, we

**Figure 2** These transmission electron microscope (TEM) micrographs illustrate the main ultrastructural features of enterocytes, the absorptive cells of the ileum. Micrograph (A) shows the regular structure of microvilli (Mv) and the three components of junctional complex at the luminal end of the lateral plasma membrane, zonula occludens (ZO), zonula adherens (ZA) and macula adherens (MA); Micrograph (B) shows the disintegration of the zonula occludens and disordered structure of junctional complexes (arrows). The lipid droplets (L) and phagosomes (P) in the cytoplasm, rough endoplasmic reticulum (rER), swollen mitochondria (M) with ballooned cristae (Bc) and apical surface edema (asterisk) viewed; Micrograph (C) illustrates the regular structure of microvilli (Mv) and junctional complexes (ZO, ZA, MA).

**Figure 3** Micrograph (A) shows the disintegration of the zonula occludens (arrow), apical surface edema (asterisk) and the desquamation of the epithelial tissue (arrow head); Micrograph (B) illustrates the swollen mitochondria with cavitations of matrix (C).

observed desquamated epithelial tissue, cytoplasmic vacuoles, phagosomes and disrupted structure of the tight junction between epithelial cells possibly due to apical surface edema. Zonulae occludens located within the plasma membranes of adjacent epithelial cells diverged (Figures 2B and 3A) and the mitochondria were swollen with electrolucent matrix and ballooned cristae. Markedly swollen mitochondria with peripherally placed, disoriented and disintegrating cristae and cavitations of the matrix were also observed in BDL group (Figures 2B and 3B). The structure of the microvilli and mitochondria were regular in the BDL + honey group. The junctional complexes had normal appearance (Figure 2C).

**Bacterial translocation**

The rates of bacterial translocation (BT) in all groups are summarized in Table 2. Sham and BDL + honey groups had similar incidence of BT. BDL group had significantly higher rates of BT as compared with sham and BDL + honey groups. Only BT to spleen was not significantly different between the BDL and BDL + honey groups. BT was predominantly detected in MLNs.

The most commonly isolated bacteria was *Escherichia coli*. The other isolated microorganisms were *Enterococcus spp.*, *Staphylococcus spp.*, *Proteus spp.*, *Staphylococcus aureus* and *Enterobacter cloacae*.

Table 2 Bacterial translocation rates of the groups				
Groups	Liver	Spleen	MLNs	Blood
Sham (Group I )	0/10 (0.0%)	0/10 (0.0%)	1/10 (10.0%)	0/10 (0.0%)
BDL (Group II)	6/8 (75.0%)	4/8 (50.0%)	7/8 (87.5%)	4/8 (50.0%)
BDL + Honey (Group III)	1/9 (11.1%)	2/9 (22.2%)	2/9 (22.2%)	0/9 (0.0%)
P values				
I vs II	0.002	0.023	0.002	0.023
II vs III	0.013	> 0.05	0.012	0.029
I vs III	> 0.05	> 0.05	> 0.05	> 0.05

**DISCUSSION**

Bacterial translocation is the migration of bacteria or bacterial products from the intestinal lumen to mesenteric lymph nodes or other extraintestinal organs and sites. In addition to nutrient absorption, the gut functions as a barrier to prevent the spread of intraluminal bacteria and endotoxin to systemic organs and tissues<sup>[4,16,17]</sup>.

Bile inhibits bacterial overgrowth, has a trophic effect on the intestinal mucosa, decreases epithelial internalization of enteric bacteria, exerts detergent actions with anti-adherence effects, and binds endotoxins. Therefore, the absence of bile in the intestine facilitates BT and enhances endotoxin-induced BT<sup>[16]</sup>. Obstructive jaundice is almost universally believed to promote bacterial translocation. Absence of bile from the lumen

of gut is also associated with a quantitative increase in small intestinal microflora<sup>[18]</sup>.

Translocation from the intestine is most commonly detected by measuring the presence of viable bacteria in the tissues. This can reflect not only the integrity of the intrinsic barrier function of the mucosa but also the numbers and types of microbes in the lumen and the ability of the host to kill the bacteria that translocate<sup>[19]</sup>.

Honey is a supersaturated sugar solution produced by honey bees from the nectar of plants. Some of the components of the honey are added by the bees during the maturation process or are derived from the plants<sup>[20]</sup>. The antimicrobial properties of honey are well documented<sup>[5-9]</sup>. The antibacterial activity of honey lies partially in its high osmolality due to its high sugar content, and in its acidity due mostly to the presence of gluconic acid. Although hydrogen peroxide is thought to be the main antibacterial factor in honey, the presence of non-peroxide activity was also notable. This activity is usually attributed to the presence of organic components such as syringic acid, methyl syringate, pinocembrin, pinobanksin, caffeic acid, ferulic acid, vanillic acid, cinnamic acid, and benzoic acid<sup>[21]</sup>.

The physicochemical properties of honey not only contribute to its antibacterial properties but also to its wound healing capabilities. The anti-inflammatory action of honey has been investigated, but no definite mechanism has been identified. Honey provides glucose supply for leucocytes. It also provides substrate for glycolysis, which is the major mechanism for energy production in the macrophages. Honey may modulate the activation state of immunocompetent cells (e.g. monocytes) within the wound. These data suggest that honey may have a number of effects on the molecular mechanisms of wound healing<sup>[20]</sup>.

As we mentioned before, the physical barrier function of the mucosa appears to have primary importance for preventing or limiting bacterial translocation, especially in a host with a normal gut flora, whereas the immune system appears to serve a secondary or supportive role to the intestinal mucosal barrier<sup>[4]</sup>. In our study, mean number of villi per centimeter, mean mucosal height, and electron microscopic changes of the honey group were significantly better than the data observed in the BDL group. In the sham and BDL + honey groups, enterocytes were tightly bound to the luminal surface by junctional complexes. Zonulae occludens, zonulae adherentes and maculae adherentes appeared normal in these groups. The luminal surface was covered with microvilli. When we evaluated the BDL group, we observed desquamated epithelial tissue, cytoplasmic vacuoles, phagosomes and disrupted structure of the tight junction between epithelial cells possibly due to apical surface edema. Zonulae occludens located within the plasma membranes of adjacent epithelial cells were diverging and the mitochondria were swollen with electrolucent matrix and ballooned cristae. Reduced bacterial translocation rates in honey group could be explained by decreased atrophy of intestinal mucosal villi and somewhat regular structure of enterocytes and microvilli. We concluded that

wound healing properties and cytoprotective effects of honey might be the reason of the decreased atrophy of intestinal mucosal villi. On the other hand, antimicrobial effects of honey on enteric bacteria could also decrease the overgrowth of these bacteria and reduce bacterial translocation.

Assimakopoulos *et al*<sup>[22]</sup> investigated the oxidative alterations in the intestinal mucosa of patients with obstructive jaundice and found that obstructive jaundice in humans induced intestinal oxidative stress, which might be a key factor contributing to intestinal barrier failure and the development of septic complications in this patient population. In another study, these authors showed that intestinal mucosal atrophy in obstructive jaundice was based on inhibition of proliferation and promotion of apoptotic death of enterocytes, and reactive oxygen species might be responsible for this effect<sup>[23]</sup>.

The antioxidant properties of honey have been well-documented in recent studies<sup>[24-27]</sup>. Schramm *et al*<sup>[25]</sup> found that phenolic antioxidants from processed honey were bioavailable, and these antioxidants increased antioxidant activity of plasma. Gheldof *et al*<sup>[11]</sup> also showed that the *in vivo* serum antioxidant capacity increased significantly following consumption of buckwheat honey in human. These studies showed that the antioxidant effect of honey was not only local, but also a systemic effect. According to the results of studies about antioxidative effects of honey and intestinal oxidative stress in obstructive jaundice, we concluded that the protective effect of honey on intestinal villi and mucosal structure might be attributable to antioxidative effects of honey in our study. Since we investigated only the effects of honey on bacterial translocation and intestinal villus atrophy, not the mechanism of this effect, we did not evaluate oxidative stress parameters. These parameters should be analyzed in further studies that investigate the mechanism of this effect of honey.

Since a normal functioning immune system is another important factor for adequate gut barrier function<sup>[4]</sup>, honey may also reduce bacterial translocation by its modulatory effects on immunocompetent cells<sup>[28-29]</sup>.

In this study, we demonstrated that honey reduced bacterial translocation rates and protected intestinal villus structure in experimental obstructive jaundice model. These effects of honey might be attributable to its antibacterial, antioxidant, anti-inflammatory, and immunomodulatory activities. Further studies are needed for evaluation of the exact mechanism of this effect. After the results of these studies, honey might be used for preventing harmful effects of obstructive jaundice in clinical settings.

## COMMENTS

### Background

Spontaneous bacterial infection and septicemia due to increased bacterial translocation in patients with obstructive jaundice result in significant morbidity and mortality.

### Research frontiers

The present study investigated the effects of honey on bacterial translocation

and intestinal morphology in experimental obstructive jaundice.

### Innovations and breakthroughs

Obstructive jaundice is a common clinical entity complicated by intestinal failure and endotoxemia, leading to high postoperative morbidity and mortality. Our experience from the present study shows that honey can be used safely in this situation.

### Applications

This study demonstrated that honey reduced bacterial translocation rates and protected intestinal villus structure in experimental obstructive jaundice model. Honey might be used for preventing harmful effects of obstructive jaundice in clinical settings.

### Peer review

The rationale behind this study is that the authors have previously shown that honey has reduced bacterial translocation rates and protected intestinal villus structure in experimental obstructive jaundice.

### Abstract

**AIM:** To conduct a multicentre retrospective review of virological response rates in Asians infected with genotype 1 chronic hepatitis C (CHC) treated with combination interferon and ribavirin and then to compare their responses to that among Caucasians.

**METHODS:** Asian patients infected with genotype 1 CHC treated at 4 Australian centres between 2001 to 2005 were identified through hospital databases. Baseline demographic characteristics, biochemical, virological and histological data and details of treatment were collected. Sustained virological responses (SVR) in this cohort were then compared to that in Caucasian subjects, matched by genotype, age, gender and the stage of hepatic fibrosis.

**RESULTS:** A total of 108 Asians with genotype 1 CHC were identified. The end of treatment response (ETR) for the cohort was 79% while the SVR was 67%. Due to the relatively advanced age of the Asian cohort, only sixty-four subjects could be matched with Caucasians. The ETR among matched Asians and Caucasians was 81% and 56% respectively ( $P = 0.003$ ), while the SVR rates were 73% and 36% ( $P < 0.001$ ) respectively. This difference remained significant after adjusting for other predictive variables.

### INTRODUCTION

Chronic hepatitis C (CHC) virus infection is the leading cause of chronic liver disease worldwide. The prevalence of hepatitis C virus (HCV) infection in western countries including Australia and the United States approximates 1%<sup>[1-2]</sup>, while it is more common in most Asian countries<sup>[3-4]</sup>. Combination therapy with pegylated interferon and ribavirin given for 24 wk or 48 wk remains the most effective antiviral treatment, achieving sustained virological response (SVR) rates ranging from 50% to 80%<sup>[5-9]</sup>.

Various factors have been identified that influence response rates, including HCV genotype, body mass index and co-existent liver disease. Ethnicity was recently noted to impact on treatment responses. Studies conducted in African Americans suggest that these individuals have lower SVR rates when compared to Caucasians, even after adjusting for confounders that could potentially influence treatment response rates<sup>[10-13]</sup>. More recently, comparative studies between Asians and Caucasians have suggested a higher SVR to antiviral therapy among Asians<sup>[14-16]</sup>.

In Asians, HCV prevalence rates are approximately

6%<sup>[3]</sup>. Often subjects acquire the infection at a younger age and are therefore at increased risk of developing advanced liver disease and hepatocellular carcinoma. Despite this, Asians seem to be under-represented in clinical trials evaluating SVRs, with the largest available study comprising only 52 individuals<sup>[16]</sup>. In addition, there has been no head-to-head comparative study evaluating responses to antiviral therapy between Asians and Caucasians. The aims of the present study were therefore to: (1) assess the overall SVR rates in Asians infected with genotype 1 CHC receiving combination antiviral therapy; and (2) to undertake a case-control study comparing SVR rates in Asians compared to that in Caucasians matched by infecting virus genotype, age, gender and the extent of hepatic fibrosis.

## MATERIALS AND METHODS

Clinical databases of HCV infected patients who received combination interferon and ribavirin therapy between 2001 to 2005 at four Australian centres were reviewed and all Asian patients identified. Individual patient files were retrieved and their clinical status confirmed. Asian and Caucasian patients over the age of 18 years who received antiviral therapy for genotype 1 CHC were subsequently identified.

Exclusion criteria included patients who were HBsAg-positive, co-infection with HIV, liver transplant recipients or those receiving dialysis for chronic renal failure. Patient demographic characteristics, baseline biochemical, virological and histological data prior to commencing anti-viral therapy were recorded. Those with bridging fibrosis or cirrhosis were considered to have advanced liver disease. While baseline viral loads of individual patients were recorded, multiple different assays and units were used at the various study centres over time, making this data not reportable, or comparable. For alcohol intake, we defined significant intake as either documented daily consumption of more than 30 grams, or medical record documentation that alcoholism was an issue. Details of antiviral therapy were recorded. These included a history of previous anti-viral treatment, treatment regimen (interferon and ribavirin or pegylated interferon and ribavirin), adverse effects on therapy and any treatment dose reductions or interruptions due to either adverse effects or non-compliance. As a standard of care, all patients with HCV genotype 1 were scheduled for 48 wk of treatment.

The primary end point of this study was the proportion of patients achieving an SVR, defined as a documented non-detectable HCV RNA at least 24 wk after treatment. The end of treatment response (ETR) was defined as non-detectable HCV RNA at the end of treatment. Patients who received at least one dose of interferon but did not complete 48 wk of treatment for any reason were defined as non-responders. Asians and Caucasians infected with HCV genotype 1 were then matched by three criteria: age (within 5 years), gender and the extent of hepatic fibrosis, and their ETR and SVR rates were compared.

**Table 1** Demographic characteristics, treatment details and treatment responses of 108 HCV genotype 1-infected Asian patients

Variables	Frequency
Countries of origin	
Vietnam	43
China	34
Cambodia	19
Korea	5
Burma	3
Others	4
Gender (%)	
Male	69%
Age (yr, range)	51 (22-76)
Median weight (kg, range)	64 (33-104)
Median ALT (IU/mL, range)	94 (11-558)
Extend of fibrosis (%)	
Bridging fibrosis or cirrhosis	21%
Treatment regimen (%)	
Pegylated interferon + Ribavirin	89%
Interferon + Ribavirin	11%
Dose reduction of either drug	33%
Dose interruption of either drug	11%
Treatment responses (%)	
End of treatment virological response	77%
SVR	67%

All statistical analyses were performed by SAS software v11 (SAS Institute Inc., Cary, NC). Continuous variables are reported as median (range). Comparison of baseline demographics was performed by the paired Student *t*-test, Mann-Whitney test or  $\chi^2$  test as appropriate. Univariate analysis was performed with SVR as the dependent variable.

## RESULTS

### Baseline features of the Asian cohort

A total of 108 HCV genotype 1 infected Asian patients were identified. Their demographic characteristics, treatment details and treatment outcomes are shown in Table 1. The majority of patients were born in Vietnam, China or Cambodia; 69% were male. The cohort had a median age of 51 (22-76) and a median body weight of 64 kg (33-104 kg). The baseline alanine aminotransaminase (ALT) was 94 IU/mL (11-558 IU/mL). 21% of those who had liver biopsies had histological evidence of bridging fibrosis or cirrhosis. Eighty-nine percent received pegylated interferon and ribavirin while the remainder received standard interferon and ribavirin. Dose reduction was required in 33%, while 11% required dose interruption, for either adverse effects or non-compliance.

### End of treatment and SVR rates in Asians

An ETR occurred in 77% of the Asian cohort while 67% achieved an SVR. Factors influencing SVR rates including treatment regimen, fibrosis stage, age, gender and weight were examined by univariate analysis (Table 2). None of these factors were found to be predictive of an SVR in the Asian cohort. In particular, we did not observe a difference in ETR or SVR between those who received pegylated interferon versus standard interferon.

**Table 2** Univariate analysis of 108 HCV genotype 1-infected Asian patients: Predictors of SVR

Variables	OR (95% CI)	P-value
Gender (male)	0.77 (0.32-1.85)	0.55
Age (yr)	1.02 (0.99-1.06)	0.20
Weight (kg)	0.98 (0.95-1.06)	0.41
Pegylated interferon <i>vs</i> standard interferon	1.00 (0.28-3.57)	0.99
Treatment naïve	0.49 (0.22-1.12)	0.09
Dose reduction not required	1.45 (0.65-3.34)	0.39
Dose interruption not required	1.50 (0.44-5.10)	0.52
Absence of bridging fibrosis or cirrhosis	1.57 (0.61-4.07)	0.35

**Table 3** Comparison of the demographic characteristics and treatment details of the matched Asian and Caucasian patients

Variables	Asians	Caucasians	P-value
Age (yr, range)	47 (28-64)	46 (30-61)	Matched
Gender	70% male	70% male	Matched
Weight (kg)			
< 75	82%	42%	< 0.01
> 75	18%	58%	
Alcohol intake			
Minimal intake	86%	71%	0.12
Significant intake	14%	29%	
Liver fibrosis			
Minimal injury	48 (75%)	48 (75%)	Matched
Bridging fibrosis/Cirrhosis	16 (25%)	16 (25%)	
Treatment naïve	80%	91%	NS
Peginterferon + Ribavirin	83%	88%	NS
Dose modification	30%	28%	NS
Dose interruption	8%	10%	NS

### Baseline features of the matched cohort

Due to the more advanced age and extent of hepatic fibrosis among Asians, we were only able to match 64 Asian subjects with Caucasians by the set criteria. Comparison of the baseline demographics between the two groups is shown in Table 3. Only 18% of Asian patients weighed more than 75 kg while 58% of their Caucasian counterparts weighed more than 75 kg ( $P < 0.01$ ). Alcohol intake was less in Asian subjects with 14% of Asians and 29% of Caucasians reporting a significant alcohol intake history ( $P = 0.12$ ). There was no difference between the two groups in terms of previous therapy, type of treatment received or in the extent of dose reduction or interruptions from treatment adverse effects or non-compliance.

### End of treatment and SVR rates in the matched cohort

Comparison of the ETR and SVR between the 64 Asian patients and the matched Caucasian cohort is illustrated in Figure 1. Compared to Caucasians, Asian subjects had a significantly better ETR, 81% *vs* 56% ( $P = 0.003$ ) and SVR, 73% *vs* 36% ( $P < 0.001$ ). On univariate analysis (Table 4), Asian ethnicity was the most predictive factor for a SVR. Other factors that were associated with an SVR in this cohort were body weight < 75 kg, and minimal alcohol intake. Due to the large number of variables and the limited number of patients, we were unable to perform a multiple logistic regression analysis with SVR as the dependent variable. Hence the effect

**Figure 1** Comparison of ETR and SVR rates between HCV genotype 1-infected Asians and Caucasians matched for age, gender and fibrosis stage.**Table 4** Univariate analysis of predictors of SVR on matched HCV genotype 1-infected Asians and Caucasians

Variables	OR (95% CI)	P-value
Ethnicity (Asians)	4.92 (2.32-10.50)	< 0.001
Gender (male)	0.83 (0.39-1.79)	0.64
Age (per year)	1.04 (1.00-1.96)	0.061
Weight (< 75 kg)	2.59 (1.20-5.61)	0.016
Minimal alcohol intake	3.20 (1.17-8.73)	0.023
Peginterferon <i>vs</i> standard interferon	1.10 (0.42-2.92)	0.84
Treatment naïve	0.77 (0.29-2.04)	0.60
Dose reduction not required	1.04 (0.48-2.23)	0.93
Dose interruption not required	2.31 (0.64-8.33)	0.20
Absence of bridging fibrosis or cirrhosis	1.80 (0.80-4.04)	0.15

**Table 5** Effects of ethnicity on SVR after adjusting for individual unmatched variables

	Adjusted OR (95% CI)	P-value
Weight (< 75 kg)	4.64 (1.97-10.94)	< 0.001
Minimal alcohol intake	2.74 (0.97-7.75)	0.057
Pegylated interferon <i>vs</i> standard interferon	5.01 (2.35-10.71)	< 0.001
Treatment naïve	5.01 (2.32-10.81)	< 0.001
Dose reduction not required	4.94 (2.32-10.50)	< 0.001
Dose interruption not required	4.84 (2.26-10.38)	< 0.001

of ethnicity on SVR was only adjusted for individual variables that were not matched. In this analysis (Table 5), Asian ethnicity remained a significant predictor of SVR after allowing for other variables that were not matched.

## DISCUSSION

In this retrospective study, we confirmed that in CHC, ethnicity is an important variable influencing response to antiviral therapy. Our study of Asians infected with HCV genotype 1 has permitted several important observations to be made. Firstly, the overall SVR among Asians approached 70%. Secondly, Asians with genotype 1 CHC were more likely to respond favourably to antiviral therapy compared to matched Caucasians. Finally, excess alcohol intake and increased body weight adversely affected treatment outcomes.

The observation of a favourable response rate among Asians is in accordance with other reports<sup>[14-16]</sup>. Importantly, the effect of ethnicity on SVR rates remained significant after adjusting for other confounders including age, gender, treatment regimen and the extent of hepatic fibrosis. The present study also observed that lower body weight and minimal alcohol intake were predictive of an SVR.

Body mass index<sup>[17-18]</sup>, insulin resistance<sup>[19-21]</sup> and hepatic steatosis<sup>[22-24]</sup> are now known to play a major role in the pathogenesis of HCV infection. Insulin resistance in genotype 1 CHC is most likely related to host factors, in particular obesity, rather than virological factors, and is associated with reduced treatment response rates<sup>[25]</sup>. It was therefore interesting to observe in our study that the matched Asian cohort overall had lower body weights than Caucasians. Similar findings were reported in the studies by Hepburn *et al.*<sup>[15]</sup> and Missiha *et al.*<sup>[16]</sup>. Although in these previous studies, as well as in the current report, the effect of ethnicity remained significant after allowing for body weight, central adiposity or underlying insulin resistance were not measured. This is a limitation of the retrospective nature of this study. There are no published data on the impact of hepatic steatosis on CHC infection among Asians. It is therefore important to examine these factors in future studies as they might potentially explain the reasons why Asians having better treatment responses.

Not surprisingly, we observed that Asian subjects consumed less alcohol, possibly a reflection of cultural influences. Our study was the first to adjust for this variable. We noted that the effect of ethnicity on SVR was modified after allowing for alcohol consumption and did not reach statistical significance ( $P = 0.057$ ). Although the difference in SVR was not significant (probably related to patient numbers), this observation highlights the importance of taking alcohol intake into account in studies comparing response rates stratified for ethnicity<sup>[26-27]</sup>.

The biological basis for the difference in SVR rates between Asians and Caucasians has not been examined previously. Studies into the effects of ethnicity on CHC treatment has to date focussed entirely on African Americans. It was found that African Americans had different class II human-leukocyte antigen alleles from Caucasians<sup>[28]</sup>, which could have accounted for their worse SVR. Further, viral kinetics studies have shown that African Americans exhibit significantly lower interferon effectiveness and achieve a lower reduction in HCV RNA in the first 24 h of treatment<sup>[29]</sup>. It was also noted that African Americans had different pre-treatment cytokine profiles<sup>[30]</sup>. In addition, while they mounted a more robust HCV-specific CD4 Th1 proliferative response, it did not translate into a higher rate of IFN-gamma production, potentially secondary to their dysfunctional nature, which was associated with a failure of interferon therapy<sup>[31-32]</sup>. The significance of these studies is that the impact of ethnicity, on treatment response is more likely to be related to host factors, particularly to genetic differences in immune regulation rather than environmental factors.

Our study suffered the usual limitations of retrospective observational reports. In particular, we now know that a proportion of Asians who were initially genotyped by INNO-LiPA as 1b, were in fact genotypes 7, 8 or 9 if direct sequencing of the core region is performed<sup>[14]</sup>. Direct core sequencing was not performed in our study. It is arguable, however, if inclusion of genotypes 7, 8 or 9 would have altered the better SVR rates achieved by the Asian cohort since the original article noted that SVR rates were identical among Asians infected with genotypes 7, 8 or 9 and those infected with genotype 1 HCV infection<sup>[14]</sup>. Similar findings were noted in another study where it was shown that there was no difference in response rates between genotype 1b infected Asians and the rest of the genotype 1 infected Asians<sup>[15]</sup>. We therefore believe that the difference in SVR rates noted in our study was more likely related to ethnicity than a bias from a potentially small group of patients who might have been mistyped. It is clear however that prospective trials on larger patient cohorts including all genotypes are needed to clarify this issue.

The other limitation of this type of retrospective comparative study, as pointed out by both Hepburn *et al.*<sup>[15]</sup> and Missiha *et al.*<sup>[16]</sup>, is that it failed to recognise the wide genetic heterogeneity and different environmental factors that might exist within the same ethnic group. While we defined Asians as those who migrated from East Asia including China, Japan, Korea and South East Asia, and of parents of those origin, we do not, and could not, know if they essentially represent the same group of patients genetically.

In conclusion, Asians infected with HCV genotype 1 achieved a higher SVR rate when compared to a cohort of matched Caucasians. Future studies should focus on confirming our observations in large prospective cohorts and on characterizing the immunogenetic basis for these observations.

## COMMENTS

### Background

Treatment with interferon and ribavirin combination therapy remains currently the most effective treatment for chronic hepatitis C (CHC) virus infection, but treatment response can only be achieved in 50% to 80% of patients. Various factors including genotype, viral load, extent of liver injury on liver biopsy, age and gender of patients were known to impact on treatment responses. Identification of these factors aids selection of patients for treatment and determination of duration of therapy.

### Research frontiers

Recent studies on African Americans suggested that ethnicity might also impact on treatment responses. Data from studies on one ethnic group may not be extrapolated to other ethnic groups, and different ethnic groups may require different treatment regimens.

### Innovations and breakthroughs

This study found that Asian patients infected with hepatitis C genotype 1 had better treatment responses than Caucasian patients, even after adjusting for other predictive factors.

### Applications

The implication of the results of this study is twofold. Firstly, it prompts further basic scientific research into difference in immune response to CHC among different ethnic groups to better understand the pathogenesis of CHC. Secondly, it suggests that clinically, different treatment regimen should be studied and compared among different ethnic groups.

**Peer review**

The results provide sufficient evidence, which allow authors to make firm conclusion that ethnicity is an important factor variable influencing response to antiviral therapy in patients with CHC. The further studies to confirm the results of this observational study for patients from different ethnic backgrounds are needed. The references are appropriate, relevant and updated.

### Abstract

**AIM:** To determine the methylation status and aberrant expression of some secreted frizzled-related protein (SFRP) genes in pancreatic cancer and explore their role in pancreatic carcinogenesis.

**METHODS:** Methylation status and expression of SFRP genes were detected by methylation-specific PCR (MSPCR) and reverse-transcription PCR (RT-PCR) respectively.

**RESULTS:** The frequencies of methylation for SFRP genes 1, 2, 4, 5 were 70%, 48.3%, 60% and 76.7% in pancreatic cancer samples, and 21.7%, 20%, 10% and 36.7% in matched cancer adjacent normal tissue samples, respectively ( $\chi^2 = 28.23$ ,  $P < 0.0001$  for SFRP gene 1;  $\chi^2 = 10.71$ ,  $P = 0.001$  for SFRP gene 2;  $\chi^2 = 32.97$ ,  $P < 0.0001$  for SFRP gene 4;  $\chi^2 = 19.55$ ,  $P < 0.0001$  for SFRP gene 5). Expression loss of SFRP genes 1, 2, 4 and 5 was found in 65%, 40%, 55% and 71.7% of 60 pancreatic cancer samples, and 25%, 15%, 18.3% and 31.7% of matched cancer adjacent normal tissue samples, respectively ( $\chi^2 = 19.39$ ,  $P < 0.0001$  for SFRP gene 1;  $\chi^2 = 9.40$ ,  $P = 0.002$  for SFRP gene 2;  $\chi^2 = 17.37$ ,  $P < 0.0001$  for SFRP gene 4;  $\chi^2 = 19.22$ ,  $P < 0.0001$  for SFRP gene 5). SFRP gene 1 was methylated but not expressed in PC-3 and PANC-1, SFRP gene 2 was methylated but not expressed in PANC-1 and CFPAC-1, SFRP gene 4 was methylated but not expressed in PC-3, and SFRP gene 5

### INTRODUCTION

Secreted frizzled-related proteins (SFRPs) are a group of negative regulators of the Wnt signaling pathway<sup>[1-3]</sup>. These proteins contain a cysteine-rich domain (CRD) which shares a sequence similarity of 30%-50% with Wnt receptor frizzled proteins. Through the CRD, SFRPs can antagonize Wnt signaling by interacting with Wnt ligand. As the Wnt signaling pathway plays an important role in cell proliferation, differentiation and apoptosis in adult tissues, aberrant activation of the Wnt pathway caused by down-regulation of SFRPs may induce tumorigenesis. It was recently reported that some members of the SFRP family are down-regulated by hypermethylation in a series of human cancers<sup>[4-9]</sup>.

The prognosis of pancreatic cancer, one of the most malignant tumors, is usually very poor. The pathogenesis of pancreatic cancer is still not very clear. It has been found that hypermethylation and subsequent expression loss of some tumor suppressor genes and tumor-related genes, such as p16<sup>[10]</sup>, RASSF1A<sup>[11]</sup>, SOCS-1<sup>[12]</sup>, and hMLH1<sup>[13]</sup> occur frequently in pancreatic cancer.

This study was designed to determine the methylation status and aberrant expression of some members of the SFRP family in pancreatic cancer and explore their role in pancreatic carcinogenesis.

## MATERIALS AND METHODS

### Cell lines, cancer and matched adjacent tissue samples

Human pancreatic cancer cell lines PC-3, PANC-1 and CFPAC-1 (from KEYGEN, Nanjing, China) were cultured in RPMI 1640 supplemented with 10% fetal bovine serum, 100 µg/mL penicillin, and 100 µg/mL streptomycin, at 37°C in a humid incubator containing 50 mL/L CO<sub>2</sub>. Pancreatic cancer and matched adjacent tissue samples were obtained from patients who underwent operation at the Second Affiliated Hospital of China Medical University. The samples were frozen in liquid nitrogen immediately after surgery. Haematoxylin and eosin staining was used to assure that cancer samples were consisted mostly of tumor cells with no tumor cells in the tumor adjacent tissue samples.

### DNA and RNA extraction

DNA was extracted by a standard phenol/chloroform extraction and ethanol precipitation procedure. RNA was isolated using Tri reagent (Takara, Dalian, China) according to its manufacturer's instructions.

### Reverse transcription-PCR (RT-PCR)

RT-PCR was performed using a RNA PCR 3.0 kit (Takara, Dalian, China). cDNA was synthesized from 1 µg RNA using a random 9 primer and AMV reverse transcriptase. One cycle was performed at 30°C for 10 min, at 42°C for 25 min, at 99°C for 5 min, and at 5°C for 5 min. The primer sequences used in PCR are described elsewhere<sup>[7]</sup>. PCR was performed for one cycle at 94°C for 2 min, followed by 30 cycles at 94°C for 30 s, at 60°C for 30 s and at 72°C for 2 min.

### Methylation-specific PCR (MSPCR)

Methylation of SFRP1 was detected with a MSPCR kit (GENMED, Shanghai, China) according to its manufacturer's instructions. The primer sequences are described elsewhere<sup>[7]</sup>. MSPCR was performed for one cycle at 95°C for 5 min, followed by 35 cycles at 95°C for 30 s, at 60°C for 30 s and at 72°C for 30 s.

### Statistical analysis

Methylation and expression of SFRP1 in primary pancreatic cancer and its adjacent tissue samples were compared by chi-square test.  $P < 0.05$  was considered statistically significant.

## RESULTS

### Hypermethylation and expression of SFRPs in pancreatic cancer cell lines

The methylation status of SFRPs was detected by MSPCR. SFRP1 was methylated in PC-3 and PANC-1, SFRP2 in PANC-1 and CFPAC-1, SFRP4 in PC-3 and SFRP5 was methylated in CFPAC-1, respectively (Figure 1). The mRNA expression of SFRPs was determined by RT-PCR. No expression of SFRP1, SFRP2, SFRP4 and SFRP5 was found in PC-3 and PANC-1, PANC-1 and CFPAC-1, PC-3 and in CFPAC-1, respectively (Figure 2).

**Figure 1** Hypermethylation of SFRP genes in pancreatic cancer cell lines detected by MSPCR. 1: PC-3; 2: PANC-1; 3: CFPAC-1; M: Methylated; U: Unmethylated.

**Figure 2** Expression of SFRPs in pancreatic cancer cell lines detected by RT-PCR. 1: PC-3; 2: PANC-1; 3: CFPAC-1.

The expression loss of SFRPs was correlated with the methylation status.

### Hypermethylation and expression of SFRPs in pancreatic cancer and its adjacent tissue samples

Hypermethylation of SFRP1, SFRP2, SFRP4 and SFRP5 was detected in 42 (70%), 29 (48.3%), 36 (60%) and 46 (76.7%) of 60 pancreatic cancer samples, and 13 (21.7%), 12 (20%), 6 (10%) and 22 (36.7%) of its adjacent tissue samples, respectively. The hypermethylation of each SFRP gene differed significantly in cancer and its adjacent tissue samples ( $\chi^2 = 28.23$ ,  $P < 0.0001$  for SFRP1;  $\chi^2 = 10.71$ ,  $P = 0.001$  for SFRP 2;  $\chi^2 = 32.97$ ,  $P < 0.0001$  for SFRP 4;  $\chi^2 = 19.55$ ,  $P < 0.0001$  for SFRP 5; Table 1). Expression loss of SFRP1, SFRP2, SFRP4 and SFRP5 was found in 39 (65%), 24 (40%), 33 (55%) and 43 (71.7%) of 60 pancreatic cancer samples, and 15 (25%), 9 (15%), 11 (18.3%) and 19 (31.7%) of its adjacent tissue samples, respectively. The expression loss of each SFRP gene differed significantly in cancer and its adjacent tissue samples ( $\chi^2 = 19.39$ ,  $P < 0.0001$  for SFRP1;  $\chi^2 = 9.40$ ,  $P = 0.002$  for SFRP2;  $\chi^2 = 17.37$ ,  $P < 0.0001$  for SFRP4;  $\chi^2 = 19.22$ ,  $P < 0.0001$  for SFRP5; Table 2).

## DISCUSSION

The Wnt signaling pathway plays an important role not only in development of cancer but also in cell proliferation, differentiation and apoptosis in adult tissues.

**Table 1** Hypermethylation of SFRPs in pancreatic cancer and its adjacent tissue samples

	<i>n</i>	SFRR1	SFRR2	SFRP4	SFRP5
Pancreatic cancer samples	60	42	29	36	46
Adjacent tissue samples	60	13	12	6	22
$\chi^2$		28.23	10.71	32.97	19.55
<i>P</i>		< 0.0001	0.001	< 0.0001	< 0.0001

**Table 2** Expression loss of SFRPs in pancreatic cancer and its adjacent tissue samples

	<i>n</i>	SFRR1	SFRR2	SFRP4	SFRP5
Pancreatic cancer samples	60	39	24	33	43
Adjacent tissue samples	60	15	9	11	19
$\chi^2$		19.39	9.40	17.37	19.22
<i>P</i>		< 0.0001	0.002	< 0.0001	< 0.0001

Aberrant activation of Wnt signaling in tumorigenesis has been reported frequently, and some members of the Wnt family are over-expressed in breast cancer, gastrointestinal cancer and prostate cancer<sup>[14-16]</sup>. Down-regulation of the Wnt inhibitors DKKs and SFRPs also occurs frequently in human cancers<sup>[17,18]</sup>. Most of these reports show that expression loss of these inhibitors is mainly caused by promoter hypermethylation, an important epigenetic gene silencing mechanism.

Aberrant Wnt signals are also involved in pancreatic cancer. It was reported that activated mutation of  $\beta$ -catenin on exon 3, a downstream component in the Wnt signaling pathway, plays an important role in pancreatic tumorigenesis. This kind of mutation leads to excessive accumulation of  $\beta$ -catenin and aberrant activation of the Wnt pathway<sup>[19-23]</sup>. Over-expression of many members of the Wnt family, such as Wnt1<sup>[24]</sup>, Wnt5a<sup>[25]</sup>, Wnt5b<sup>[25]</sup>, Wnt7a<sup>[26]</sup>, Wnt10b<sup>[27]</sup> in pancreatic cancer, has been reported in recent years, further suggesting that the Wnt pathway plays a role in the pathogenesis of pancreatic cancer. It has recently been shown that epigenetic inactivation of Wnt inhibitory factor 1 by hypermethylation occurs frequently in pancreatic cancer<sup>[28]</sup>.

The pathogenesis of pancreatic cancer, a very malignant carcinoma, has been poorly understood. In this study, we analyzed the hypermethylation and expression of SFRPs in pancreatic cancer and explored their role in pancreatic carcinogenesis, showing that hypermethylation and expression loss of SFRPs occur frequently in pancreatic cancer. The frequencies of hypermethylation and expression loss of SFRPs in pancreatic cancer samples were significantly higher than those in its adjacent normal tissue samples, suggesting that hypermethylation and subsequent expression loss of SFRPs occur early and play an important role in the pathogenesis of pancreatic cancer.

As we know, Wnt signaling can be divided into canonical Wnt/ $\beta$ -catenin pathway and non-canonical pathway which includes the planar cell polarity pathway and the Wnt/ $\text{Ca}^{2+}$  pathway. As we did not measure the level of  $\beta$ -catenin, we could not determine whether the pathway through which SFRP1 expression loss is involved in

the pancreatic carcinogenesis. Further study is needed to elucidate its mechanism.

## COMMENTS

### Background

Secreted frizzled-related proteins (SFRPs) are a group of negative regulators of the Wnt signaling pathway. Aberrant activation of the Wnt pathway caused by down-regulation of SFRPs may induce tumorigenesis.

### Research frontiers

The pathogenesis of pancreatic cancer, a very malignant carcinoma, is poorly understood. In this study, we found that hypermethylation status and expression of SFRPs played an important role in pancreatic carcinogenesis.

### Innovations and breakthroughs

In this study, we analyzed the hypermethylation status and expression of SFRPs in pancreatic cancer and explored their role in pancreatic carcinogenesis.

### Applications

Our study suggested that hypermethylation and subsequent expression loss of SFRPs play an important role in pancreatic carcinogenesis. For this reason, demethylated agents may be used to treat cancer in clinical practice.

### Peer review

In this study, the authors reported that the expression loss of some SFRP genes caused by hypermethylation was common in pancreatic cancer, which may play an important role in pancreatic carcinogenesis. This paper is original and informative.

### Abstract

**AIM:** To characterize the factors of the improved survival following combined pancreaticoduodenectomy (PD) and gastrectomy for the treatment of advanced gastric cancer with pancreaticoduodenal region involvement.

**METHODS:** From 1995 to 2004, 53 patients with primary gastric cancer were diagnosed with synchronous ( $n = 44$ ) or metachronous ( $n = 9$ ) pancreaticoduodenal region involvement. Of these, 17 patients (32%) underwent total gastrectomy (TG) or distal subtotal gastrectomy (SG) combined with PD simultaneously. The preoperative demographic, clinical information, clinicopathologic features and the surgical results of these 17 patients were considered as factors influencing survival and were analyzed by the Kaplan-Meier method with log-rank comparison.

**RESULTS:** The actual 1- and 3-year survival rates of these 17 patients after resection were 77% and 34%, respectively, and three patients survived for more than 5 years after surgery. The tumor-free resection margin ( $P = 0.0174$ ) and a well-differentiated histologic type ( $P = 0.0011$ ) were significant prognostic factors on univariate analysis. No mortality occurred within one mo after operation, postoperative weight loss of different degree was present in all the patients with TG and 12 cases had other complications. There were 9 (53%) cases of recurrence in 5-48 mo after operation. The survival rate in the palliative and explorative group was significantly ( $P = 0.0064$ ) lower than in the combined PD group.

**CONCLUSION:** Judicious use of en bloc PD and gastrectomy and strictly preventing postoperative complications may improve the long-term survival for advanced gastric cancer patients with pancreaticoduodenal region involvement. Well-differentiated histology and negative resection margin are the most important predictors of long survival.

Pancreaticoduodenectomy for advanced gastric cancer with pancreaticoduodenal region involvement. *World J Gastroenterol* 2008; 14(21): 3425-3429 Available from: URL: <http://www.wjg-net.com/1007-9327/14/3425.asp> DOI: <http://dx.doi.org/10.3748/wjg.14.3425>

### INTRODUCTION

Because of earlier diagnosis, more accurate staging and safer operations, outcomes after treatment of gastric cancer are being improved, especially for early gastric cancer the results have become satisfactory<sup>[1]</sup>. And in the treatment of advanced carcinoma of the stomach, gastrectomy with extensive lymph node dissection has been reported to acquire a substantial improvement in survival<sup>[2-4]</sup>. In spite of these advances, there were still some problems as for areas of resection for advanced gastric cancer involving local organs. Arguments against enlarged resection are based on the observed increase in the morbidity and mortality rates, with little objective benefit in survival<sup>[5]</sup>. And some surgeons still consider the invasion of adjacent organs by the carcinoma of stomach as a sign of incurable disease. But others believe patients with T4 gastric cancer will benefit from extended en bloc surgical resection<sup>[6-8]</sup>.

For the anatomic reason, pancreaticoduodenal region involved in advanced gastric cancer was not scarce. But few articles about its surgical treatment were available. The aim of this study was to report our experience in undergoing pancreaticoduodenectomy

(PD) with gastrectomy for advanced gastric cancer with pancreaticoduodenal region involvement.

## MATERIALS AND METHODS

### Patients

From January 1995 to January 2004, 916 patients with gastric carcinoma underwent surgical treatment in the Department of Hepatobiliary-Pancreatic-Gastric Surgery, Zhejiang Cancer Hospital. Of the 916 cases, 44 were found to have synchronous pancreaticoduodenal region involved and 9 metachronous pancreaticoduodenal region invaded or involved. Among the 53 patients, palliative gastrectomy was performed in 6 patients, bypass through exploration performed in 14, explorations in 7 and surgical treatment was given up in 9 because of additional organs metastasis or poor physical state. And 17 patients who underwent PD with gastrectomy were selected for this study, including 11 men and 6 women with a mean age of 56 years (range from 38 to 71 years). Overall radical resectability was 32.1% (17/53) for the 53 patients, 32% (14/44) for synchronous metastases, and 33.3% (3/9) for metachronous lesions. Follow-up period ranged from 2 to 72 mo (median 38 mo).

### Methods

PD was indicated for patients with visibly synchronous pancreaticoduodenal region involved lesions who did not have peritoneal dissemination or any other distant metastasis, or for patients with metachronous pancreaticoduodenal region involved who did not have any other recurrent lesions. Three patients who had a desmoplastic reaction at the site of presumed tumor invasion were not included in this study. Confirmation of cancerous invasion of pancreaticoduodenal region was established histologically in operation. In addition to PD, TG was done in 11 (64.4%) and SG in 6 (35.6%) patients, depending on the location of the primary gastric lesion. En bloc surgical resection and D2 lymphadenectomy were performed as the standard radical gastrectomy for these 17 patients. As for reconstruction of digestive tract, binding pancreaticojejunostomy<sup>[9]</sup> and Roux-en-Y anastomosis were adopted for all the cases. In this group, two patients underwent right hemicolectomy and one patient underwent cholangiocystectomy additionally at the same time. All patients were treated with postoperative adjuvant chemotherapy using the same chemotherapy regimens (ELF regimens: etoposide + leucovorin + fluorouracil)<sup>[10,11]</sup>.

The preoperative demographic and clinical information was obtained from the patient records: age, gender, interval between gastrectomy and PD, surgical procedure and recurrence. The number and size of the tumors, extent of lymph node metastasis and surgical margin of the tumors were also recorded. The pathologic diagnosis and classification of the tumors were performed by a minimum of two pathologists.

### Data analysis

All data were treated with statistic software kit of

**Table 1** Characteristics and their prognostic significance for PD group

SPSS 12.0. Parameters influencing survival were compared using the Kaplan-Meier method with log-rank comparison.  $P < 0.05$  was considered significant differences.

## RESULTS

No patient died during the initial hospital stay or within 1 mo after surgery. The median diameter of the tumors was 4.0 cm (range 2.8-9.5 cm). Only four patients had well differentiated tumors and the other 13 patients had moderately or poorly differentiated tumors. According to Borrmann Type, six patients were Borrmann III and 11 were Borrmann IV. Ten patients had positive lymph node metastasis and seven had negative lymph node metastasis. Resection margins in five patients were tumor-positive and 12 were tumor-free. The actual 1- and 3-year survival rates after PD with gastrectomy were 77% and 34%, respectively. The results of the analysis of the prognostic factors are given in Table 1. Tumor-free (negative) resection margin ( $P = 0.0174$ ) was significant determinants for a favorable prognosis after PD. In terms of pathologic features, a well-differentiated type of metastases ( $P = 0.0011$ ) was a significant prognostic factor. Factors associated with the primary lesion and surgical procedures were not significant prognostic determinants. Cancer recurred in 11 (59%) of the 17 patients between 5 mo and 48 mo after PD resection. The site of initial recurrence after PD and gastrectomy was the gastric and pancreaticoduodenal

**Figure 1** Comparison of survival between patients with palliative surgery and PD. Significant difference was found between the two groups ( $P = 0.0064$ ).

bed in 6 patients, the liver in 3, and the retroperitoneal lymph nodes in 2, which were diagnosed by image methods (CT, MRI or US). Three patients survived more than 5 years after PD. No mortality occurred in one mo after operation, postoperative weight loss of different degree was present in all the patients with TG. Twelve had other complications among the 17 patients, including intra-abdominal abscesses 5 (41.7%) and anastomotic leak 3 (gastrointestinal leak 1 and bile leak 2) (25%), pneumonia 2 (16.7%), returned esophagitis 1 (8.3%) and acute renal failure 1 (8.3%). All the complications were cured by operative or conservative treatment.

Of the 36 patients with pancreaticoduodenal region involvement who did not undergo radical resection, the actual 1- and 3-year survival rates were 41.7%(15/36) and 5.6%(2/36), respectively. The survival rate of these 36 patients (palliative group) was significantly ( $P = 0.0064$ ) lower than that of PD group (Figure 1).

## DISCUSSION

Surgery remains the only method of treatment that offers the potential for cure of gastric cancer<sup>[12]</sup>. But gastric cancer is usually diagnosed at an advanced stage because of its vague and nonspecific symptoms. And poor survival will be followed by late stage, especially when tumors invade the serosa or other organs. There is a report that with serosal involvement alone, less than 30% of the patients are living five years after surgery, and with involvement of both serosa and lymph nodes, the 5-year survival is less than 15%<sup>[13]</sup>. At the same time, opinions about extended surgical resections for advanced gastric cancer remains controversial. Takeuchi *et al*<sup>[12]</sup> retrospectively studied 65 patients without distant metastasis who underwent TG with pancreaticosplenectomy (PS) and 98 patients without distant metastasis who underwent TG alone (the TG alone group) by essentially the same technique, and concluded that combined PS with TG should never be performed as the standard surgical procedure for every stage of gastric cancer, especially stage II. But we think that in his report the PS was performed with TG to facilitate dissection of the lymph nodes around the splenic artery and splenic hilus, but not performed to

resect the involved lesions of spleen or pancreas tail.

On the other hand, some authors agreed to extend gastric resection in patients with adjacent organs involved. In the report by Kodama *et al*<sup>[14]</sup>, 77 patients with carcinoma of the stomach directly invading adjacent organs or structures were analyzed retrospectively to investigate the efficacy of en bloc resection. Forty-one patients underwent gastrectomy combined with resection of one or more invaded organs (combined resection group), while the other 36 patients underwent gastrectomy with palliative abrasion between the primary tumor and the invasion site (non-combined resection group). The results demonstrated that the five-year survival rate was 23% in the combined resection group and 0% in the non-combined resection group. They thought that an en bloc combined resection would be worth trying. Iriyama *et al*<sup>[15]</sup> reported the highest 5-year survival rate of 46% after extended gastric resection with adjacent organs in patients with T4 gastric cancer. And Korenaga *et al*<sup>[16]</sup> reported that the 5-year survival was 36.7% for those who underwent radical resection of adjacent organs and 17.4% for those who underwent palliative resection of adjacent involved organs. Ozaki *et al*<sup>[17]</sup> and others<sup>[16]</sup> have found that an aggressive approach to resection of the stomach with the body and tail of the pancreas or PD and right hemicolectomy can lead to an acceptable 5-year survival rate of 29%. Yonemura *et al*<sup>[18]</sup> have performed 26 SG with PD in combination with right hemicolectomy without any operative mortality and a 5-year survival of 33% even for patients with N3 metastases (e.g. retropancreatic nodes or superior mesenteric nodes). Cho *et al*<sup>[19]</sup> reported their 15-year experience of extended gastrectomy for advanced gastric cancer. The median survival time of the positive margin group was 34 mo. The negative margin group had a significantly longer median survival of 69 mo ( $P = 0.025$ ). When both groups of patients were stratified according to nodal stage, a positive resection margin determined a worse prognosis only in patients with node-negative disease (174 mo *vs* 37 mo,  $P = 0.0001$ ). In patients with nodal metastasis, the median survival time was similar in both groups. Their results suggested that a positive microscopic margin was associated with a worse outcome in patients with node-negative disease. Therefore, a more aggressive treatment, such as reoperation, was needed in node-negative patients with a positive microscopic disease. Our results have shown that three patients survived more than five years in radical resection group (PD group) and no patient survived more than five years in the palliative group. And the actual survival of these two groups is statistically different. Although factors associated with the primary lesion, patient demographic data and surgical procedures were not significant prognostic determinants, but negative resection margin was very important for the higher survival rate. And when pancreaticoduodenal region is involved by advanced gastric cancer, combined PD and gastrectomy will bring the chance of tumor-free resection margin. And curative (R0) resection improves prognosis<sup>[19,20]</sup>. PD with gastrectomy will benefit the lymphadenectomy of No. 7, 8, 9 and 11. Sometimes, it

**Figure 2** Lymphadenectomy of lymph nodes of No. 7, 8, 9, 11 and 16.

is helpful for lymphadenectomy of No. 16 (Figure 2), though lymph nodes of the No.16 were not resected routinely in our group. We proposed the indication of PD with gastrectomy as follows: (1) head of pancreas was invaded by gastric cancer, (2) metastasis of lymph nodes of No.6 and head of pancreas was infiltrated, (3) duodenum below pylorus 2 cm was invaded by gastric cancer, and (4) the inferior segment of common bile duct was invaded by gastric cancer. Occasionally, the above condition was not found by preoperative examination. In our group, three cases were not found till during operations. So it is necessary to check the head of pancreas, the inferior segment of common bile duct and the superior segment of duodenum below pylorus during operations when tumor was near the pancreaticoduodenal region. As for the pattern of gastrectomy, we adopted TG or SG according to the different locations of the cancer within the stomach, its pattern of growth, and the level of local spread. Subtotal gastrectomies were reserved for exophytic and small infiltrative tumors located in the lower third of the stomach. Total gastrectomy was used for tumors located in the middle and upper third of the stomach, or tumors with an infiltrative growth pattern. Our results manifested that tumor-free resection margins will benefit the survival. And we emphasize that frozen-histologic examination during operation should benefit both the definition of resection margins and the definition of tumor invasion on pancreaticoduodenal region. Large inflammatory perigastric lymph nodes or desmoplastic reaction around gastric cancer can be inaccurately presumed to be tumor invasion and adopt extended gastric resection mistakenly. Three patients who had desmoplastic reaction at the site of presumed tumor invasion were found in our hospital during operation, the pancreas and duodenum were reserved. And no inflammatory perigastric lymph nodes or desmoplastic reaction around gastric cancer were found during postoperative histologic examination in our data.

Upon decision of extended resection, as the procedure of PD and gastrectomy was relatively complicated and status of most patients was poor, a high complication rate could not be ignored. The complication rates of additional organ resection with gastrectomy have been consistently reported to be higher when compared with the patients

undergoing gastrectomy alone<sup>[21-23]</sup>. And the increasing overall complications and infectious complications have been found to be factors for the decrease in the survival of the patients. So, reinforcing perioperative management is a key point to prevent postoperative complications. Our data demonstrate that the overall complication rate was very high, and postoperative weight loss of different degree was present in all the patients with TG. Judicious use of additional PD with gastrectomy is also important for reducing postoperative complications. If a patient could not tolerate a prolonged operation, we would take simple operative method such as bypass operation. And simple gastroenterostomy or esophagojejunostomy should be adopted to reduce postoperative complications and postoperative nutritional support would improve the state of weight loss.

We adopted total parenteral nutrition (TPN) at the early stage after TG to spur positive nitrogen balance and reduce weight loss, and after an interval we adopted suitable enteral nutrition to reduce complications. A leak or fistula from the pancreatic anastomosis is the leading cause of morbidity and mortality after PD, but no pancreaticoenteral anastomosis leak occurred in our study, as we adopted binding pancreaticojejunostomy<sup>[9]</sup>, by which 3 cm of the serosa-muscular sheath of the jejunum was bound to the pancreatic remnant and could effectively prevent the development of pancreatic leak or fistula. It is a safe, simple and efficient technique.

Our study confirmed that patients with advanced gastric cancer could benefit from aggressive en bloc surgical resection and should not render unresectable when pancreaticoduodenal region was found invaded or involved. With careful patient selection, gastrectomy with PD can be performed with acceptable morbidity and minimum mortality. Well histologic differentiation and negative resection margin are the most powerful determinants of survival following an extended resection. The survival rate in the palliative and explorative group was significantly ( $P = 0.0064$ ) lower than in the combined PD group, partially because that their baseline conditions were different. And in this article, we did not analyze the survival rates of patients with TG or SG, because the number of the patients was too large to follow up. We have no complete data of these patients. So we can not compare the survival rates between patients with TG or SG and those with TG or SG combined with PD. It is the default of this study.

## COMMENTS

### Background

For advanced gastric carcinoma, gastrectomy with extensive lymph node dissection has been reported to acquire a substantial improvement in survival. But there are still some problems as for areas of resection for advanced gastric cancer involved local organs. For the anatomic reason, pancreaticoduodenal region involved in advanced gastric cancer was not scarce. But few articles about its surgical treatment have been reported. This study was to report the authors' experience in undergoing pancreaticoduodenectomy (PD) and gastrectomy for advanced gastric cancer with pancreaticoduodenal region involved.

### Research frontiers

The focus of controversy for the advanced gastric cancer involved organ

is either performing the extensive resection or giving up surgical resection. Arguments against enlarged resection are based on the observed increase in the morbidity and mortality rates, with little objective benefit in survival. And some surgeons still consider the invasion of adjacent organs by the carcinoma of stomach as a sign of incurable disease. But others believe patients with T4 gastric cancer will benefit from extended en bloc surgical resection.

### Innovations and breakthroughs

This study confirmed that patients with advanced gastric cancer could benefit from aggressive en bloc surgical resection, which should not be rendered unresectable when pancreaticoduodenal region was found invaded or involved. Negative resection margin is an important factor for the patients with extended resection.

### Applications

For the patients with advanced gastric cancer with pancreaticoduodenal region invaded, PD and extensive resection should be performed if the status of the patients permits.

### Peer review

This retrospective study assessed the performance of PD for advanced gastric cancer with pancreaticoduodenal region involvement, and observed that the 1-year and 3-year survival rates after total gastrectomy (TG) or distal subtotal gastrectomy (SG) combined with PD were 77% and 34%, which were significantly higher than in the patients with palliative treatment. It was also found that histological differentiation and negative resection margin were most important predictors.

## INTRODUCTION

Endometriosis is characterized by the presence of functional endometrial tissue consisting of glands and/or stroma located outside the uterus<sup>[1]</sup>. It is a painful chronic disease occurring in 5%-15% of menstruating women<sup>[1-3]</sup>.

The reported prevalence of endometriosis is 1%-20% in asymptomatic women, 10%-25% in infertile patients and 60%-70% in women with chronic pelvic pain<sup>[4-5]</sup>.

Endometriosis can be divided into intra- and extra-peritoneal sites. In decreasing order of frequency, the intra-peritoneal locations are ovaries (30%), uterosacral and large ligaments (18%-24%), fallopian tubes (20%), pelvic peritoneum, pouch of Douglas, and gastrointestinal (GI) tract. Extra-peritoneal locations include cervical portio (0.5%), vagina and rectovaginal septum, round ligament and inguinal hernia sac (0.3%-0.6%), navel (1%), abdominal scars after gynaecological surgery (1.5%) and caesarian section (0.5%). Endometriosis rarely affects extra-abdominal organs such as the lungs, urinary system, skin and the central nervous system<sup>[6-9]</sup>.

GI involvement of endometriosis has been found in 3%-37% of women, most commonly in the sigmoid colon, rectum and terminal ileum<sup>[10-13]</sup>.

We report a case in which endometrial infiltration of the small bowel caused acute obstruction, requiring emergency surgery. Diagnosis of ileal endometriosis was made by pathological examination of the resected specimen.

## Abstract

Gastrointestinal involvement of endometriosis has been found in 3%-37% of menstruating women and exclusive localization on the ileum is very rare (1%-7%). Endometriosis of the distal ileum is an infrequent cause of intestinal obstruction, ranging from 7% to 23% of all cases with intestinal involvement. We report a case in which endometrial infiltration of the small bowel caused acute obstruction requiring emergency surgery, in a woman whose symptoms were not related to menses. Histology of the resected specimen showed that endometriosis was mainly prevalent in the muscularis propria and submucosa and that the mucosa was not ulcerated but had inflammation and glandular alteration. Endometrial lymph node involvement, with a cystic glandular pattern was also detected.

## CASE REPORT

A 44-year old woman was referred to our unit because of diffuse abdominal pain, associated with diarrhoea alternating with constipation.

The patient began complaining of mild abdominal discomfort nine months earlier. Episodes of pain relapsed irregularly, lasted a few hours and were not related to menses. She had two normal labors at the age of 30 and 32 years, regular menses and no history of dyspareunia. No other symptoms were present. Her past medical history was unremarkable.

Three months earlier, evaluation by her primary care physician revealed normal blood tests, and an abdominal ultrasound examination was unremarkable. Faecal analysis was negative for both parasites and occult blood. Antispasmodic drugs were administered, but the patient experienced a progressive worsening of the cramping abdominal pain and the onset of constipation.

Physical examination showed mild diffuse abdominal tenderness. No abdominal masses or enlarged lymph nodes were noted. Auscultation detected an increase of bowel sounds and peristaltic rushes. Colonoscopy and abdominal computed tomography (CT) scan were planned. However, 48 h later, the patient required emergency admission for small bowel occlusion. Abdominal X-ray examination showed dilated loops of the small intestine with no air in the colon, and CT scan revealed an irregular mass involving the ileum with dilation of the small intestine. A colonoscopy was performed to refine the diagnosis. The colon was

**Figure 3** Endometriosis involving lymph nodes with a cystic glandular pattern.

normal, but the ileum, at about 5 cm from the ileocecal valve, showed a tight extrinsic compression with intact mucosa.

Surgery was immediately carried out and an obstructing mass 5 cm in length involving the distal ileum was detected, with diffuse dilation of the small intestine. A right hemicolectomy with resection of 25 cm of ileum was performed. There was no evidence of macroscopic lesions in other abdominal and pelvic organs. The post-operative course was uneventful and the patient left the hospital 9 d later.

Histology of the resected specimen showed endometriosis involving the ileum and causing a stricture. The bowel wall was infiltrated, but the mucosa was not ulcerated. Endometriosis was mainly prevalent in the muscularis propria and submucosa. The mucosal involvement showed inflammation and glandular alteration (Figure 1). Immunocytochemistry with cytokeratin (CK) of different molecular weight (CK7 and CK20) was performed. Endometrioid glands and the intestinal epithelium were positive for CK7 and CK20, respectively (Figure 2). Endometrial lymph node involvement, with a cystic glandular pattern, was also detected (Figure 3).

## DISCUSSION

Endometriosis is a common disease of unknown etiology. Many theories have been proposed to explain this condition. The most widely accepted is Sampson's retrograde menstruation theory: during menstruation, endometrial tissue refluxes through the fallopian tubes, implanting and growing on the serosal surface of abdominal and pelvic organs<sup>[14-15]</sup>.

Alternatively, extrauterine growth of endometriotic tissue could occur as a result of metaplastic transformation of pluripotential peritoneal mesothelium (Minh's theory)<sup>[16]</sup>.

Another theory implies the migration of cells through the lymphatic system or via hematogenous spread<sup>[17]</sup>. Donnez *et al*<sup>[18]</sup> hypothesized that endometrial nodules may develop from metaplasia of mullerian remnants. In some cases, they could result from iatrogenic displacement of the decidua during a caesarean section<sup>[19]</sup>.

The "neurologic hypothesis" is a new concept in the pathogenesis of endometriosis: the lesions seem

to infiltrate the large bowel wall along the nerves, at a distance from the primary lesion<sup>[20]</sup>. However, other factors, immunological, genetic and familial, could be involved in the pathogenesis of this disease<sup>[21-23]</sup>.

Endometriosis usually becomes apparent in the reproductive years when the lesions are stimulated by ovarian hormones. Forty percent of the patients present symptoms in a cyclic manner, which are usually related with menses<sup>[24]</sup>. In our patient, symptoms relapsed irregularly and were not related with menses.

At present, superficial endometriosis is considered a normal phenomenon in women at the childbearing age, whereas deep infiltrative endometriosis (DIE) and endometrial ovarian cysts are the severe and painful manifestations of the condition<sup>[25]</sup>. DIE occurs in 30%-40% of the patients with endometriosis<sup>[26]</sup>.

Pelvic pain, infertility and dyspareunia are the characteristic symptoms of the disease<sup>[25]</sup>, but the clinical presentation is often non-specific.

Extra-pelvic endometriosis affects the GI tract of 5% of women with this condition<sup>[27]</sup>. The rectosigmoid is the most common site for intestinal endometriosis, accounting for 70% of all cases, while small bowel involvement, usually confined to the distal ileum, is less frequent (1%-7%) and exclusive localization on the ileum is very rare (1%-7%)<sup>[13]</sup>. Different incidence rates of endometriosis at different sites may be due to the fact that endometriosis is often an incidental finding at surgery<sup>[9]</sup>.

In a review of 1000 women who underwent laparotomy for gynecological symptoms, Jubanyik *et al*<sup>[28]</sup> described 181 (18%) cases of GI endometriosis, but only one patient had small bowel involvement. Melody *et al*<sup>[29]</sup> reported distal ileum involvement in 35 out of 36 patients. In a radiologic study, Scarmato *et al*<sup>[30]</sup> detected endometriosis of the terminal and mid-ileum in four patients and one patient, respectively. Endometriosis in the jejunum<sup>[31]</sup> and proximal ileum has also been documented<sup>[32]</sup>. Anaf *et al*<sup>[20]</sup>, considering bowel endometriosis an "infiltration or invasion phenomenon", found that there is a histological continuity between the superficial and underlying deep lesions of the large bowel wall, suggesting that lesions originating from the serosa progressively invade the muscularis propria. The mucosa is rarely involved as it is poorly innervated. Pelvic, pericolic and para-aortic lymph node involvement of endometriosis has also been reported, often coexisting with endometriosis of the bowel wall<sup>[33]</sup>. Lymph node involvement may be a consequence of lymphatic dissemination from endometrial foci in the intestinal wall<sup>[34-35]</sup>.

Symptoms are initially cyclical but may become permanent when the lesions progress.

It is difficult to establish a preoperative diagnosis of GI endometriosis, because GI tract symptoms can mimic a wide spectrum of diseases, including irritable bowel syndrome, infectious diseases, ischemic enteritis/colitis, inflammatory bowel disease and neoplasm<sup>[10,30,36-37]</sup>. GI endometriosis patients present with relapsing bouts of abdominal pain, abdominal distention, tenesmus,

constipation and diarrhoea<sup>[9]</sup>. Rectal bleeding and pain during defecation may also occur<sup>[38]</sup>.

Endometriosis infiltrating the muscularis propria may lead to localized fibrosis in the bowel wall, strictures, and small or large bowel obstruction<sup>[9-10]</sup>.

The true incidence of endometriosis causing bowel obstruction is unknown<sup>[11]</sup>, although complete obstruction of the bowel lumen occurs in less than 1% of cases<sup>[39]</sup>.

Endometriosis of the distal ileum is an infrequent cause of intestinal obstruction, ranging from 7% to 23% of all cases with intestinal involvement<sup>[31,33,40-41]</sup>.

The incidence of intestinal resection for bowel obstruction is 0.7% among patients undergone surgical treatment for abdominopelvic endometriosis<sup>[39]</sup>.

In our case, as in others previously reported in the literature, it was impossible to establish a timely and accurate preoperative diagnosis for the vagueness of symptoms, similar to other cases of bowel obstruction.

However, endometriosis of the small bowel should be suspected in young, nulliparous patients with abdominal pain, in conjunction with signs of obstruction<sup>[12]</sup>. Mussa *et al*<sup>[42]</sup> reported a case of small bowel endometriosis with intestinal obstruction, protein-losing enteropathy and anasarca. Wong *et al*<sup>[43]</sup> described a case of endometriosis of the small bowel mimicking pancreatitis.

Rarely, intestinal endometriosis may occur with perforation<sup>[44-45]</sup>. Malignancy has been reported in 0.7%-1% of patients and 78.7% of the cases occur in the ovary<sup>[46]</sup>. The colorectum is involved in only 5% of patients<sup>[47]</sup>.

The differential histologic diagnosis of endometrioid adenocarcinoma (AC) and colonic AC is difficult because colonic AC has a significant mucosal component, while endometrioid AC usually involves the outer layers of the colon<sup>[45,47-48]</sup>. Immunohistochemical staining for CK7 and CK20 seems to be useful in differentiating colonic and endometrioid AC<sup>[49-50]</sup>. Approximately, 75%-95% of primary colonic AC cases have a CK7-negative and CK20-positive phenotype, whereas 80%-100% of endometrial AC cases have a CK7-positive and CK20-negative phenotype<sup>[50]</sup>. Although endoscopic diagnosis of colonic endometriosis has been reported<sup>[51]</sup>, the mucosa is usually normal or shows minimal mucosal abnormalities<sup>[45,47-48]</sup>, friability<sup>[52]</sup>, extrinsic process or fibrosed stenoses<sup>[53]</sup>.

Rectal bleeding may be caused by mucosal injury during the passage of stools through a stenosed colon with the intramural endometriotic tissue increased at the time of menses if it occurs. Colonic mucosa heals rapidly and no signs are detectable at endoscopy<sup>[54]</sup>.

Endoscopic biopsies usually yield insufficient tissue for a definitive pathologic diagnosis as endometriosis involves the deep layers of the bowel wall. Endometriosis can induce mucosal changes without any specific pattern, which mimic findings of other diseases such as inflammatory bowel disease, ischemic colitis or neoplasm<sup>[55]</sup>.

Radiologically, lesions of endometriosis are either of

constricting and polypoid type or both<sup>[54]</sup>. On barium studies, radiographic findings caused by implants in the ileum are similar to those in the colon. Rectosigmoid or cecal endometriosis on double contrast barium enema studies is seen as an extrinsic mass with spiculation and tethering of folds<sup>[30,56]</sup>.

The diagnosis of endometriosis may be suspected on the basis of the clinical history<sup>[30]</sup>. Less than 50% of patients have concurrent pelvic endometriosis<sup>[57]</sup>.

CT is not the primary imaging modality for evaluation of bowel endometriosis, although it can occasionally demonstrate a stenosing rectosigmoid mass<sup>[58]</sup>.

Multislice CT (MSCT) has a great potential for detecting alterations in the intestinal wall, especially if it is combined with enteroclysis (MSCTe). Biscaldi *et al*<sup>[59]</sup> carried out a study on 98 women with symptoms suggestive of colorectal endometriosis and MSCTe identified 94.8% of bowel endometriotic nodules.

Magnetic resonance imaging (MRI) has a high sensitivity (77%-93%) in the diagnosis of bowel endometriosis<sup>[60-61]</sup>.

The depth of rectal wall infiltration by endometriosis is poorly defined by MRI. A combination of MRI and rectal endoscopic ultrasonography (EUS) has recently been proposed<sup>[62]</sup>. When retroperitoneal infiltration is present, it is mandatory to know if the bowel wall is involved in order to identify patients requiring bowel resection.

Both rectal EUS sensitivity and negative predictive value range from 92% to 100%. The specificity and positive predictive value are rather poor, which are 66% and 64%, 83% and 94%, respectively, as reported in two different studies<sup>[63-64]</sup>.

There is a great interest in the use of serum markers to diagnose endometriosis, but they are not sufficiently accurate for use in clinical practice<sup>[65]</sup>.

Cancer antigen CA-125 has been used to monitor the progress of endometriosis<sup>[66]</sup>. CA19-9 has a lower sensitivity than CA-125, and cytokine interleukin-6 may be more sensitive and specific than CA-125.

Surgery is the choice of treatment for intestinal endometriosis in most cases. For the accidental finding without symptoms of obstruction, hormone therapy with danazol or gonadotrophin-releasing hormone (GnRH) analogs may be considered<sup>[9]</sup>. Surgical treatment should be indicated for women with pain, bleeding, changes in bowel habits and intestinal obstruction<sup>[51]</sup>. In the small bowel, the treatment of endometriosis is surgical resection of the involved bowel, while medical therapy is only a temporary treatment<sup>[12]</sup>.

Intestinal endometriosis may be active in the peri- and post- menopausal years and even surgery may be necessary for these patients<sup>[54]</sup>.

In this paper, we report an unusual presentation of endometriosis characterized by abrupt onset of small bowel occlusion. The present report points out that endometriosis remains a challenging condition for clinicians, especially, as in our case, when the symptoms are not related to menses. Intestinal endometriosis should be considered in patients with epigastric,

abdominal and/or pelvic pain, in conjunction with signs of obstruction.

## Abstract

Laparoscopic resection of rectal cancer or gastric cancer has been advocated for the benefits of a reduced morbidity, a shorter treatment time, and similar outcomes. However, simultaneous laparoscopy-assisted low anterior resection and distal gastrectomy for synchronous carcinoma of rectum and stomach are rarely documented in literature. Endoscopic examination revealed a synchronous carcinoma of rectum and stomach in a 55-year-old male patient with rectal bleeding and epigastric discomfort. He underwent a simultaneous laparoscopy-assisted low anterior resection and distal gastrectomy with regional lymph nodes dissected. The operation time was 270 min and the estimated blood loss was 120 mL. The patient required parenteral analgesia for less than 24 h. Flatus was passed on postoperative day 3, and a solid diet was resumed on postoperative day 7. He was discharged on postoperative day 13. With the advances in laparoscopic technology and experience, simultaneous resection is an attractive alternative to a synchronous gastrointestinal cancer.

Simultaneous laparoscopy-assisted low anterior resection and distal gastrectomy for synchronous carcinoma of rectum and stomach. *World J Gastroenterol* 2008; 14(21): 3435-3437 Available from: URL: <http://www.wjgnet.com/1007-9327/14/3435.asp> DOI: <http://dx.doi.org/10.3748/wjg.14.3435>

## INTRODUCTION

Rectal and gastric cancers are sometimes diagnosed simultaneously as a synchronous carcinoma of rectum and stomach in a single patient. An enlarged open procedure combining both rectal resection and gastrectomy with a curable intention is normally performed for such cases, but a long operation time and severe surgical trauma often result in a reluctant recovery.

Laparoscopic resection is feasible and safe for both rectal and gastric cancers nowadays. It has been widely advocated for the benefits of a reduced morbidity and a shorter hospitalization time without sacrificing the oncological outcome. As this novel technique permits a multiple segmental resection, simultaneous laparoscopy-assisted low anterior resection and distal gastrectomy for a single patient have become attractive to a synchronous carcinoma of rectum and stomach. We present such a case.

## CASE REPORT

A 55-year-old male patient presented with rectal bleeding and epigastric discomfort with alternation in bowel habit, mucus, and weight loss for 6 mo. Colonoscopy revealed a circumferential mass 8 cm from the anal verge, which was confirmed to be a rectal adenocarcinoma by biopsy. Meanwhile, gastroscopy revealed a 3 cm × 3 cm ulcerative lesion located at the lesser curvature near the

**Figure 1** A: Position of the working ports; B: Transection of the rectum with a linear stapler; C: Dissection of short gastric vessels with harmonic scalpel; D: Placement of drainage tubes.

pylorus, which was confirmed to be a signet-ring cell adenocarcinoma by biopsy. Computed tomography (CT) of the abdomen and thorax demonstrated no significant metastatic lesions. Various treatment strategies were discussed and the patient underwent simultaneous laparoscopy-assisted low anterior resection and distal gastrectomy (LADG) and D2 lymphadenectomy.

The operation was performed under general anesthesia. The patient was first at a Lloyd-Davis position to accomplish the low anterior resection, and then changed into a Trendelenburg position to complete the distal gastrectomy. We used the Veress method to establish pneumoperitoneum and maintain the intra-abdominal pressure at around 15 mmHg. Trocars for low anterior resection were placed. In brief, an umbilical port (10 mm) was used for a video scope (usually a 30-degree scope), and two ports were created for working in the right and left low quadrants of abdomen, with the lower port in the right quadrant for main working (12 mm) and the rest three for assistance (5 mm). When gastrectomy was performed, another 5 mm assistant port was made in the left subcostal region (Figure 1A). The main surgeon stood on the right of the patient and then between the split legs of the patient after completion of the low anterior resection.

The right peritoneum was dissected along the iliac vessels with a harmonic scalpel, then the sigmoid colon and rectum as well as their mesenteries were mobilized down to the pelvic floor. The lymphovascular pedicle was ligated at the radical site of the inferior mesenteric vessel with a polymer plastic clip, while the distal rectum was transected intracorporeally with a laparoscopic linear stapler (Figure 1B). The first part of the operation was

completed within 75 min.

The gastrocolic ligament was divided from the hepatic flexure towards the splenic flexure for gastric mobilization, while the gastroepiploic vessels and short gastric vessels were ligated simultaneously (Figure 1C). The gastrohepatic and duodenohepatic ligaments were then divided to allow ligation of the right and left gastric vessels. After completion of the whole procedure, the proximal stomach was entirely mobilized with an adequate perigastric lymphadenectomy. This part of the operation was accomplished within 2 h and 30 min, and the estimated blood loss was 120 mL.

A 5 cm median epigastric incision was made and protected with a plastic bag to ensure the transection of the two specimens. The bowels were then anastomosed intra-corporeally with a double stapler. The first portion of the duodenum and stomach body was transected with the gastrointestinal continuity performed in a Billroth-I fashion. Four protective drainage tubes were placed near the two anastomotic junctions (Figure 1D). The total operation time was 4 h and 30 min. The patient received parenteral analgesia for less than one day. Flatus was passed on postoperative day 3, the patient resumed a liquid diet on postoperative day 5 and a solid diet on postoperative day 7. No clinically significant complication occurred postoperatively and all the drainage tubes were pulled out consecutively. The patient was discharged 13 d after the operation. Pathologic examination of the rectum showed a moderately differentiated adenocarcinoma invading the subserosal tissue without breaching the serosa. The distal margin measured 2 cm, and no involvement of tumor was found in the mesenteric or paracolic lymph nodes. Pathological examination of the

**Figure 2** Specimens obtained at distal gastrectomy, regional lymphadenectomy and low anterior resection from their anatomical sites.

stomach showed a poorly differentiated adenocarcinoma invading the muscular layer, involvement of tumor was observed in 8 of the 20 lymph nodes (Figure 2).

## DISCUSSION

Synchronous gastrointestinal cancers are normally treated with conventional surgical approaches. In brief, a long medial incision from the xiphoid to the pubic symphysis is made to ensure the upper-abdominal and pelvic procedures, with a dissection of regional lymph nodes. These maneuvers might cause surgical traumas, and result in a slow postoperative recovery, with a negative influence on the prognosis of tumors. Laparoscopic technique provides a simultaneous resection of the rectal and gastric lesions and minimizes the surgical influence on human body. For the rectal procedure, the amplifying effect of laparoscopy helps the surgeons to identify and protect the ureter and automatic nerve plexus in a narrow pelvic cavity in spite of a bulky tumor and thickened mesentery. A 30-degree camera offers a multi-angle image, which greatly assists the surgeon to complete a TME approach as well as the intra-corporeal transection and anastomosis of the bowels<sup>[1]</sup>. For the gastric procedure, advanced laparoscopic instruments and materials, such as harmonic scalpel, multi-sized titanium or polymer clips significantly

reduce the intra-operative hemorrhage. A broad view of the intra-peritoneal cavity under laparoscope facilitates the multi-plane manipulation of gastrectomy, especially during the dissection of the upper branches of perigastric vessels like short gastric vessels<sup>[2]</sup>. We transected the two specimens and reconstructed the upper gastrointestinal duct extra-corporeally with a manual method, which could obviously reduce the operation time and cost. To summarize, laparoscopic colorectal and gastric surgery is feasible and safe in clinical trials with the benefit of avoiding a second operation, thus reducing morbidity, and shortening the hospital stay without sacrificing the oncological outcome<sup>[3,4]</sup>. As some other radical surgeries for synchronous gastrointestinal cancers have also been reported, simultaneous laparoscopic approach obviously reduces the morbidity and recurrence rate<sup>[5,6]</sup>.

To the best of our knowledge, this is the first report of simultaneous laparoscopy-assisted low anterior resection and distal gastrectomy for synchronous carcinoma of the rectum and stomach. A good recovery of the patient reveals that this technique is advantageous over the conventional approaches in treating gastrointestinal malignancies and broadens the indications for laparoscopic approaches. This minimally invasive technique may have a bright future.

### TO THE EDITOR

The pathogenesis of hepatic encephalopathy (HE), a common complication of liver cirrhosis, remains incompletely understood but it is probably multifactorial in most cases<sup>[1]</sup>. Malnutrition is also commonly encountered in patients with cirrhosis and it has been reported to have an effect on health related quality of life<sup>[2]</sup>. Although experimental studies suggest that low energy intake and poor nutritional status may facilitate the development of HE<sup>[3]</sup>, there are scarce data on the potential role of malnutrition in HE in patients with liver cirrhosis.

Recently Soros *et al*<sup>[4]</sup> performed a study investigating the potential role of malnutrition and hypermetabolism in HE in which 223 patients with non-alcoholic cirrhosis were enrolled. They were evaluated for the presence of HE according to the West Haven criteria and for malnutrition by means of body mass index (BMI), anthropometric measurements, and bioelectrical impedance analysis. Energy metabolism was also assessed by means of indirect calorimetry. Eighty-five (38%) out of 223 patients had no clinically evident HE, 123/223 (55%) had HE grade 1 and 15/223 (7%) had HE grade 2 or 3. Neither metabolic variables or BMI nor fat free mass or muscle mass differed significantly in patients with HE grade 1-3 from those without HE. In multivariate analysis none of these parameters was found to be independently related to HE. The authors concluded that malnutrition or catabolism does not seem to be independent risk factors for the presence of HE in patients with liver cirrhosis<sup>[4]</sup>.

Recently, we performed a prospective study evaluating HE in 128 patients with liver cirrhosis of various etiologies<sup>[5]</sup>. HE was evaluated by means of the West Haven criteria and two psychometric tests (number connection test A and B). HE was defined as overt HE according to the West Haven criteria and/or number connection test A and/or B > 3 standard deviations of the general population. Nutritional status was evaluated with BMI and anthropometric measurement as well as estimation of recent weight change. Malnutrition was defined as anthropometric measurement below the 5th

### Abstract

Hepatic encephalopathy (HE) is a common complication in patients with liver cirrhosis but its pathogenesis remains incompletely understood. Malnutrition is commonly encountered in patients with liver cirrhosis and it has been reported to affect the quality of life of this group of patients. Experimental studies suggest that low energy intake and poor nutritional status may facilitate the development of HE but there are scarce data on the potential role of malnutrition in HE in patients with liver cirrhosis. Two recently published studies have evaluated the potential role of malnutrition in the development of HE in cirrhotic patients with conflicting results. In this letter to the editor we briefly present the results of the two studies as well as potential reasons for the conflicting results reported.

Kalaitzakis E, Björnsson E. Hepatic encephalopathy in patients with liver cirrhosis: Is there a role of malnutrition? *World J Gastroenterol* 2008; 14(21): 3438-3439 Available from: URL:

percentile according to standard values for the general population and/or BMI < 20 kg/m<sup>2</sup> and/or weight loss ≥ 5%-10% in the previous 3-6 mo. The presence of diabetes mellitus was also assessed with fasting glucose measurement. Forty percent of our patients were malnourished, 26% had diabetes, and 34% had HE. Patients with malnutrition suffered more frequently from HE compared to those without malnutrition (46% *vs* 27%, *P* = 0.031), but there was no difference in age, etiology, or severity of liver cirrhosis. In multivariate analysis, the time needed to perform number connection test A was independently correlated to age, severity of cirrhosis expressed as the Child-Pugh score, diabetes and malnutrition<sup>[5]</sup>. This is in agreement with a previous study showing that diabetes mellitus is associated with HE in patients with hepatitis C cirrhosis<sup>[6]</sup>.

In the paper of Soros *et al*<sup>[4]</sup>, they did not report how many patients had diabetes mellitus. However, the risk of diabetes mellitus has been reported to be increased in patients with cirrhosis due to hepatitis C<sup>[7]</sup> and the majority of patients enrolled in the study of Soros *et al*<sup>[4]</sup> (56%) had viral cirrhosis<sup>[4]</sup>. It is therefore unknown whether the patients with HE had a higher proportion of diabetes compared with the patients without HE. This might have had an effect on the median BMI in the two groups as diabetes is more prevalent in patients with increased BMI, thus accounting for the lack of difference in median BMI between patients with HE and those without HE<sup>[4]</sup>. In fact, the BMI of patients with HE ranged from 14.5 to 36.3 kg/m<sup>2</sup> as compared to 17.5-28.4 kg/m<sup>2</sup> in those without HE<sup>[4]</sup>. Furthermore, in our study, recent weight change was included in the definition of malnutrition<sup>[4]</sup> whereas in the study of Sörös *et al* no definition of malnutrition was provided<sup>[4]</sup>. Interestingly we found that although patients with and without low fat or muscle mass did not differ in number connection A performance times, a recent weight loss was related to longer performance times [81 s (51) *vs* 54 s (32), *P* = 0.001]<sup>[5]</sup>. It is therefore conceivable that deterioration in nutritional status, rather than nutritional

status itself, may be of great importance for cognitive dysfunction in patients with liver cirrhosis. Finally, another factor that may, at least in part, explain the differences between the results of the two studies<sup>[4,5]</sup> is that we also included patients with minimal HE in our analyses<sup>[5]</sup> whereas as Soros *et al*<sup>[4]</sup> included only patients with clinically overt HE in their study.

In conclusion, methodological differences regarding the definitions of HE and malnutrition as well as the assessment of the role of diabetes mellitus in cognitive dysfunction may explain the differences in the results of the two studies<sup>[4,5]</sup>. As both studies had limitations mentioned by their authors<sup>[4,5]</sup> and the pathophysiology of HE is complex, it is clear that further studies are warranted to fully delineate the potential role of malnutrition in cognitive dysfunction in patients with liver cirrhosis.

### Christian D Stone, MD, MPH, Director

Inflammatory Bowel Disease Program, Assistant Professor of Medicine, Division of Gastroenterology, Washington University School of Medicine, 660 South Euclid Avenue, Campus Box 8124, Saint Louis, MO 63110, United States

### Andrew Ukleja, MD, Assistant Professor

Clinical Assistant Professor of Medicine, Director of Nutrition Support Team, Director of Esophageal Motility Laboratory, Cleveland Clinic Florida, Department of Gastroenterology, 2950 Cleveland Clinic Blvd., Weston, FL 33331, United States

### Marie-Catherine Vozenin-brottons, PhD

UPRES EA 27-10, IRSN/IGR, 39 rue C. Desmoulins, Villejuif Cedex 94305, France

### Eddie Wisse, Professor

Irisweg 16, Keerbergen 3140, Belgium

### Harry HX Xia, PhD, MD

Novartis Pharmaceuticals Corporation, One Health Plaza, East Hanover, NJ 07936-1080, United States

### Kentaro Yoshika, Associate Professor

Division of Gastroenterology, Department of I, Fujita Health University School of Medicine, 1-98 Dengakugakubo, Kutsukade, Toyoake 470-1190, Japan

## Meetings

### Events Calendar 2008-2009

**FALK SYMPOSIA 2008**  
 January 24-25, Frankfurt, Germany  
 Falk Workshop: Perspectives in Liver Transplantation

International Gastroenterological Congresses 2008  
 February 14-16, Paris, France  
 EASL-AASLD-APASL-ALEH-IASL Conference Hepatitis B and C virus resistance to antiviral therapies  
[www.easl.ch/hepatitis-conference](http://www.easl.ch/hepatitis-conference)

February 14-17, Berlin, Germany  
 8<sup>th</sup> International Conference on New Trends in Immunosuppression and Immunotherapy  
[www.kenes.com/immuno](http://www.kenes.com/immuno)

February 28, Lyon, France  
 3<sup>rd</sup> Congress of ECCO - the European Crohn's and Colitis Organisation  
 Inflammatory Bowel Diseases 2008  
[www.ecco-ibd.eu](http://www.ecco-ibd.eu)

February 29, Québec, Canada  
 Canadian Association of Gastroenterology  
 E-mail: [general@cag-acg.org](mailto:general@cag-acg.org)

March 10-13, Birmingham, UK  
 British Society of Gastroenterology Annual Meeting  
 E-mail: [BSG@mailbox.ulcc.ac.uk](mailto:BSG@mailbox.ulcc.ac.uk)

March 14-15, HangZhou, China  
 Falk Symposium 163: Chronic Inflammation of Liver and Gut

March 23-26, Seoul, Korea  
 Asian Pacific Association for the Study of the Liver  
 18<sup>th</sup> Conference of APASL: New Horizons in Hepatology  
[www.apaslseoul2008.org](http://www.apaslseoul2008.org)

March 29-April 1, Shanghai, China  
 Shanghai-Hong Kong International Liver Congress  
[www.livercongress.org](http://www.livercongress.org)

April 05-09, Monte-Carlo (Grimaldi Forum), Monaco  
 OESO 9<sup>th</sup> World Congress, The Gastro-esophageal Reflux Disease: from Reflux to Mucosal Inflammation-Management of Adeno-carcinomas  
 E-mail: [robert.giuli@oeso.org](mailto:robert.giuli@oeso.org)

April 9-12, Los Angeles, USA  
 SAGES 2008 Annual Meeting - part of Surgical Spring Week  
[www.sages.org/08program/html/](http://www.sages.org/08program/html/)

April 18-22, Buenos Aires, Argentina  
 9<sup>th</sup> World Congress of the International Hepato-Pancreato Biliary Association  
 Association for the Study of the Liver  
[www.ca-ihpba.com.ar](http://www.ca-ihpba.com.ar)

April 23-27, Milan, Italy  
 43<sup>rd</sup> Annual Meeting of the European Association for the Study of the Liver  
[www.easl.ch](http://www.easl.ch)

May 2-3, Budapest, Hungary

Falk Symposium 164: Intestinal Disorders

May 18-21, San Diego, California, USA  
 Digestive Disease Week 2008

May 21-22, California, USA  
 ASGE Annual Postgraduate Course  
 Endoscopic Practice 2008: At the Interface of Evidence and Expert Opinion  
 E-mail: [education@fsg.org](mailto:education@fsg.org)

June 4-7, Helsinki, Finland  
 The 39<sup>th</sup> Nordic Meeting of Gastroenterology  
[www.congex.com/ngc2008](http://www.congex.com/ngc2008)

June 5-8, Sitges (Barcelona), Spain  
 Semana de las Enfermedades Digestivas  
 E-mail: [sepd@sepd.es](mailto:sepd@sepd.es)

June 6-8, Prague, Czech Republic  
 3<sup>rd</sup> Annual European Meeting: Perspectives in Inflammatory Bowel Diseases  
 E-mail: [meetings@imedex.com](mailto:meetings@imedex.com)

June 10-13, Istanbul, Turkey  
 ESGAR 2008 19<sup>th</sup> Annual Meeting and Postgraduate Course  
 E-mail: [fca@netvisao.pt](mailto:fca@netvisao.pt)

June 11-13, Stockholm, Sweden  
 16<sup>th</sup> International Congress of the European Association for Endoscopic Surgery  
 E-mail: [info@aes-eur.org](mailto:info@aes-eur.org)

June 13-14, Amsterdam, Netherlands  
 Falk Symposium 165: XX International Bile Acid Meeting. Bile Acid Biology and Therapeutic Actions

June 13-14, Prague, Czech Republic  
 Central and Eastern European Conference on Colorectal "Cancer" Screening, Prevention and Management  
 E-mail: [idla2008@guarant.cz](mailto:idla2008@guarant.cz)

June 25-28, Barcelona, Spain  
 10<sup>th</sup> World Congress on Gastrointestinal Cancer  
 Imedex and ESMO  
 E-mail: [meetings@imedex.com](mailto:meetings@imedex.com)

June 25-28, Lodz, Poland  
 Joint Meeting of the European Pancreatic Club (EPC) and the International Association of Pancreatologists (IAP)  
 E-mail: [office@epc-iap2008.org](mailto:office@epc-iap2008.org)  
[www.e-p-c.org](http://www.e-p-c.org)

International Gastroenterological Congresses 2009  
 March 23-26, Glasgow, Scotland  
 Meeting of the British Society of Gastroenterology (BSG)  
 E-mail: [bsg@mailbox.ulcc.ac.uk](mailto:bsg@mailbox.ulcc.ac.uk)

May 17-20, Denver, Colorado, USA  
 Digestive Disease Week 2009

November 21-25, London, UK  
 Gastro 2009 UEGW/World Congress of Gastroenterology  
[www.gastro2009.org](http://www.gastro2009.org)

### Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

## Instructions to authors

### GENERAL INFORMATION

*World Journal of Gastroenterology* (World J Gastroenterol ISSN 1007-9327 CN 14-1219/R) is a weekly open access peer-reviewed journal supported by an editorial board consisting of 1215 experts in gastroenterology and hepatology from 60 countries. The aim of the journal is to deliver the most clinically relevant original and commentary articles to readers, and to make the full text publicly available to all clinicians, scientists, patients and biomedical students on an unrestricted platform, so that they can access and learn about the most recent key advances in the field.

In addition to the open access nature, another key characteristic of *WJG* is its reading guidance for each article which includes background, research frontier, related reports, breakthroughs, applications, terminology, and comments of peer reviewers for the general readers.

*WJG* publishes articles on esophageal, gastrointestinal, hepatobiliary and pancreatic tumors, and other esophageal, gastrointestinal, hepatic-biliary and pancreatic diseases in relation to epidemiology, immunology, microbiology, motility & nerve-gut interaction, endocrinology, nutrition & obesity, endoscopy, imaging and advanced hi-technology.

The main goal of *WJG* is to publish high quality commentary articles contributed by leading experts in gastroenterology and hepatology and original articles that combine the clinical practice and advanced basic research, to provide an interactive platform for clinicians and researchers in internal medicine, surgery, infectious diseases, traditional Chinese medicine, oncology, integrated Chinese and Western medicine, imaging, endoscopy, interventional therapy, pathology and other basic medical specialties, and thus eventually improving the clinical practice and healthcare for patients.

### Indexed and abstracted in

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/Science Edition, Index Medicus, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

### Published by

The WJG Press

### SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

### Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://wjg.wjgnet.com>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to [submission@wjgnet.com](mailto:submission@wjgnet.com), or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

### MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

#### Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was carried out; author contributions; disclosure of any financial support for the research; and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (remove all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s), and full family name.

**Author contributions:** The format of this section should be like this: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed research; Wang CL, Zou CC, Hong F and Wu XM performed research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed data; and Wang CL, Liang L and Fu JF wrote the paper.

**Peer reviewers:** All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

#### Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipment, and the experimental procedures should be included. RESULTS: The observed and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and also include any significant data. CONCLUSION: Accurate view and the value of the results should be included.

The format for structured abstracts can be found at: <http://www.wjgnet.com/wjg/help/11.doc>.

#### Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

#### Text

For articles of these sections, original articles, rapid communication

and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, should be found at: <http://www.wjgnet.com/wjg/help/instructions.jsp>.

### Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ... *etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

### Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

### Notes in tables and illustrations

Data that are not statistically significant should not be noted. <sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01 should be noted (*P* > 0.05 should not be noted). If there are other series of *P* values, <sup>c</sup>*P* < 0.05 and <sup>d</sup>*P* < 0.01 are used. A third series of *P* values can be expressed as <sup>e</sup>*P* < 0.05 and <sup>f</sup>*P* < 0.01. Other notes in tables or under illustrations should be expressed as <sup>1</sup>F, <sup>2</sup>F, <sup>3</sup>F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

### Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

## REFERENCES

### Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability<sup>[1,2]</sup>". If references are cited directly in the text, they should be put together within the text, for example, "From references<sup>[19,22-24]</sup>, we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

### PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information for journal citations is very important. Using the reference testing system, the authors and editor should check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in an ASP file so that the readers can immediately access the abstract of the citations online.

### DOI requirement

A CrossRef DOI® (Digital Object Identifier) name is a unique string created to identify a piece of scholarly content in the online environment. The author should supply the DOIs for journal citation (doi:10.3748/wjg.13.6458). This link (<http://www.crossref.org/SimpleTextQuery/>) allows you to retrieve Digital Object Identifiers (DOIs) for journal articles, books, and chapters by simply cutting and pasting the reference list into the box. You may use the form with any reference style, although the tool works most reliably if references are formatted in a standard style such as shown in this example: Assimakopoulos SF, Scopa CD, Vagianos CE. Pathophysiology of increased intestinal permeability in obstructive jaundice. *World J Gastroenterol* 2007; 13(48): 6458-6464

The accuracy of the information of journal citations is very important. We will interlink all references with DOI in ASP file so that readers can access the abstracts of cited articles online immediately.

### Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

### Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

EuroGP 2002: Proceedings of the 5th European Conference on Genetic Programming; 2002 Apr 3-5; Kinsdale, Ireland. Berlin: Springer, 2002: 182-191

## Electronic journal (list all authors)

Morse SS. Factors in the emergence of infectious diseases. *Emerg Infect Dis* serial online, 1995-01-03, cited 1996-06-05; 1(1): 24 screens. Available from: URL: <http://www.cdc.gov/ncidod/EID/eid.htm>

## Patent (list all authors)

- 16 Pagedas AC, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

## Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those linked with a hyphen when the difference between the two numbers is greater than five. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered inappropriate references. Authors should not cite their own unrelated published articles.

## Statistical data

Write as mean  $\pm$  SD or mean  $\pm$  SE.

## Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as  $\chi^2$  (in Greek), related coefficient as *r* (in italics), degree of freedom as *v* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

## Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose)  $6.4 \pm 2.1$  mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6  $24.5 \mu\text{g/L}$ ; CO<sub>2</sub> volume fraction, 50 mL/L CO<sub>2</sub>, not 5% CO<sub>2</sub>; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantum numbers can be found at: <http://www.wjgnet.com/wjg/help/15.doc>.

## Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of

Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

## Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindIII*, *BamHI*, *Kpn I*, *Kpn I*, etc.

Biology: *H pylori*, *E coli*, etc.

## SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

## Editorial Office

### World Journal of Gastroenterology

Editorial Department: Room 903

Ocean International Center, Building D

No. 62 Dongsihuan Zhonglu

Chaoyang District, Beijing 100025, China

E-mail: [wjg@wjgnet.com](mailto:wjg@wjgnet.com)

<http://www.wjgnet.com>

Telephone: +86-10-59080039

Fax: +86-10-85381893

## Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

## Copyright assignment form

Please download a Copyright assignment form from <http://www.wjgnet.com/wjg/help/9.doc>.

## Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: <http://www.wjgnet.com/wjg/help/10.doc>.

## Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

## Links to documents related to the manuscript

*WJG* will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

## Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

## Publication fee

Authors of accepted articles must pay a publication fee.

EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

# WJG

## Contents

<b>EDITORIAL</b>	<b>3445</b>	Cardiac evaluation of liver transplant candidates <i>Mandell MS, Lindenfeld J, Tsou MY, Zimmerman M</i>
	<b>3452</b>	Selection criteria for liver resection in patients with hepatocellular carcinoma and chronic liver disease <i>Delis SG, Derveniz C</i>
<b>OBSERVER</b>	<b>3461</b>	Heterogeneity of colorectal adenomas, the serrated adenoma, and implications for screening and surveillance <i>Freeman HJ</i>
<b>REVIEW</b>	<b>3464</b>	Liver cell transplantation for Crigler-Najjar syndrome type I : Update and perspectives <i>Lysy PA, Najimi M, Stéphenne X, Bourgois A, Smets F, Sokal EM</i>
	<b>3471</b>	Food-borne parasitic zoonosis: Distribution of trichinosis in Thailand <i>Kaewpitoon N, Kaewpitoon SJ, Pengsaa P</i>
<b>TOPIC HIGHLIGHT</b>	<b>3476</b>	Non-invasive means of measuring hepatic fat content <i>Mehta SR, Thomas EL, Bell JD, Johnston DG, Taylor-Robinson SD</i>
<b>COLORECTAL CANCER</b>	<b>3484</b>	Risk of colorectal neoplasm in patients with acromegaly: A meta-analysis <i>Rokkas T, Pistiolas D, Sechopoulos P, Margantinis G, Koukoulis G</i>
<b>VIRAL HEPATITIS</b>	<b>3490</b>	Replication of clinical hepatitis B virus isolate and its application for selecting antiviral agents for chronic hepatitis B patients <i>Lu YP, Guo T, Wang BJ, Dong JH, Zhu JF, Liu Z, Lu MJ, Yang DL</i>
<b>CLINICAL RESEARCH</b>	<b>3497</b>	Disease activity and cancer risk in inflammatory bowel disease associated with primary sclerosing cholangitis <i>Sokol H, Cosnes J, Chazouilleres O, Beaugerie L, Tiret E, Poupon R, Seksik P</i>
	<b>3504</b>	Endorectal ultrasonography <i>versus</i> phased-array magnetic resonance imaging for preoperative staging of rectal cancer <i>Halefoglu AM, Yildirim S, Avlanmis O, Sakiz D, Baykan A</i>
<b>BASIC RESEARCH</b>	<b>3511</b>	Influence of dexamethasone on mesenteric lymph node of rats with severe acute pancreatitis <i>Zhang XP, Xu HM, Jiang YY, Yu S, Cai Y, Lu B, Xie Q, Ju TF</i>
<b>RAPID COMMUNICATION</b>	<b>3518</b>	Prevalence of Barrett's esophagus in patients with moderate to severe erosive esophagitis <i>Gilani N, Gerkin RD, Ramirez FC, Hakim S, Randolph AC</i>
	<b>3523</b>	Can 5-aminosalicylic acid suppository decrease the pain after rectal band ligation? <i>Kayhan B, Ozer D, Akdogan M, Ozaslan E, Yuksel O</i>

- 3526 Fragile histidine triad gene alterations are not essential for hepatocellular carcinoma development in South Korea  
*Nam CW, Shin JW, Park NH*
- 3534 Relationship between T-lymphocyte cytokine levels and sero-response to hepatitis B vaccines  
*Velu V, Saravanan S, Nandakumar S, Shankar EM, Vengatesan A, Jadhav SS, Kulkarni PS, Thyagarajan SP*
- 3541 Abdominal compartment syndrome in patients with severe acute pancreatitis in early stage  
*Chen H, Li F, Sun JB, Jia JG*
- 3549 Clinical features of adverse reactions associated with telbivudine  
*Zhang XS, Jin R, Zhang SB, Tao ML*
- 3554 Preparation of chitosan-polyaspartic acid-5-fluorouracil nanoparticles and its anti-carcinoma effect on tumor growth in nude mice  
*Zhang DY, Shen XZ, Wang JY, Dong L, Zheng YL, Wu LL*
- 3563 Imaging findings and transcatheter arterial chemoembolization of hepatic malignancy with right atrial embolus in 46 patients  
*Cheng HY, Wang XY, Zhao GL, Chen D*
- 3569 Preventive effect of *Qianggan-Rongxian* Decoction on rat liver fibrosis  
*Li CH, Pan LH, Yang ZW, Li CY, Xu WX*
- 3574 Treatment of abdominal compartment syndrome in severe acute pancreatitis patients with traditional Chinese medicine  
*Zhang MJ, Zhang GL, Yuan WB, Ni J, Huang LF*
- 3579 Ultrasonic diagnosis of biliary atresia: A retrospective analysis of 20 patients  
*Li SX, Zhang Y, Sun M, Shi B, Xu ZY, Huang Y, Mao ZQ*

**CASE REPORT**

- 3583 Subclinical peritonitis due to perforated sigmoid diverticulitis 14 years after heart-lung transplantation  
*Markogiannakis H, Konstadoulakis M, Tzertzemelis D, Antonakis P, Gomatos I, Bramis C, Manouras A*
- 3587 Resection of a locally advanced hilar tumor and the hepatic artery after stepwise hepatic arterial embolization: A case report  
*Miura T, Hakamada K, Ohata T, Narumi S, Toyoki Y, Nara M, Ishido K, Ohashi M, Akasaka H, Jin H, Kubo N, Ono S, Kijima H, Sasaki M*
- 3591 Ischemic colitis associated with intestinal vasculitis: Histological proof in systemic lupus erythematosus

### Abstract

Physicians previously thought that heart disease was rare in patients with end stage liver disease. However, recent evidence shows that the prevalence of ischemic heart disease and cardiomyopathy is increased in transplant candidates compared to most other surgical candidates. Investigators estimate that up to 26% of all liver transplant candidates have at least one critical coronary artery stenosis and that at least half of these patients will die perioperatively of cardiac complications. Cardiomyopathy also occurs in greater frequency. While all patients with advanced cardiac disease have defects in cardiac performance, a larger than expected number of patients have classical findings of dilated, restrictive and hypertrophic cardiomyopathy. This may explain why up to 56% of patients suffer from hypoxemia due to pulmonary edema following transplant surgery. There is considerable controversy on how to screen transplant candidates for the presence of heart disease. Questions focus upon, which patients should be screened and what tests should be used. This review examines screening strategies for transplant candidates and details the prognostic value of common tests used to identify ischemic heart disease. We also review the physiological consequences of cardiomyopathy in transplant candidates and explore the specific syndrome of "cirrhotic cardiomyopathy".

### INTRODUCTION

Physicians previously thought that heart disease was rare in patients with cirrhosis<sup>[1]</sup>. Postoperative mortality was previously due to operative complications and poor donor graft function. Better surgical technique and donor organ management have significantly improved patient survival. However, as long term patient survival increased, cardiac complications emerged as a more common cause of early morbidity and mortality. Recent studies report a high incidence of post-transplant cardiovascular complications with arrhythmias and overt congestive heart failure in as many as 25% and 56% of all transplant recipients respectively<sup>[2,3]</sup>.

It is now clear that patients with end stage liver disease are at increased risk of acute coronary occlusion, myocardial failure, arrhythmia and complete cardiovascular collapse following transplantation compared to other major surgical procedures. However, there is no consensus on how to efficiently detect cardiovascular disease in asymptomatic patients prior to transplantation or to determine what risk a transplant candidate with heart disease has of suffering from a serious perioperative adverse event. Without this information it is difficult to determine what type or severity of heart disease should exclude a patient from transplantation.

### CARDIOVASCULAR DISEASES IN CANDIDATES FOR LIVER TRANSPLANTATION

The most common cardiovascular diseases in

transplant candidates are ischemic coronary artery disease (CAD) and cardiomyopathy. These diseases are independent negative predictors of outcome following transplantation. However, the poor exercise capacity in patients with advanced liver disease makes it difficult to identify cardiac disease. These patients may not experience common symptoms brought on by exercise such as chest pain or shortness of breath. Further, it may be impossible to determine if some symptoms such as shortness of breath are caused by cardiac or liver disease. Thus, screening asymptomatic patients for underlying cardiac disease is an essential step in the evaluation of transplant candidates.

### Ischemic heart disease

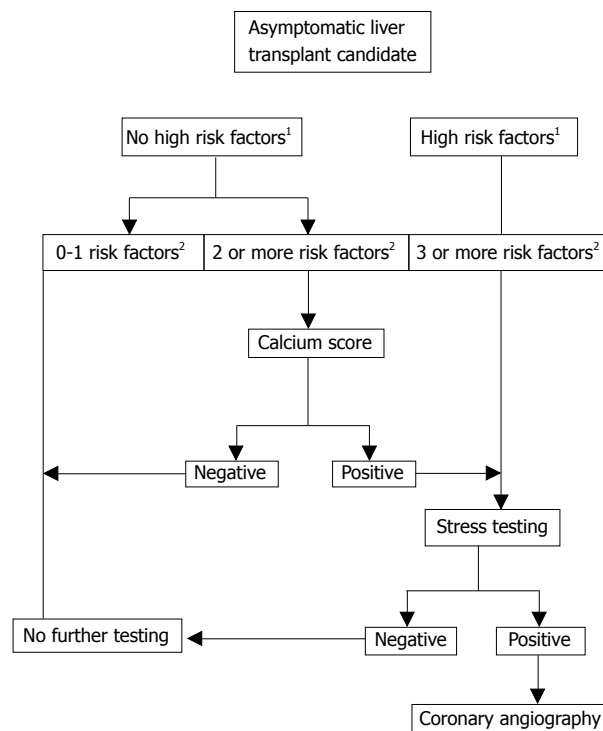

Patients can have substantial atherosclerosis, but remain asymptomatic. Symptoms only develop once the amount of coronary blood flow is insufficient to meet the oxygen needs of the myocardial tissue. This usually occurs when the degree of occlusion exceeds 50%<sup>[4]</sup>. However, lesion size alone does not always predict the onset of symptoms. Rather, symptoms are influenced by myocardial tissue demands. Vigorous exercise increases myocardial oxygen demand and may cause symptoms with lesions that are less than 50%. Figure 1 shows the algorithm for the diagnosis of ischemic heart disease.

Myocardial infarction can occur in patients who have lesions that occupy less than 50% of the coronary lumen<sup>[4,5]</sup>. This is caused by plaque rupture, resulting in acute vessel thrombosis. Liver disease may increase the risk of coronary complications in patients with non-occlusive disease. Chronic inflammation coupled with increased blood flow can predispose to plaque rupture. These adverse conditions are worsened by the high metabolic demand that occurs during liver transplantation.

Evidence suggests that CAD is more prevalent in transplant candidates. Studies show that at least one critical coronary artery lesion occurs in 5% to 26% of all liver transplant candidates who are asymptomatic<sup>[6-9]</sup>. Up to 50% of patients with significant CAD will die perioperatively from cardiac complications<sup>[7]</sup>. This is substantially greater than the one year mortality rate (10%) for all liver transplant recipients<sup>[10]</sup>, or the mortality rate from cardiac complications for other study populations<sup>[11,12]</sup>. A previous history or classic symptoms of CAD places patients in well-tested protocols that direct further evaluation<sup>[13,14]</sup>. However, the challenge remains in identifying those patients who are asymptomatic, but have significant CAD.

### RISK FACTORS FOR CAD IN CIRRHOSIS

Specific patient attributes are correlated with CAD<sup>[15]</sup>. The actual demographic profile of a patient with CAD is remarkably similar throughout the world<sup>[16,17]</sup>. High blood pressure, elevated cholesterol, diabetes and obesity are the most prevalent attributes. Risk factors for CAD are also prevalent in liver transplant candidates<sup>[9]</sup>. Age > 50 years, male gender, diabetes and obesity are

**Figure 1** Algorithm for the diagnosis of ischemic heart disease. There is no consensus on how to evaluate asymptomatic liver transplant recipients for the presence of CAD. However, a logical algorithm can be constructed using the current evidence from a limited number of outcome studies. The utility of this algorithm will require outcome testing to determine its sensitivity and specificity. In this approach, asymptomatic liver transplant recipients are divided according to the presence risk factors for CAD. Patients with 0-1 risk factor require no further evaluation. Those with 2 risk factors are first assessed by calcium scoring. If the score is zero, no further testing is required. If the test is not zero patients are referred for stress testing. Patients referred directly for stress testing include those with 3 or more risk factors and those with high risk factors. A positive stress test is an indication for coronary catheterization. <sup>1</sup>High Risk Factors for CAD include diabetes, NASH, previous CAD, peripheral vascular disease; <sup>2</sup>Risk Factors for CAD include age > 50 yr, hypertension, elevated cholesterol and obesity.

common. In addition, altered lipid metabolism and other unknown factors may make cirrhosis an independent risk factor. Cirrhotic patients with 0-1 risk factors have a low likelihood for CAD. However, the presence of two or more factors (other than age) places patients at moderate to severe risk of CAD<sup>[9]</sup>. A diagnosis of non-alcoholic steatohepatitis (NASH) independently increases the risk of CAD<sup>[18]</sup>. Critical CAD occurs in approximately 23% of patient with NASH<sup>[18]</sup>. Even though NASH patients have additional risk factors including obesity and diabetes, the prevalence of CAD is greater than the sum of associated risk factors<sup>[19,20]</sup>. Overall transplant candidates with diabetes, peripheral vascular disease including carotid atherosclerosis, abdominal aneurysm, chronic renal failure or high risk-Framington Score are likely to have CAD and need further evaluation<sup>[14]</sup>.

### SCREENING TESTS FOR CAD IN CIRRHOSIS

The prognostic value of any screening test is related to the prevalence of the disease in the population under

study<sup>[14]</sup>. Some investigators argue that the prevalence of CAD in transplant candidates is insufficient to warrant testing all asymptomatic patients greater than 50 years of age<sup>[21]</sup>. However, this opinion does not take into account the high perioperative mortality associated with CAD in these patients. Therefore, it is reasonable to err on the side of caution by optimizing sensitivity at the expense of lowering specificity. While few patients with only one risk factor have positive findings, 2 risk factors significantly increases the chance of critical CAD in this population<sup>[6,21]</sup>. However, not all risk factors confer an equal chance of CAD. Diabetes and NASH are more predictive of CAD than other attributes such as age or gender<sup>[21,22]</sup>. Therefore, the decision to proceed with noninvasive testing must be tempered by the relative predictive strength of each risk factor rather than just the number of factors present.

### Calcium scores

Calcium crystals are commonly deposited in coronary atherosclerotic lesions and the degree of calcification correlates with the severity of occlusive coronary atherosclerosis<sup>[23]</sup>. Computerized tomography is a non-invasive and rapid way to measure calcium deposits within the coronary vasculature. The amount of cardiac calcium is summated into scores (CACS) that are reported as a percentile according to age and gender. Higher scores suggest a greater degree of coronary artery stenosis<sup>[24]</sup>. Calcium scores are, therefore, used to detect and grade the severity of CAD<sup>[25]</sup>. However, the CACS has limited predictive value as a single screening study for CAD. The CACS is relatively insensitive with a weighted average of only 40% for detecting critical lesions<sup>[25]</sup>. A comparison of CACS with echocardiography also suggests a lack of specificity<sup>[26-30]</sup>. Despite these limitations, CACS does provide incremental prognostic information to assess cardiac risk with respect to cardiac death, myocardial revascularization or myocardial infarction<sup>[31]</sup>. Patients with a CACS > 100 are 5 times more likely to have ischemic coronary events compared to those with a CACS < 100 and significant coronary disease is rare with a score of zero.

Non-calcified coronary plaque can also cause myocardial infarction and death. However, non-calcified lesions are uncommon in patients with a CACS of zero<sup>[32]</sup>. When present, stenosis is usually less than 50% of the luminal diameter. This finding reinforces the strong predictive value of a CACS of zero. However, non-calcified lesions and their degree of stenosis increase significantly as the CACS increases. Current evidence suggest that CACS as a single test has limited value except to separate patients with minimal risk of CAD (CACS = zero) from those who have more advanced disease.

### Stress testing

Stress testing is used to increase myocardial oxygen demand in order to identify critically obstructed coronary vessels. Graded exercise and the intravenous administration of drugs that increase oxygen consumption are the two most efficient ways to test for reversible ischemia. Ischemic changes are captured using common imaging techniques such as echocardiographic wall motion abnormalities and

radionuclide myocardial perfusion defects. A stress test cannot identify disease caused by atherosclerotic plaques that are too small to limit coronary blood flow, even if these lesions are at risk of rupture.

More severe disease (more vessels involved and/or more severe stenosis) improves the predictive power of the test. In general, graded exercise stress tests coupled with echocardiography or myocardial perfusion imaging have similar sensitivity and specificity<sup>[33]</sup> but, the predictive values of the tests diverge when pharmacologic agents are used. Echocardiography is less sensitive but more specific than myocardial perfusion with dobutamine<sup>[34]</sup> and dobutamine is better than vasodilators such as adenosine or dipyridamole for inducing ischemia with either technique<sup>[35]</sup>.

Dobutamine myocardial perfusion imaging is more sensitive than dobutamine echocardiography for detecting myocardial ischemia in patients with liver disease<sup>[36]</sup>. In transplant candidates these tests have a better negative rather than positive predictive value<sup>[37]</sup>. Thus, a negative test confers a minimal chance of CAD. There is a greater chance that no lesion will be identified angiographically if the test is positive. However, the unique physiological stress associated with liver transplantation places patients at greater risk of plaque rupture, even if less than 50% of the vessel is occluded. There are more false positive stress tests in transplant candidates. However, there are also more postoperative deaths in transplant recipients who had abnormal myocardial perfusion studies but no angiographic lesions<sup>[36]</sup>. These patients die of perioperative cardiovascular complications, sepsis and donor graft failure<sup>[38]</sup>. Investigators suggest that myocardial perfusion defects with a normal angiogram are not necessarily benign findings and could be caused by reduced microvascular coronary blood flow<sup>[38]</sup>.

Questions remain as to what degree of lesion requires intervention and what type of treatment is best. Most subcritical coronary stenoses in surgical patients can be medically managed. However, investigators report a perioperative death rate of more than 50% in transplant recipients with CAD who were managed medically<sup>[7]</sup>. Further myocardial infarction during transplant surgery has occurred with as little as 30% vessel occlusion<sup>[36]</sup>. To date there is no consensus on what degree of stenosis needs treatment in liver transplant candidates because there are very few reports on the outcomes of coronary interventions in transplant candidates.

## CARDIOMYOPATHY

The prevalence of cardiomyopathy is greater in patients with end stage liver disease than the general population<sup>[39-41]</sup>. Conditions such as hepatitis C can cause immune-mediated myocarditis and fibrosis resulting in restrictive cardiomyopathy<sup>[41]</sup>. Hemochromatosis and amyloidosis also cause restrictive cardiomyopathy due to the infiltration of iron and protein respectively. Findings similar to dilated cardiomyopathy are also commonly reported from routine echocardiographic screening of

transplant candidates<sup>[40]</sup>. Further, an increased reporting of hypertrophic cardiomyopathy in transplant candidates suggests that this disorder may also be more prevalent in cirrhotic patients<sup>[42,43]</sup>.

Symptoms of liver disease are often similar to those of heart failure. Therefore, it is difficult to determine if fatigue, shortness of breath and adventitious heart sounds are due to liver disease alone or if patients have cardiac failure. Routine screening of transplant candidates with echocardiography is an effective way to identify comorbid cardiac disease. Even though cardiac disease can be readily identified, there is no agreement on how disease influences transplant candidacy. Currently, there is no outcome data using cardiomyopathy as a primary study variable. However, investigators have reported that patients with dilated cardiomyopathy seem to improve after successful transplantation<sup>[40]</sup>. In contrast, the prognosis for infiltrative processes such as Hepatitis C, amyloidosis and hemochromatosis does not seem as good and cardiac disease is reported to progress to overt heart failure despite successful transplantation<sup>[41,44]</sup>.

### **Cirrhotic cardiomyopathy**

Some cirrhotic patients have obvious features of cardiomyopathy, however most have more subtle defects in myocardial function that are not apparent on cursory examination. Early cardiac decompensation is often missed because the cardiac workload is reduced by peripheral vasodilation caused by liver failure<sup>[45]</sup>. These patients are dismissed as having normal heart function. However, when these patients are subject to physiological or pharmacological stress, they develop clinical signs of suboptimal perfusion including renal failure and acidosis. Investigators have concluded that exercise uncovers an intrinsic defect in myocardial function that predisposes to heart failure<sup>[46,47]</sup>. This condition is called "cirrhotic cardiomyopathy" and although the clinical presentation can be variable, all patients have four common features. These are: (1) Baseline increased cardiac output; (2) Attenuated systolic contraction and diastolic relaxation; (3) Electrophysiological abnormalities including repolarization change; and (4) A reduced response of the heart to direct beta stimulation ( $\beta$ -incompetence)<sup>[48]</sup>. These changes occur in the absence of overt congestive failure.

### **Myocardial function in cirrhotic cardiomyopathy**

Indices of left ventricular contractility such as the stroke index, mean systolic ejection rate, left ventricular stroke-work and left ventricular stroke-power are greater than expected in the cirrhotic patient at rest. The only clue early that the heart may not be normal is a blunted response to exercise<sup>[49]</sup>. The standing position and physical or mental stress have minimal impact on cardiac output in cirrhotic patients. But, the absolute and relative increase in cardiac output in response to exercise is reduced compared to controls<sup>[49]</sup>. Thus, aerobic exercise capacity and maximal heart rate are lower than expected<sup>[49-51]</sup>.

Early histological changes include myocardial hypertrophy, interstitial and cellular edema and signs of cellular injury<sup>[52]</sup>. This causes thickening of the left

ventricle with the septum affected more than the free wall<sup>[49]</sup>. Overall, these effects are more pronounced in patient with ascites compared to those without<sup>[46]</sup>. As wall thickness increases so does the degree of diastolic dysfunction. Impaired diastolic relaxation prolongs isovolumetric relaxation and the ventricular pressure is greater than normal for any given end diastolic volume. The left atrium dilates in response to the higher impedance to left ventricular filling. When these patients experience circulatory changes that rapidly increase filling pressure, congestive heart failure develops. This likely explains why patients experience an increased incidence of congestive heart failure after procedures such as transjugular intrahepatic shunts and liver transplantation<sup>[53]</sup>. In fact, diastolic disturbance is such a consistent feature of cirrhotic cardiomyopathy that many investigators suggest that some degree of diastolic dysfunction is present in all patients with liver disease<sup>[52]</sup>.

At rest, systolic function appears to be normal in most patients with liver disease. However, the mechanics of systolic contraction are commonly disturbed. This is shown by examination of the systolic time interval. The length of systole remains constant, but left ventricular ejection period takes up a larger percentage of the time interval. This in turn shortens the pre-ejection period<sup>[54]</sup>. In contrast to changes in diastole, systolic dysfunction usually only becomes evident during exercise. Ejection fraction does not increase as expected under conditions of stress. Further, an increase in filling pressures does not increase ejection fraction and the Frank Starling curve flattens<sup>[54]</sup>. As liver disease progresses systolic function can be insufficient to meet the resting tissue oxygen demands<sup>[55]</sup>. The impaired systolic response to stress is etiologic in the increased incidence of pulmonary edema and congestive heart failure following procedures that abruptly increase blood flow to the heart<sup>[54]</sup>.

### **Electromechanical disorders in cirrhotic cardiomyopathy**

The events of electrical depolarization and mechanical systole are normally tightly linked in time and exhibit little variability. Thus, the events are considered "coupled". The time interval needed for ventricular repolarization is limited and also has little variability. This is to prevent the next depolarizing current from advancing into a partially depolarized conducting system and causing re-entry arrhythmias. Patients with liver disease exhibit three common cardiac electrophysiological disturbances in cardiac function. These include: (1) Electromechanical dissociation; (2) Prolongation of ventricular repolarization (the QT interval); and (3) Chronotropic incompetence<sup>[52]</sup>.

The time period between electrical and mechanical systole is longer in patients with cirrhosis<sup>[56]</sup>. If the conducting system is still partially depolarized when the next action potential arrives, electrical depolarization cannot capture all the mechanical activity of the myocardium. Thus investigators think that defects in electromechanical coupling may contribute to impaired systolic performance in cirrhosis by failing to recruit all available myocardium for the next ventricular contraction<sup>[57]</sup>. Once electromechanical dissociation

becomes severe, it prolongs the time required for repolarization (QT interval). Prolongation and variability in the QT interval can affect cardiac rhythm and cause serious disturbances including ventricular fibrillation. The severity of electromechanical dissociation is clearly related to the severity of liver disease. This is shown by the fact that the length of the QT interval correlates directly with the Child-Pugh score<sup>[54]</sup>. Further, the QT interval in cirrhotics varies in different regions of the heart<sup>[58]</sup>. This dispersion of the QT interval is distinctly abnormal and the degree of abnormality is also related to the severity of liver disease. While patients with congenital prolonged QT appear to have defects in the sodium receptors that regulate electrical gating, the potassium gates of the conducting system are primarily affected in patients with liver disease<sup>[59]</sup>.

Normally, stimulation of  $\beta$ -adrenergic cardiac receptors in healthy subjects causes an increase in both the rate and force of cardiac contractions. However, cirrhotic patients exhibit a blunted response to both physiological and pharmacological  $\beta$  stimulation<sup>[55]</sup>. A suboptimal response of heart rate to  $\beta$  stimulation, termed chronotropic incompetence is found in patients with heart failure in addition those with cirrhosis. It is a proven poor prognostic indicator in all types of heart failure<sup>[60]</sup>. Chronotropic incompetence is likely also a predictor of mortality in patients with liver disease<sup>[47]</sup>.

Studies of experimental animals show that the progressive failure of  $\beta$ -agonists to elicit a positive chronotropic and inotropic response is caused by an acquired defect in the mechanism of  $\beta$ -receptor signaling. There is both a reduction in the number of  $\beta$ -adrenoceptors in the cell membrane and multiple defects in the pathway that link receptor stimulation to contractility<sup>[61]</sup>. These findings occur to some degree in all patients with liver disease<sup>[48]</sup>. The response to  $\beta$ -stimulation is relatively preserved early in the course of liver disease but becomes increasingly "incompetent" as liver disease progresses. In end stage liver disease, no significant increase in heart rate occurs in response to Valsalva maneuver or tilting. Further, the dose of isoproterenol required to raise heart rate is much larger than in healthy subjects<sup>[62]</sup>. Investigators think that failure of  $\beta$ -adrenergic receptors to appropriately stimulate all potential myocardial activity may also contribute to systolic dysfunction in cirrhotic cardiomyopathy<sup>[48]</sup>. This helps to explain why signs of cardiomyopathy are only observed under conditions of physical or pharmacological stress.

## CONCLUSION

Cardiac disease appears more frequently in patients with end stage liver disease. The two most common conditions are ischemic heart disease and cardiomyopathy. Some question whether it is cost effective to screen all transplant candidates for CAD. The unusually high perioperative mortality in transplant patients who do have CAD warrants a systematic evaluation in every patient which presumes a greater risk of atherosclerotic coronary disease. No single test has 100% predictive value. Therefore diagnostic protocols must account for the

variation in prevalence that occurs in subsets of transplant candidates and the limitation of each type of test.

In contrast to ischemic heart disease, most patients with advanced liver disease have myocardial defects that cause systolic and diastolic impairment that is not always evident at rest. There are also underlying electrophysiological defects that cause an uncoupling of mechanical and electrical activity. Diagnosis of "cirrhotic cardiomyopathy" is difficult since the findings can be subtle as some patients will develop frank heart failure when exposed to pharmacological or physiological stress such as liver transplantation.

## INTRODUCTION

Surgery, including liver transplantation (OLT) remains the most efficient treatment of patients with hepatocellular carcinoma (HCC)<sup>[1,2]</sup>. However, less than 30% of patients are eligible for liver resection (LR) due to HCC multifocality on a background of chronic liver disease<sup>[1,2]</sup>. Over the past 10 years, there has been considerable progress in both diagnosis and surgical outcome of HCC patients<sup>[1,2]</sup>. Selective preoperative morphological assessment, preoperative use of portal vein embolization<sup>[3]</sup> and the improvement of surgical techniques<sup>[4,5]</sup> are factors that improve the safety of LR. In addition, better selection of the candidates for LR has been accomplished by both imaging advancements and preoperative accurate evaluation of liver functional reserve. We review herein the available data regarding selection criteria for LR in the setting of HCC and underlying liver disease.

## CLINICAL CLASSIFICATION

Cancer classification aims to establish prognosis and select the adequate treatment for the best candidates. The Barcelona-Clinic Liver Cancer (BCLC) classification has emerged as the standard classification for clinical management of HCC<sup>[2,6]</sup>. This system links tumor stage with treatment strategy and has been externally validated. Three stages of HCC have been reported according to BCLC group: Early stages, Intermediate-advanced HCC and End-stage HCC. At the early stages tumor status is defined by size of the main nodule and multicentricity (single < 2 cm, single 2-5 cm, 3 nodules < 3 cm). Variables related to liver function are relevant in patients not suitable for transplantation as portal hypertension and normal bilirubin in patients undergoing resection. The limitations of one-dimensional systems, such as the Okuda staging and the Child-Pugh classification have been overcome. Several proposals reported recently and sub-classify patients at advanced stages such as the CUP

## Abstract

Hepatocellular carcinoma (HCC) is one of the most common malignancies worldwide with an annual occurrence of one million new cases. An etiologic association between HBV infection and the development of HCC has been established with a relative risk 200-fold greater than in non-infected individuals. Hepatitis C virus is also proving an important predisposing factor for this malignancy with an incidence rate of 7% at 5 years and 14% at 10 years. The prognosis depends on tumor stage and degree of liver function, which affect the tolerance to invasive treatments. Although surgical resection is generally accepted as the treatment of choice for HCC, new treatment strategies, such as local ablative therapies, transarterial embolization and liver transplantation, have been developed nowadays. With increasing detection of small HCCs from screening programs for cirrhotic patients, it is foreseen that locoregional therapy will play an important role in the near future.

and the CLIP score<sup>[7,8]</sup>. The new TNM in accordance with the AJCC is based on series of patients undergoing resection. Pathological information is needed, thus representing a limitation for preoperative clinical use. Finally, the Japan Integrated Staging (JIS) includes two previous classifications: the TNM and the Japanese version of the Child-Pugh classification and offers advantages compared to CLIP score<sup>[9]</sup>.

## MILAN CRITERIA FOR LIVER TRANSPLANTATION

In the past 10 years, results of OLT have improved steadily because of careful patient selection pioneered by the introduction of the Conventional Milan Criteria (CMC)<sup>[10]</sup>. The aim of these criteria was to achieve a good outcome in patients who fulfilled the criteria and avoid a poor prognosis in patients who exceed them. These are patients with single HCC < 5 cm or up to three nodules < 3 cm who in major units achieve 70% survival at 5 years with a recurrence below 15%. The major drawback of OLT is the scarcity of donors. The increase of waiting time has led to 20% of the candidates to drop out due to progression of disease jeopardizing the outcome according to intention-to-treat analysis.

### *Pre-transplantation neoadjuvant treatments*

Several attempts have been made to prevent tumor progression during waiting time by applying adjuvant therapies, mainly percutaneous ablation and transcatheter arterial chemoembolization (TACE). These therapies have been tested only in the setting of observational studies, case series and cohort studies that provide limited information because of heterogeneity of patient and tumor characteristics, variable waiting times, use of different treatment modalities, variable evaluation of response and lack of consensus about criteria of drop-out<sup>[1,2,9]</sup>. Among the case series and cohort studies, some investigators suggest a favorable impact of treatment in decreasing the dropout rate. Mazzaferro reported no dropouts in 50 patients within Milan criteria treated with RFA<sup>[11]</sup>. Some studies reported no dropouts in patients within Milan treated by TACE and short waiting time (178 d) while others documented a probability of dropout of 15% at 6 mo and 25% at 12 mo<sup>[9]</sup>. Cumulative results show that RFA achieves the highest rates of complete necrosis (12%-55%) compared with TACE (22%-29%). Complete necrosis is best achieved with percutaneous ablation in tumors < 3 cm in diameter. It is estimated that drop-out rates will increase with the expansion of selection criteria as demonstrated by Roayaie<sup>[12]</sup>. Recurrence rates are majorly related to tumor stage than to neo-adjuvant therapies. It is recognized that recurrence rates are low when applying the Milan criteria, compared to a wide selection of candidates.

### *Milan versus expanded criteria for OLT*

The growing experience and success of OLT for HCC

have fuelled controversies related to expansion of Milan criteria. Among the proposed expanded criteria the UCSF criteria (single tumor nodule up to 6.5 cm; or three or fewer tumors, the largest of which is  $\leq$  4.5 cm with the sum of the tumor diameters  $\leq$  8 cm) reflect a modest expansion of tumor size limits<sup>[13]</sup>. However, there are limitations in applicability of the UCSF criteria in the pre-transplant setting, considering that most of the patients adhering to the UCSF were also within the Milan criteria. More to the point, the overlapping population of patients adhering to the UCSF, but not the Milan criteria is often negligible and estimated to be less than 10% of the total transplanted population<sup>[1,2,9]</sup>. In addition, the limitations of pre-transplant imaging studies, exemplified by tumor under-staging in 20% of patients, have been a major concern for liberalizing the existing criteria for OLT.

Down-staging refers to a change as a result of treatment so that disease will reach the Milan criteria, as assessed by imaging techniques. In the seminal study from Majno *et al*<sup>[14]</sup>, TACE induced down-staging of HCC > 3 cm and resulted in good survival rates after OLT, but the benefit was not confirmed in other investigations that studied TACE or RFA. The UCSF group reported a cohort of 30 patients treated heterogeneously, so that disease would reach the Milan criteria. Half the patients with down-staged tumors were effectively transplanted, although some bias exists and control studies required. Therefore, nowadays down-staging should be assessed in the setting of clinical research.

## LIVER RESECTION

Although surgery remains the only treatment for HCC in patients with or without cirrhosis, most individuals with HCC are ineligible for surgical intervention. In eligible patients, the methods of surgical therapy are partial hepatectomy and liver transplantation. In addition to resection and liver transplantation, percutaneous ablation is considered as a treatment option that offers a high rate of complete response and thus a potential for cure. In selected patients, a 5-year survival rate of 60% to 75% can be achieved after surgery<sup>[1,2,9]</sup>. However, in those with advanced HCC, the consequent improvement in long-term survival is poor because of the high rate of recurrence or the development of intra-hepatic metastases that disseminate *via* the portal vein or spread to other parts of the liver. Nevertheless, the management of HCC has undergone major changes over the last few decades. Earlier detection enabled by screening methods that use ultrasonographic evaluation and AFP analysis in high-risk populations, more accurate patient assessment, advances in imaging, improved surgical techniques, and the availability of local treatment options have improved outcomes.

### *HCC in patients with a non-cirrhotic liver*

Only 5% of the cases of HCC in Western countries (as opposed to 40% in Asia) develop in a non-cirrhotic liver<sup>[1]</sup>. When HCC occurs in a non-cirrhotic liver,

solitary tumor nodes that are limited to one liver lobe and lack satellite foci are frequently present. Without predisposing cirrhosis, HCC is often not diagnosed, until the tumor causes symptoms because of its size. Sometimes HCC is an incidental finding revealed by ultrasonographic studies<sup>[1]</sup>.

The treatment approach for patients with HCC without cirrhosis should be based on factors such as extra-hepatic tumor manifestation, tumor size and the number and distribution of nodules. In such patients, curative resection should be considered whenever possible.

Major hepatectomy defined as resection of more than three liver segments is feasible if the remnant liver volume is adequate. The evolution of transection devices and postoperative care had a major impact in both morbidity and mortality after LR. Most centers documented a less than 5% mortality rate recently<sup>[1,2,4,5]</sup> compared to a higher incidence reported 10 years ago. Blood transfusion requirements have also been restricted from 80% to 20% in major reference centres. This was accomplished by bloodless techniques with intermittent inflow occlusion and better selection of candidates with single lesion and absence of portal hypertension<sup>[1,2,4,5,15,16]</sup>.

Pre-treatment imaging studies such as high-resolution triple-phase computed tomography (CT) and nuclear magnetic resonance imaging (MRI), either with or without angiography, can be used to match patients and their most appropriate treatment. Positron emission tomography (PET) is also useful in the identification of extra-hepatic metastases that considerably influence clinical decision-making. Knowledge about the relation of the tumor to regional anatomic structures such as large vessels is crucial because it provides valuable information about resectability. Furthermore, volumetric studies can be used to define the residual parenchyma exactly. If there is any suspicion of lymph node metastasis or peritoneal dissemination, diagnostic laparoscopy with intra-operative ultrasonography is useful, and if multiple metastases are confirmed, explorative laparotomy can be prevented.

The determination of hepatic reserve is also significant when resection is considered. The healthy liver has a great capability for regeneration and adjusts to the metabolic requirements of the host after LR due to hypertrophy of the residual liver. Therefore, even in patients with a large tumor, extensive resection is possible. In an otherwise healthy liver, up to 75% of the parenchyma can be resected.

Patients with a localized unilobar tumor in a non-cirrhotic liver or Child class A cirrhosis with adequate remnant liver parenchyma may be considered for partial hepatectomy (lobectomy). Partial hepatectomy usually ensures a safety margin of at least 1 cm and is associated with an operative mortality rate of less than 5%. From an oncologic perspective, anatomic resection that may include satellite lesions is more effective than limited resection without a surrounding margin. For patients with inadequate or borderline remnant parenchyma, hypertrophy of the prospective liver remnant can be induced by preoperative portal vein embolization (PVE).

In certain circumstances, an unfavorable location of the tumor and involvement of the confluence of the three hepatic veins and either the caval vein or the retro-hepatic caval vein can render resection by conventional techniques impossible. In these rare cases, special techniques such as *in situ* or ante situm resection can be used.

The overall long-term results after resection are favourable. However, only 20% to 30% of patients with HCC are eligible for resection because of advanced or multifocal disease or inadequate functional hepatic reserve. In patients with solitary lesions of less than 5 cm, no vascular invasion, and a negative surgical margin of at least 1 cm, the 5-year survival rate after resection is reported to be greater than 70%<sup>[17]</sup>. Despite earlier detection, safer surgical procedures, and more aggressive treatment of HCC, recurrence (because of multicentric carcinogenesis or intrahepatic metastases from the primary tumor) is likely. In selected patients, repeated resection provides good long-term benefits and is an option for those with solitary peripheral tumors that can be treated with segmental or atypical resection.

### **HCC in patients with cirrhosis**

HCC in patients with cirrhosis is a challenge due to both pre-existing liver damage and possible tumor multifocality. Portal hypertension and reduced functional capacity of the cirrhotic liver significantly increase the peri-operative risk. These facts influence two significant decisions regarding surgery: patient selection and the choice of the surgical therapeutic method.

The resection margin of HCC in cirrhotic patients does not represent a significant predictive factor for recurrence, unless residual tumor directly invades the raw surface of the liver<sup>[1]</sup>. In most HCC patients, tumor recurrence results from disseminated tumor, and in the remaining patients, recurrence is caused by metachronous tumors that arise in the oncogenic cirrhotic liver, as is typical in the cirrhosis that develops after hepatitis C infection<sup>[1]</sup>. Because of the difficulty to prevent recurrence by resection with an adequate safety margin, resection (preferably segmentectomy or subsegmentectomy rather than wedge resection) should be as limited as possible. Because of the threat of insufficient liver function coupled with a greater risk of mortality, the decision to perform major resection should be considered with caution.

The reduced functional reserve capacity in patients with cirrhosis of the liver limits the choice of surgical therapy. Various tests have been developed to quantify liver function.

Refined selection criteria and technical advances, including a broader knowledge of segmental anatomy, vascular occlusion techniques, and the use of intra-operative ultrasonography, have facilitated resection and improved outcome. Operative mortality rates have decreased to less than 5%<sup>[2,9]</sup>. A considerable decrease in intra-operative blood loss has been achieved by means of numerous technical improvements such as the use of ultrasonographic dissectors and bipolar and argon beamer coagulation. In individual cases, hilar occlusion

(the Pringle manoeuvre) has become either unnecessary or the occlusion time can be shortened, both of which result in reduced ischemia-reperfusion damage. Despite a decrease in the operative mortality rate and improved results after resection, overall survival after the resection of HCC has changed little due to absence of effective adjuvant treatment to eliminate postoperative recurrence.

**Liver function assessment:** The clinical assessment of hepatic function by the use of “Child” system, developed to understand the significance of cirrhotic liver injury and portal hypertension as they related to patient survival after portal-systemic shunt surgery was used mainly in the past in its original version. In general, Child class A or Child class B patients may tolerate a resection of up to 50% and 25% of liver parenchyma, respectively. However, evaluating hepatic reserve by means of the CTP classification may lead to an inconsistent predictive value, because as Child class A patients may already have significant functional impairment and may demonstrate an increase in the bilirubin level as well as portal hypertension and fluid retention. These features indicate advanced liver disease and preclude resection. Limited discriminatory ability, subjective interpretation of parameters, and variability in the measurement of laboratory parameters are further limitations of CPT. Makuuchi *et al*<sup>[18]</sup> was first to described three parameters in patients with cirrhosis associated with morbidity after hepatectomy. Ascites, abnormal serum bilirubin and ICG clearance were defined as independent factors affected postoperative morbidity. They noted that a cut-off ICG clearance level below 20% is adequate for safe hepatectomy. Other groups use a cut-off level of 14% to discriminate high-risk candidates<sup>[19]</sup>. If that level is greater than 40% postoperative liver failure is likely, even with minimal resection. However, ICG clearance criteria are not absolute and every effort for further extension depends on the liver remnant size and severity of cirrhosis. In addition ICG retention measurement is cumbersome requiring accurate sampling. Furthermore, the dynamic tests (ICG, Galactose elimination capacity *etc*) cannot take into account all the complexities of liver function and, therefore, they have limitations. ICG clearance is not a true index of parenchymal function because there is also a substantial influence of hepatic blood flow. Clearance is considered to be impaired when 15% or more of the dye remains within the plasma 15 min following the injection of 0.5 mg/kg ICG. Thus, patients with CP scores of 5 or 6 (Child A) and ICG15 of greater than 14% are the “high risk” CP-A patients with limited functional reserve.

Nuclear imaging has been used recently to evaluate liver function. A functional imaging with great promise involves receptor targeting with radio-labelled synthetic asialoglycoproteins (99 m-Tc-GSA). GSA provides volumetric receptor data and kinetic distribution curves. However, GSA is still preliminary and although is correlated with CP and ICG clearance its potential role in evaluating resection must demonstrate that they are

improvements over CP stratification.

In Europe and North America, the selection of optimal candidates for LR is usually based on the degree of portal hypertension and an elevated bilirubin level. Portocaval pressure gradient > 10 mmHg or the presence of oesophageal varices (grade 2, 3) are good indicators of portal hypertension (PH). A low platelet count < 100 000/mL and splenomegaly is also used as a surrogate marker of PH. A bilirubin concentration that is within normal limits and a hepatic vein pressure gradient of less than 10 mmHg (measured by hepatic vein catheterization) are the best predictors of excellent outcome after resection and are associated with almost no risk of postoperative liver failure<sup>[2]</sup>. In the setting of Child A cirrhosis with none of these factors presented, a 70% 5-year survival was documented despite the fact that portal hypertension and abnormal bilirubin decrease long-term survival by half. Measurement of the liver remnant volume is helpful in selecting patients for major hepatic resection, however, preoperative evaluation of the severity of cirrhosis may be mandatory by biopsy of non- tumorous liver for histological grading.

The Model for End-Stage Liver Disease (MELD) score has gained widespread acceptance to prioritize candidates for liver transplantation. Few studies<sup>[20-23]</sup> including the one performed in our department<sup>[24]</sup>, demonstrated a strong correlation of postoperative morbidity after hepatectomy and MELD value. More precisely a cut-off value of 8 was associated with higher morbidity and a cut-off value of 11 with high mortality rate. In this particular situation, our group suggests liver transplantation rather than resection.

Apart from the factors mentioned above the presence of co-morbid illnesses such as cardiovascular disease has been shown to increase the risk of hepatectomy. While the presence of severe co-morbid illnesses such as congestive heart failure and chronic renal failure should be considered a contraindication for hepatectomy, HCC patients with less severe co-morbid illnesses, such as diabetes, may still benefit from hepatic resection provided with meticulous peri-operative care. However, the importance of optimum peri-operative control of the blood glucose level and vigilant postoperative care in such cases needs to be emphasized. Finally, the Memorial Sloan Kettering data reported by Jarnagin<sup>[25-28]</sup> suggests that experience may play a critical, positive role in patient selection. The avoidance of greater than four segment resections in “bad-risk” Child-Pugh Class A patients is a clear-cut goal, unless the option of portal vein occlusion is to be pursued.

**Portal vein embolization:** Portal vein embolization (PVE) has been applied in the setting of inadequate liver remnant volume to induce hypertrophy. Although the concept of contra-lateral liver hypertrophy after PVE has been challenged by some due to the impaired cirrhotic liver regenerative capacity, a better selection of those patients not amenable to major resection is feasible. Proposed guidelines for PVE application include less than 40% remnant liver volume in the

**Figure 1** A: Before portal vein embolization (PVE); B: After portal vein embolization (PVE).

**Figure 2** CT indicated, A: Before PVE; B: Six weeks after PVE on the same patient. Hypertrophy of the left hepatic lobe is obvious.

non-cirrhotic group of patients underwent major hepatectomy or less than 60% in the group of cirrhotic individuals with ICG15 < 20%.

The volume of functional liver mass left after resection is an important factor in the development of postoperative complications and subsequent mortality<sup>[29,30]</sup>. Liver volume measurement for adult living donor liver transplantation is standardized to achieve a graft weight to recipient weight of at least 1% because of the clear link between adequate functional hepatic mass of the donor graft to recipient weight and postoperative complications.

In the non-transplant LR setting, the minimum acceptable liver volume remaining post-resection has not been well assessed but is generally thought to be about 25% of the normal liver volume. In cases where there is liver dysfunction such as cirrhosis or cholestasis, 40% of the normal volume is acceptable<sup>[31]</sup>. The advent of PVE allows optimization of the remnant liver volume in cases where it is projected to be less than ideal. However, no randomized trials examining the effectiveness of portal vein embolization on liver regeneration or its impact on LR exist. The use of portal vein embolization of the hepatic lobe that hosts the tumor to induce compensatory hypertrophy in the non-affected liver before major resection is controversial. Uncontrolled tumor progression because of the proliferation of malignant cells stimulated by this method and the risk of variceal bleeding resulting from acute portal hypertension are some of the concerns.

PVE blocks portal flow to the side of the liver ipsilateral to the lesion to be resected (Figure 1A and B)

and causes an increase in size of the future liver remnant (FLR) (Figure 2A and B). The increased size is due to both clonal expansion and cellular hypertrophy<sup>[32]</sup>. The assumption that increase in liver volume correlates with increased function post-PVE has been demonstrated in studies showing increase in asialoglycoprotein receptor binding sites in the FLR before resection<sup>[33-36]</sup>. Percutaneous transhepatic PVE can be performed by either of two standard approaches: the transhepatic ipsilateral<sup>[37]</sup> and transhepatic contralateral<sup>[38]</sup>.

Many commercially available embolic agents have been used for preoperative PVE without significant differences in degrees or rates of hypertrophy of the nonembolized segments<sup>[39]</sup>. The ideal agent is well tolerated by the patient and causes permanent embolization of the portal vein and its branches with minimal risk of recanalization<sup>[40]</sup>. In addition, it should be widely available and easily administered without causing inflammatory reaction and be associated with a low risk of post-embolization syndrome and hepatic necrosis. Although each of the embolic agents has advantages and disadvantages, no single agent has been proven to be consistently superior<sup>[41,42]</sup>.

All patients have a volumetric assessment of their liver volumes both before PVE and before surgery using CT imaging. Post-embolization CT is essential for assessment of liver volume change and planning of LR<sup>[39]</sup>. The average interval for the CT volumetric study from portal vein embolization to surgery is 4 to 6 wk. CT is used to make direct measurements of total liver volume, volume to be resected, and volume of the future liver remnant. The future liver remnant volume

is considered to be the volume of the liver segments expected to remain after hepatectomy. More precisely Computed Tomography scans of the liver are necessary. Serial transverse scans at 1-cm intervals from the dome of the liver to the most inferior part of the organ must be obtained, with enhancement by intravenous bolus injection of contrast and with the patient suspending respiration in expiration. Each slice of the liver is traced with a cursor, and computer calculates the corresponding area. The middle hepatic vein and gallbladder are used as landmarks to define the borders between the right and left livers. Segment IV volume is measured using the middle hepatic vein and the umbilical portion of the left portal vein as landmarks. The total volumes measured (whole liver volume, tumor volume, and remnant liver volume) are calculated by multiplying the area of each part by the interval thickness and by adding all the interval volumes of each part. The estimated rate of remnant functional liver parenchyma (ERRFLP) is calculated by the formula:  $\text{FLR volume} = (\text{remnant liver volume} \times 100) / (\text{total liver volume} - \text{tumor volume})^{[43,44]}$ .

The increase in FLR volume after portal vein embolization can be calculated with the following formula:  $(\text{volume of the FLR before surgery} - \text{volume of the FLR before PVE}) \times 100 / (\text{volume of the FLR before PVE})$ . The increase in the %FLR after portal vein embolization can also be calculated from:  $(\% \text{FLR after PVE} - \% \text{FLR before surgery})$ . The total liver volume can be estimated on the basis of the body surface area using the formula;  $\text{total liver volume} = 706.2 \times \text{body surface area} + 2.4$ . The calculated range of percentage increase of future liver remnant volume following portal vein embolization is 8% to 27% in different studies including our experience.

**Preoperative imaging:** Selection of candidates with HCC for LR requires adequate preoperative staging<sup>[1,2]</sup>. Sensitivity and diagnostic value of preoperative imaging (CT, MR) approximates 80% but is limited for satellite nodules or less than 1 cm lesions. MR angiography although is more sensitive for identification of 1-2 cm lesions has limitations for subcentimeter tumors. Intraoperative ultrasound is more accurate for very early less than 1 cm HCC. Positron emission tomography (PET) is also useful in the identification of extra-hepatic disease that considerably influence clinical decision-making. If there is any suspicion of lymph node metastasis or tumor dissemination, diagnostic laparoscopy with intraoperative ultra-sonography is useful to avoid an unnecessary laparotomy. There is widespread acceptance that liver biopsy is not necessary as a routine for lesions more than 2 cm with imaging compatible for HCC in a patient with history of underlying cirrhosis or high AFP levels.

## PROGNOSTIC FACTORS

The most significant predictive factors for early recurrence are the size and number of tumors, the presence of satellite nodules, the histologic grade, the severity of cirrhosis, and the serum AFP level<sup>[45-49]</sup>.

Tumor size and the number of nodules are important factors that predict vascular invasion. However, tumor size is not an absolute contraindication for LR<sup>[50]</sup>. Long-term survival varies from 66% in cases of less than 5 cm lesions to 37% in the group of large (> 5 cm) HCC<sup>[46-50]</sup>. Vascular invasion is an independent factor affect prognosis and is strongly associated with both size and histological grade. More precisely lesions less than 2 cm in diameter have a 20% rate of micro-vascular invasion although the rate increases progressively for lesions more than 5 cm in diameter (60%-90%). Even though vascular invasion is not easily identified preoperatively by imaging techniques, tumor size and grading are surrogate markers. According to the results of a study reported recently, a tumor size larger than 5 cm was an indicator of high histological grade in more than 40% of patients with HCC. Needle core biopsy (NCB) is notorious, unreliable to confirm preoperatively tumor grading due to heterogenous nature of HCC as reported by Pawlik and associates<sup>[51]</sup>.

The number of lesions is strongly related with incidence of recurrence<sup>[49]</sup>. Long-term survival is 57% for solitary lesions but only 26% for multifocal HCC. Other factors affect prognosis includes AFP levels, age and concomitant diseases<sup>[46,49]</sup>. In addition, genetic signature of the tumor is attributed to both disease free and overall survival<sup>[46,49,50]</sup>. The role of hepatic resection for bilobar HCCs is controversial. Bilobar HCCs may represent advanced disease with intrahepatic metastasis or may represent multifocal HCCs derived from multicentric hepatocarcinogenesis. Major hepatectomy in one lobe combined with wedge resection for a smaller lesion in the other lobe is possible in some cases. Alternatively, hepatic resection in one lobe can be combined with local ablation of a smaller lesion in the other lobe using ethanol injection or newer ablative modalities such as radiofrequency ablation. In a recent study by Poon and associates, they demonstrated that hepatic resection for patients with bilobar HCCs resulted in a better survival outcome than non-resectional therapies<sup>[52]</sup>. Hence, in accordance with others we recommend that hepatic resection should be considered in selected patients with bilobar HCCs, especially those with a small solitary lesion in the contra lateral lobe that are amenable to wedge resection or local ablative therapy.

Although hepatic resection with removal of tumor thrombus in the inferior vena cava or main portal vein has been advocated by some authors<sup>[53]</sup>, most liver surgeons consider the presence of tumor thrombus in the inferior vena cava or main portal vein a contraindication for hepatic resection because the prognosis is usually poor even with such an aggressive approach. However, hepatic resection for patients with tumor invasion of the hepatic veins or major intrahepatic branches of the portal vein is justified because favourable survival results may be expected compared with non-surgical treatment<sup>[54,55]</sup>.

A major drawback of LR in the setting of HCC is the high recurrence rate (70%) due to intrahepatic dissemination or *de novo* appearance of new lesions.

Molecular techniques differentiate widespread liver disease (60%-70%) from de novo HCC development (30%-40%). Intrahepatic metastases occurred early (less than 2 years) after LR and related to primary tumor biologic aggressiveness (low grade, vascular invasion, satellite nodules). De novo HCC occurrence is related mostly to the underlying liver disease and appears later.

## TREATMENT STRATEGY

Although surgery remains the gold standard for HCC in patients with or without cirrhosis, most individuals are ineligible for surgical intervention. In fact, only 20% to 30% of cases are amenable to resection using the previous mentioned selection criteria. Despite the difficulty of exposing patients to the risks and consequences of transplantation-associated immune suppression, liver transplantation is the ultimate treatment option in patients with HCC who fulfil Milan selection criteria. Transplantation restores liver function and decrease tumor recurrence due to removal of the oncogenic potential dysplastic lesions. However when compared with LR the results of liver transplantation in patients with HCC and without cirrhosis are less favorable. Shortage of available donors is an additional limitation associated with a high dropout rate especially in large tumors that do not fulfil Milan criteria. Recently, several groups compared resection and transplantation demonstrated similar survival rates when the different tumor invasiveness was taken into account<sup>[47]</sup>. The inclusion of patients with more advanced cancer in the waiting list for transplantation result in a higher dropout rate that leads in turn to poor survival rates in an intent-to-treat analysis. In such cases, LR if feasible is the only curative option. The relative benefits of transplantation and resection are, therefore, likely to depend upon local organ allocation policy and waiting times. Another approach to reduce both waiting-list dropout rate and the demand for donor organs is primary resection followed by salvage transplantation in case of recurrence. Two studies have compared this strategy of primary transplantation with conflicting conclusions. Opposite results applying salvage transplantation have been published by two groups reporting peri-operative mortality ranging from 5% to 30%. The BCLC group proposed a policy of listing patients for liver transplant without evident HCC based on pathological risk of recurrence after resection (vascular invasion or satellites). However, in current clinical practice the applicability of this policy is low, about 10% of cases especially if there is underlying hepatitis C.

The recent development of laparoscopic LR has added new possibilities for the limited removal of peripheral lesions<sup>[56]</sup>. The avoidance of long sub-costal incisions seems to be associated with reduced morbidity and earlier recovery. Re-operations are easy after laparoscopic resection, which allows it to be used as a neoadjuvant treatment in those awaiting liver transplantation without compromising subsequent surgery. An additional advantage of resecting small

HCCs is that it allows histopathological study of the whole tumour and identifies patients at high risk of intra-hepatic recurrence (those with poorly differentiated tumor, microvascular invasion, and satellite nodules). This raises the concept of pre-emptive transplantation when these criteria apply to the resected specimen.

## CONCLUSION

In conclusion, the selection of the treatment options in patients with HCC must be based on the patient's condition, the number and size of the hepatic tumors, the functional reserve capacity and the available resources. LR is strongly recommended in non-cirrhotic and selected cirrhotic individuals. Appropriate selection of candidates achieved by accurate estimation of hepatic liver reserve is of paramount importance. Technical advances in imaging and surgery facilitates resection and improves outcome.

### Abstract

Current algorithms for screening and surveillance for colon cancer are valuable, but may be limited by the underlying nature of the targeted neoplastic lesions. Although part of the success of adenoma removal relates to interruption of so-called "adenoma-carcinoma sequence", an alternate serrated pathway to colon cancer may pose difficulties with the ultimate results achieved by traditional colonoscopic methods. The endpoint carcinoma in this unique pathway may be derived from a dysplastic serrated adenoma. These tend to be located primarily in the right colon, especially in females, and are frequently associated with co-existent colon cancer. Unfortunately, however, there are few, if any, other identifiable risk factors, including age or family history of colon polyps or colon cancer. Moreover, this alternate serrated pathway may itself also be quite biologically heterogeneous as reflected in sessile serrated adenomas (SSA) with virtually exclusive molecular signatures defined by the presence of either BRAF or KRAS mutations. Screening algorithms in the future may need to be modified and individualized, depending on new information that likely will emerge on the natural history of these biologically heterogeneous lesions that differs from traditional adenomatous polyps.

### INTRODUCTION

Clinician endoscopists have witnessed an evolution in the application of the colonoscope. Initially, it was used primarily as an investigative modality to explore patient symptoms (abdominal pain, diarrhea, bleeding). Later, it also became widely applied as a therapeutic tool, particularly for removal of colorectal neoplasms. Now, colonoscopy has increasingly been used to screen for colon polyps and cancer in those with few or no symptoms demanding peace of mind. As a result, various agencies have developed (and promoted) guidelines for use that might aid in this endeavour, largely based on various risk factors, including familial colon polyps and cancers. For some, these are described as "evidence-based" with the goal of being "cost-effective" for an increasingly scarce service resource. These guidelines have also been based, at least in part, on the "Vogelstein" hypothesis that colon cancer results from a multistage and sequential series of mutational events that proceed from a benign adenomatous proliferation of altered epithelial cells to an increasingly larger and more complex invasive neoplastic (and even metastatic) lesion or lesions, the so-called "polyp-cancer sequence"<sup>[1]</sup>. Reasonably, interruption of this sequence could be accomplished by an intervening polypectomy and reduce the individual's risk for colon cancer. Recent information emphasizing the heterogeneous nature of these precursor colon epithelial polyps has suggested that this perspective may be an oversimplification of a more difficult problem.

### TRADITIONAL ADENOMAS AND SCREENING

Although different degrees of altered cytological

differentiation and atypia have often been described for individual polyps, recognition that colon polyp heterogeneity might have some prognostic clinical significance has traditionally been limited to discerning the degree of villous architectural change in the resected polyp (as opposed to tubular change), estimating polyp size (or more precisely, dimension) along with the number of colon polyps (albeit macroscopically visible). Any one (or more) of these has been considered by some to warrant alteration in the general guideline leading to shortened intervals of screening and/or surveillance, particularly if there were multiple polyps of large size that were histologically complex, primarily with villous architecture. Other factors may have also been entered into the equation in the mind of the practicing clinician including a background of chronic inflammatory bowel disease, certain ethnic or racial backgrounds, and, likely, individual financial means to facilitate performance of the actual screening procedure.

## ALTERNATE SERRATED PATHWAY

More recently, there has also been increased recognition that the serrated polyp (including the hyperplastic polyp (HP) with its serrated morphological features) may be more than a simple clinically innocuous bystander in the process of cancer development<sup>[2,3]</sup>.

These polyps appear quite distinct from traditional adenomatous polyps and may also exhibit morphological and molecular heterogeneity. Recent evidence suggests that some subtypes may pose a substantive potential risk for eventual malignant transformation. As such, it appears that this serrated pathway may represent an alternate road to development of colon cancer with potentially important implications for the “guideline approach” to screening and surveillance for colonic neoplastic lesions.

Some of the difficulty in this area relates to the pathological terminology along with evolution in methods of classification of serrated lesions that reflects the so-called “saw-tooth” architectural appearance of this polyp group<sup>[4]</sup>. Moreover, distinction between different forms of serrated polyps and interobserver

Table 2 Comparison of SSA polyps and HP polyps

	SSA	HP
Location	Right colon	Rectosigmoid
Shape	Flat	Pedunculated or flat
Size	> 5 mm	< 5 mm

SSA: Sessile serrated adenoma; HP: Hyperplastic polyp. Adapted from Li and Burgart<sup>[11]</sup>.

agreement among expert pathologists may be limited<sup>[5]</sup>. It appears that HPs are the most common type and these have been further sub-divided into microvesicular, goblet-cell rich and mucin-poor types. Other kinds of serrated polyps include sessile serrated adenomas (SSA), traditional serrated adenomas (TSA) and mixed polyps containing components of sessile serrated and tubular adenomas. Significant differences in the expression of specific genetic and molecular markers have also been shown between SSA and TSA<sup>[6]</sup>. While HPs seem to remain small and localized to the distal colorectum, other serrated polyps may progress to cancer through an apparently unique pathway. An early recognized form of this entity, initially labeled “hyperplastic polyposis” or “serrated adenomatous polyposis”, consisted of larger sessile polyps developing mainly in the right colon. These were associated with synchronous colon cancer in over 50%<sup>[7,8]</sup>. For TSA, dysplasia or intramucosal carcinoma were also noted in almost 50%<sup>[9]</sup>. Of note, about 10% of all colon polyps may be SSA type and about 15% have multiple lesions, based on detection with magnification chromoendoscopy<sup>[10]</sup>. Most were located in the right colon, particularly in females, however, there was no correlation with age or personal or family history of colon polyps or colon cancer<sup>[10]</sup>. Other characteristics of SSA are listed in Tables 1 and 2.

## MOLECULAR HETEROGENEITY OF SSA TYPE POLYPS

The molecular heterogeneity of lesions in this alternate serrated pathway has been nicely reviewed elsewhere by O'Brien<sup>[3]</sup>. The carcinomas that occur demonstrate microsatellite instability (MSI-high) due to hMLH1 inactivation and consequent DNA mismatch repair (MMR). In addition, heterogeneity is evident in that some carcinomas are also microsatellite stable (MSS or MSI-low). The pathway is believed to originate in a HP, or precursor aberrant crypt focus, and progresses through an intermediate disordered type of HP that eventually becomes dysplastic (dysplastic serrated polyp), and ultimately to a serrated adenocarcinoma<sup>[3]</sup>. Definition of the phenomenon of epigenetic mutagenesis by CpG-island methylation and its key role in sporadic MSI colorectal carcinomas have been stated to be at the molecular genetic core of this newly defined serrated

pathway<sup>[3]</sup>. CpG island methylation phenotype (CIMP) refers to nonrandom methylation of gene promoter regions that concordantly affects multiple susceptible suppressor, mutator, and other genes that have roles in carcinogenesis<sup>[12]</sup>. Epigenetic gene silencing of cancer-related genes has been shown in precursor polyps and endpoint carcinomas in the serrated polyp pathway<sup>[3]</sup>. This mechanism differs from the mutagenic process of the traditional “adenoma-carcinoma sequence”, where adenomas progress to carcinoma by deletions and homozygous loss of suppressor genes due to APC mutation-induced chromosomal instability<sup>[1]</sup>. Another interesting observation has been the discovery of an oncogene BRAF mutation in these neoplasms<sup>[10]</sup>. A specific activating mutation (V600E) of this phosphokinase appears to be present in most CIMP-high and MSI colon cancers, serrated polyps, including hyperplastic aberrant crypt foci, and dysplastic serrated adenomas. Although the BRAF serrated pathway is predominant (up to 80% of SSA), a second is associated with KRAS mutations. It contrasts with the BRAF pathway in that most of these are distal rather than proximal lesions with lower levels of CpG-island methylation and MSS or MSI-L rather than MSI endpoint carcinomas<sup>[3]</sup>.

## FUTURE SCREENING FOR COLON POLYPS

The high proportion of SSA is noteworthy as these are not exactly rare and most disconcerting is that routine colonoscopy may not be adequate for their detection<sup>[2,13]</sup>.

Moreover, there does not appear to be a definite profile of high risk for this SSA type that might actually lead to initiation of the screening process, particularly family history<sup>[2]</sup>. Thus, current screening algorithms may not be adequate for detection. Moreover, hyperplastic/serrated polyposis has also been observed in patients with chronic inflammatory bowel disease<sup>[14]</sup>. A prudent approach has been suggested to include complete resection and surveillance examinations as often as the intervals defined for the more traditional adenomatous polyps but this approach is not necessarily reflective of the natural biological history of these lesions. A prudent colonoscopist will also emphasize prior to embarking on a screening procedure with the patient that small lesions may be not be readily detectable. While still the gold standard for polyp detection, colonoscopic procedures have a definitive “miss rate” so that it can come close to, but does not appear able to reach perfection. Recent comparative and prospective studies using pan-colonic narrow-band imaging suggest that its use for surveillance of even small adenomas may be superior to conventional colonoscopy and equivalent to chromoendoscopy<sup>[15-18]</sup>. More widespread application of these evolving technologies in the future may also impact on the detection of serrated adenomas and current screening and surveillance guidelines.

### Abstract

Liver cell transplantation is an attractive technique to treat liver-based inborn errors of metabolism. The feasibility and efficacy of the procedure has been demonstrated, leading to medium term partial metabolic control of various diseases. Crigler-Najjar is the paradigm of such diseases in that the host liver is lacking one function with an otherwise normal parenchyma. The patient is at permanent risk for irreversible brain damage. The goal of liver cell transplantation is to reduce serum bilirubin levels within safe limits and to alleviate phototherapy requirements to improve quality of life. Preliminary data on Gunn rats, the rodent model of the disease, were encouraging and have led to successful clinical trials. Herein we report on two additional patients and describe the current limits of the technique in terms of durability of the response as compared to alternative therapeutic procedures. We discuss the future developments of the technique and new emerging perspectives.

### INTRODUCTION

Crigler-Najjar (CN) syndrome is the paradigm of an inborn error of liver metabolism affecting the function of one enzyme, the 1A1 isoform of the bilirubin-uridine diphosphate glucuronosyltransferase (UGT1A1)<sup>[1]</sup>. The parenchyma and thousands of other metabolic functions are normal, but the patient is at risk for severe neurological complications. Quality of life is deeply impaired, requiring phototherapy up to 12 h daily with efficacy lessening with ageing (probably due to unfavorable body surface/weight ratio and to increased skin thickness and pigmentation). Orthotopic liver transplantation (OLT) is a curative for the disorder<sup>[2,3]</sup>, but seems disproportionate to correct one single missing enzymatic function in an otherwise normal liver. Patients and physicians are often reluctant to undertake such an irreversible procedure and are seeking less invasive alternative options. Indeed, up to 15% of OLT patients require re-transplantation, and progressive fibrosis of the graft is a subject of concern at long term<sup>[4]</sup>.

Auxiliary liver transplantation (ALT) is another curative approach that has the advantage of being reversible. However, ALT remains associated with major pitfalls. In addition to being an invasive surgical procedure, the technique is difficult mainly because of perilous anastomosis that can hamper the venous in- or outflow and can lead to graft atrophy/ischemia or vascular thrombosis. Another complication is the small-for-size liver syndrome, defined as liver impairment, following inadequate liver mass replacement<sup>[5]</sup>. The diagnosis of rejection is difficult because of minimal enzyme elevation.

Hc: Hepatocyte; IHC: Immunohistochemistry; PCNA: Proliferating cell nuclear antigen; WB: Western blot.

Successful long-term results were recently obtained with gene therapy in Gunn rats<sup>[6,7]</sup>. This technique was described to depend on vector serotypes and allowed a reduction of serum bilirubin up to 64% after one year<sup>[8]</sup>. Globally, this technique is still facing with anti-UGT1A1 antibody production in the host organism, impeding the perpetuation of the metabolic effect<sup>[9]</sup>. Although encouraging, *ex vivo* gene transfer and cell injection is closely related to the quality of cell preparation<sup>[10,11]</sup> and has not been documented in CN patients.

Other experimental protocols have been described, such as tin-mesoporphyrin treatment, for which feasibility has been demonstrated in two 17 year old patients<sup>[12]</sup>, or treatment with chimeric oligonucleotides that allowed a significant reduction of serum bilirubin in Gunn rats for up to 11 mo<sup>[13]</sup>.

Since the princeps report by Fox *et al*<sup>[14]</sup>, liver cell therapy (LCT) appeared as a new alternative treatment, which is intermediate between whole organ transplantation and gene therapy. Cells can be infused safely in the diseased liver, and are expected to bring sufficient enzyme activity to restore bilirubin metabolism, setting the patients within safer metabolic limits and improving quality of life. LCT has been shown to be able to restore metabolic function not only in CN patients<sup>[15]</sup>, but also in disorders of ammonium metabolism<sup>[16,17]</sup>, glucose metabolism<sup>[18]</sup>, clotting factor deficiencies<sup>[19]</sup>, and even complex enzyme systems such as Refsum disease<sup>[20]</sup>.

However, the technique remains insufficient; metabolic control is partial and durability of the result is limited to less than one year in most cases. Our aim is to review the current knowledge on the role of LCT to treat CN patients, report two additional patients, and

review animal experiments performed as preclinical studies.

## LCT FOR CN DISEASE TYPE I

### Lessons from the animal model

The Gunn rat model represents the rodent equivalent of CN disease and is characterized by a single mutation in the *ugt1A1* gene. In this model, many experimental protocols using free or encapsulated liver cells have been designed with syngeneic/congenic or allogeneic transplantation procedures<sup>[21-32]</sup>. Table 1 summarizes representative experiments. The best results were obtained when a hepatic injury was caused before LCT to create a niche and a regenerative stimulus for engrafting cells. The explanation for why the injury was beneficial is Gunn rats global liver function is normal, except for bilirubin conjugation, and the lack of host hepatocyte impairment fails to provide to donor cells a proliferative advantage. The repopulation rate necessary to observe a metabolic efficacy ranges from 5% to 10%<sup>[33]</sup>. Significant lowering of serum bilirubin could be observed up to 12 mo while using congenic procedures<sup>[27]</sup>.

### On the clinical side

Reports of human LCT for CN disease have shown encouraging results. The first demonstration of the efficacy of the technique was provided by Fox *et al*<sup>[14]</sup>. In this case, 7.5 × 10<sup>9</sup> viable liver cells were infused in a 10-year-old patient and the effect was a significant decrease of bilirubin levels for up to 11 mo (Table 2). UGT1A1 enzyme activity was detected in the host liver and glucuronoconjugates were found in bile confirming

Table 2 Summary of clinical liver cell transplantation procedures for liver-based inborn errors of metabolism

Indication	<i>n</i>	Patient age	Cell amount (% liver cell mass)	Follow-up	References

				Improvement of psychomotor development and of ammonia levels	17
	1 (ASL)	3.5 yr	$4.7 \times 10^9$ (9%)	Donor hepatocytes detected by FISH at 12 mo and by enzyme activity at 8 mo	

ASL: Arginino-succinate lyase; (F)ISH: (Fluorescent) in situ hybridization; LDL: Low density lipoproteins; ND: Not documented; OTC: Ornithine transcarbamylase; PCR: Polymerase chain reaction; PFIC: Progressive familial intrahepatic cholestasis.

Table 3 Presentation of LCT procedures in two Crigler-Najjar disease type I patients

	Patient 1	Patient 2
Age/Gender	9 yr/Female	1 yr/Female
Infusion procedure	Porth-a-cath in jejunal vein	Broviac in portal vein
Timing of infusions	18 infusions/5 mo	14 infusions/15 d
Donor cells	Fresh and cryopreserved from 3 donors	Fresh and cryopreserved from 1 donor
Cell amount	6.1 billion	2.6 billion
	0.16 billion/kg	0.35 billion/kg
% Liver cell mass	4%	8%
Mean viability	80%	83%

the integration of functional, healthy hepatocytes. Dhawan *et al* reported two additional patients ages 18 mo and 3 years, in which the reduction of serum bilirubin reached up to 50% and 30%, respectively over a follow-up period up of 7 mo (Table 2). Donor hepatocyte engraftment was illustrated by short tandem repeat analysis at 8 mo follow-up. Ambrosino *et al* also described a decrease of bilirubin levels up to 3 mo post-LCT, whereas they did not detect donor cells by using a short tandem repeat assay at 40 d follow-up<sup>[34]</sup>.

We performed LCT in two CN pediatric cases (Table 3, Figure 1). The first patient was a 9 year old girl in whom a port-a-cath was placed in the jejunal

vein. She received 18 cell infusions from three different donors over a period of 5 mo for a total of 4% of her estimated liver cell mass. Mean cell viability was high (80%) and no adverse events were noticed during the procedure. Pre-transplant serum bilirubin values attained  $17.5 \pm 0.49$  mg/dL (mean  $\pm$  SD) and dropped after LCT to the lowest value of 11.4 mg/dL (mean  $\pm$  SD:  $13.6 \pm 0.42$  mg/dL,  $P < 0.001$ ). After a period of 6 mo, bilirubin values increased suddenly without a concomitant event and the patient was scheduled for OLT. For the second patient, the protocol was revised in order to provide a higher amount of cells within a shorter infusion period. She was 1 year old at the time

**Figure 1** Evolution of serum bilirubin before and after LCT in two CN patients performed in our center. **A:** After fluctuating over a period of 5 yr, serum bilirubin of patient 1 decreased significantly to the lesser value of 11.4 mg/dL in 6 mo. Subsequently, increasing values were observed and the patient was listed for OLT. **B:** For patient 2, after cell infusions, the serum bilirubin dramatically decreased to the value of 6 mg/dL in 4 mo. At this time, concomitantly to an EBV infection, higher values were observed and the patient underwent OLT. Arrows indicate the timing of cell infusions. TRP: Transplantation.

of the procedure and received 14 infusions from one single donor over 15 d to reach a total of 8.6% of her estimated liver cell mass. Cells were infused *via* a broviac catheter surgically inserted *via* a colonic vein to the spleno-mesaraic confluent. Cell viability (mean 83%) and clinical tolerance were optimal. With pre-LCT levels of  $17.6 \pm 3.5$  mg/dL (mean  $\pm$  SD), the serum bilirubin dramatically decreased to values of  $13.3 \pm 2.4$  mg/dL (mean  $\pm$  SD) with the lowest value at 6 mg/dL. Skin jaundice reduced rapidly and the daily phototherapy schedule was alleviated from 10 to 8 h without any influence on the bilirubin levels. After 4 mo of progressive decrease of serum bilirubin, the values increased suddenly following an intercurrent Epstein-Barr virus (EBV) infection. The child underwent OLT without complications related to the previous LCT. Both patients received a methylprednisolone bolus and tacrolimus the day before and for 12 d after LCT. Subsequently they were given tacrolimus as long-term monotherapy.

## PERSPECTIVES

At present, LCT remains limited by incomplete and time-limited metabolic control, mainly due to unfavorable immunological cell interactions, impaired donor cell quality and poor repopulation rates. Whereas the immunogenicity of liver cells is quite different compared to whole liver<sup>[35]</sup>, the same immunosuppression protocols are applied for LCT and OLT. Additional fundamental *in vivo* studies are necessary for the development of the optimal immunosuppression protocol. In that way, Wu *et al* recently compared the effects of tacrolimus, rapamycin and mycophenolate mofetil on the engraftment and proliferation of engrafted liver cells in a allogeneic setting<sup>[36]</sup>. They observed a deleterious effect of rapamycin on the proliferation of the transplanted cells. Serrano *et al* reported the lack of toxicity of tacrolimus and methylprednisolone on human hepatocytes *in vitro*<sup>[37]</sup>. Other experimental protocols were designed to reduce the immunological pressure occurring in LCT procedures. For example, Mashalova

*et al* obtained similar engraftment levels with syngeneic or allogeneic hepatocytes after their transduction with adenoviral early region 3 genes, suggesting a protective effect against rejection<sup>[38]</sup>. This was related to the down-expression of Fas receptor at the cell surface leading to inhibition of Fas-mediated apoptosis. Protocols combining LCT with bone marrow transplantation with<sup>[39]</sup> or without<sup>[40]</sup> elimination of natural killer cells are being investigated. Liver cell encapsulation aiming to protect cells from the immune system has demonstrated promising results in Gunn rats<sup>[41-43]</sup>. The technique is reversible and allows delivery of the cells to extrahepatic sites that are easy to access for sampling. However, major remaining hurdles are the creation of an adequate 'intracapsular' microenvironment allowing long-term cell functionality and the restriction of this technique to an enzyme-delivery role. Host immunity can be modulated by co-transplantation of immunomodulatory cells, as developed by Le Blanc *et al*, using mesenchymal stem cells to control graft *versus* host disease in the bone marrow transplant setting<sup>[44,45]</sup>. These cells and others, as non-parenchymal cells<sup>[46]</sup> or liver-derived mesenchymal lineages<sup>[47,48]</sup>, could provide permissive factors or a microenvironment allowing more favorable immunological cell interactions, although this has not been tested so far in LCT protocols. Study of inner mechanisms of cell rejection may also lead to improved clinical efficiency of LCT. For example, it has been shown recently that human hepatocytes exert a procoagulant activity depending on tissue factor expression<sup>[49]</sup>, as previously demonstrated with pancreatic islet cells<sup>[50,51]</sup>. In this work, St  phenne *et al* demonstrated the improvement of the procoagulant activity by incubating the cells with N-acetylcysteine, making this drug valuable for additional *in vivo* studies.

Enhancement of liver cell engraftment capacity is another challenge. Engraftment depends on liver cell quality and host liver environment. While LCT is highly dependent on banking of cryopreserved cells, this procedure has been demonstrated to deteriorate cell quality. Indeed, although cryopreserved/thawed hepatocytes have been shown to possess *in vivo* clonal

replicative potential identical to freshly isolated cells<sup>[52]</sup>, their *in vivo* potential seems to be restricted in time<sup>[53-55]</sup> and their *in vitro* functionality remains lower than that of freshly isolated hepatocytes<sup>[56]</sup>. Furthermore, we recently demonstrated that, with the current protocols, cryopreservation/thawing of hepatocytes induces cell alteration and especially mitochondrial defects (complex 1 impairment)<sup>[57]</sup>. Intracellular ice formation remains the major factor affecting the quality of cells. Protection delivered by non-permeating cryoprotectants must be further analyzed in terms of cell death and mitochondrial functions. New perspectives, such as vitrification, to avoid the crystalline state, coupled or not with encapsulation, must be validated in the future while considering the problem of hepatocyte de-differentiation at long term that could occur in this type of configuration.

Actions on the liver microenvironment have been evaluated in a recent report using monocrotaline, which is an alkaloid showing toxicity against liver endothelial and Kupffer cells<sup>[58]</sup>. Authors reported an enhanced liver cell engraftment in a syngeneic background mainly related to endothelial cell damage. Comparable studies were performed on dipeptidyl peptidase IV<sup>-/-</sup>F344 rats using doxorubicin, irinotecan, or vincristine<sup>[59]</sup>. In this study, Kim *et al* showed improved cell engraftment after doxorubicin treatment attributed to endothelial cell disruption. While interesting, these approaches will not be applicable in a clinical setting. Physical alteration of the liver architecture was studied by Dagher *et al* on nonhuman primates using partial portal vein ligation or embolization in an autologous LCT procedure<sup>[60]</sup>. The authors reported hepatic regeneration rates up to 10% obtained at short term (15 d) after embolization of the portal vein. Others have successfully used chemicals as vascular endothelial growth factor delivered *in situ*<sup>[61]</sup> or by peripheral route<sup>[62]</sup> to promote cell engraftment.

As stem cells were recently described to have a hepatocyte differentiation potential<sup>[63,64]</sup>, these are currently considered with growing interest for liver cell therapy. The most potent candidates are mesenchymal stem cells isolated from various tissues, with predilection for bone marrow<sup>[65]</sup> and umbilical cord<sup>[66]</sup>. Liver progenitor cells<sup>[67]</sup> or mesenchymal-like cells<sup>[47,48]</sup> also deserve detailed attention. However, stem cells only display partial hepatocyte-like functionality<sup>[64,68]</sup> and further advance is necessary to consider such cell types for therapy.

## CONCLUSION

While LCT seems currently efficient and safe to improve the quality of life of CN diseased patients for a medium period of time, the technique still requires development to be considered for longer term or curative purposes. Advances must be focused on the quality of cell preparations together with the management of immunological barriers hampering reliable cell engraftment. Furthermore, other research areas, such as gene or stem cell therapy, are currently encountering

exciting expansion, and combined therapeutic approaches would be justified in the near future.

## Abstract

Trichinosis is among the most common food-borne parasitic zoonoses in Thailand and many outbreaks are reported each year. This paper investigates the distribution of the disease in regions of north, north-east, central and south Thailand. Between the earliest recorded outbreak of trichinosis in Mae Hong Son Province in 1962 and 2006, there have been 135 outbreaks involving 7340 patients and 97 deaths in Thailand. The highest number of cases, 557, was recorded in 1983. Most infected patients were in the 35-44 year age group, and the disease occurred more frequently in men than women during 1962-2003, with no significant sex difference during 2004-2006. Outbreaks were most common in the northern areas, especially in rural areas where raw and under-cooked pork and/or wild animals are eaten. Human infections occur annually in northern Thailand during communal feasts celebrating the Thai New Year. Trichinosis causes have been reported every year, supporting the need for planning education programs.

## INTRODUCTION

Trichinosis is a parasitic disease of mammals caused by the nematode parasite *Trichinella spp.* It is an important zoonotic infection caused by humans eating raw or inadequately cooked meat of infected animals. Infection is most common in omnivores (horses, humans, pigs and rats) and carnivores (cats, dogs, and seals), and pigs and rodents play an important role in the epidemiology of the disease. The main source of infection in Thailand has been pigs, but wild boar, jackal and black bear have also been identified as sources of trichinosis<sup>[1]</sup>. Unlike other parasitic infections, trichinosis has been a major public health problem in Asia, including Korea and Thailand<sup>[2-4]</sup>.

Since 1962, more than 7300 infections and 97 deaths have occurred in Thailand in 135 outbreaks (morbidity rate 0.04 per 100 000 people); however, this figure may underestimate the actual number of cases<sup>[4]</sup>. Until recently, *T. spiralis*, *T. pseudospiralis* and *T. papuae* were the only human-infecting species in Thailand. *T. spiralis* was the causative agent of most early outbreaks of trichinosis<sup>[5]</sup>. More recently, *T. pseudospiralis* and *T. papuae* infections in some areas of Thailand have been reported<sup>[6,7]</sup>. The first outbreak of trichinosis in Thailand in 1962 involved 56 patients and resulted in 11 deaths in the Mae Sariang District, Mae Hong Son Province<sup>[5]</sup>. The highest annual number of hospital recorded trichinosis cases recorded in Thailand was 557 in 1983. Historically, most infections result from consumption of raw pork in the form of “lahb” and “nahm,” favorite dishes of north, Thailand<sup>[8]</sup>. The incidence of *T. spiralis* larvae in dog meat in the areas favoring dog meat consumption is a major public health problem in the future, the popular food of people in the northeast area. Srikitjakarn *et al* reported *T. spiralis* was found in 1.67% of 421 samples of dog meat in Tarae District, Sakonnakon Province<sup>[9]</sup>. Raw dog meat was a source of infection in Kaeng Khlo District, Chaiyaphum Province in December 1984<sup>[10]</sup>.

From the past to present, trichinosis is still reported every year in Thailand; therefore, this article reviews the literature on the distribution, prevalence and cause of trichinosis in Thailand, including the annual epidemiological surveillance, a report by the Bureau of Epidemiology, Department of Disease Control, Ministry of Public Health, Thailand, 1971-2006. Morbidity is described by year, month of the year, age group, region and province.

## REPORT CASES OF TRICHINOSIS PER 100 000 PER CAPITA BY YEAR, THAILAND

The first outbreak of trichinosis in Thailand, in 1962, involved 56 patients resulting in 11 deaths<sup>[5]</sup>. In an April 1973 outbreak, 31 persons were involved, ranging from 9 to 72 years, and one adult female died<sup>[8]</sup>. In 1980, trichinosis was reported, the infection being caused by the consumption of wild squirrel<sup>[11]</sup>. An epidemic of trichinosis involving 177 patients and 13 deaths occurred in 1981<sup>[12]</sup>. The highest annual number of hospital recorded trichinosis cases was 557 in 1983<sup>[13]</sup>. This figure is considered an underestimation of the actual number of cases involved in the outbreaks. Khambooruang reported 118 discrete outbreaks of the disease involving 5400 patients and 95 deaths<sup>[14]</sup>. In 8 cases of childhood trichinosis reported<sup>[15]</sup>. An outbreak of trichinosis affecting 59 individuals resulting in one death occurred in during 1994-1995. This was the first report of an epidemic of human infection caused by *T. pseudospiralis*<sup>[6]</sup>. Takahashi *et al* (2000) reported 120 outbreaks from 1962 to 2000 involving nearly 6700 patients and 97 deaths<sup>[16]</sup>. Chotmongkol *et al* presented the progressive generalized muscle hypertrophy weakness for 3 mo with the 49-year-old man who infected with *T. spiralis*<sup>[17]</sup>. More than 7300 infections with 97 deaths occurred in about 130 outbreaks, since 1962<sup>[18]</sup>. Recently, *T. papuae* was identified as the etiological agent of trichinosis involving 19 people after eating raw wild pig<sup>[13]</sup>. More than 5 outbreaks were reported by the Bureau of Epidemiology, Department of Disease Control, Ministry of Public Health, Thailand. Reported morbidity rate of trichinosis cases increased from 0.04 in 1997 to 0.57 in 1998. In 1999 and 2000, the number of reported morbidity rate decreased to 0.03 and 0.21 respectively. No cases were recorded in 2001, but then 0.46, 0.20 and 0.34 occurred in 2002, 2003 and 2004, respectively. In 2005 and 2006, 0.12 and 0.03 of morbidity rates were reported by the Bureau of Epidemiology, Department of Disease Control, Ministry of Public Health (Figure 1A). Morbidity rate of trichinosis cases during 1997, 1998, 1999, 2000, 2001, 2002, 2003, 2004, 2005 and 2006 were 61, 351, 16, 128, 0, 289, 126, 154, 73 and 19, respectively. More than 135 outbreaks have been reported totaling 7340 patients and 97 deaths. Most of cases were classified by occupation and place of treatment were agriculture and community hospital<sup>[18]</sup>.

## REPORT CASES OF TRICHINOSIS BY MONTH, THAILAND

The distribution of trichinosis was reported by month

www.wjgnet.com

from 1962 and 2006, more frequently during October to January. Cases were reported most frequently in months during communal feasts celebrating the Thai New Year, though few of them have been documented. During 2002 to 2006, the number of reported trichinosis cases differed from previously recorded reports. In 2002, the highest of number of trichinosis cases was reported in January. The number of cases was decreased in 2003 overall, and February had the highest of reported trichinosis cases. In 2004, May and June were the months with the highest trichinosis cases, and in 2005, October was the highest trichinosis report month. The most recent data from 2006 shows that June is the month with the highest number of trichinosis cases (Figure 1B)<sup>[18]</sup>.

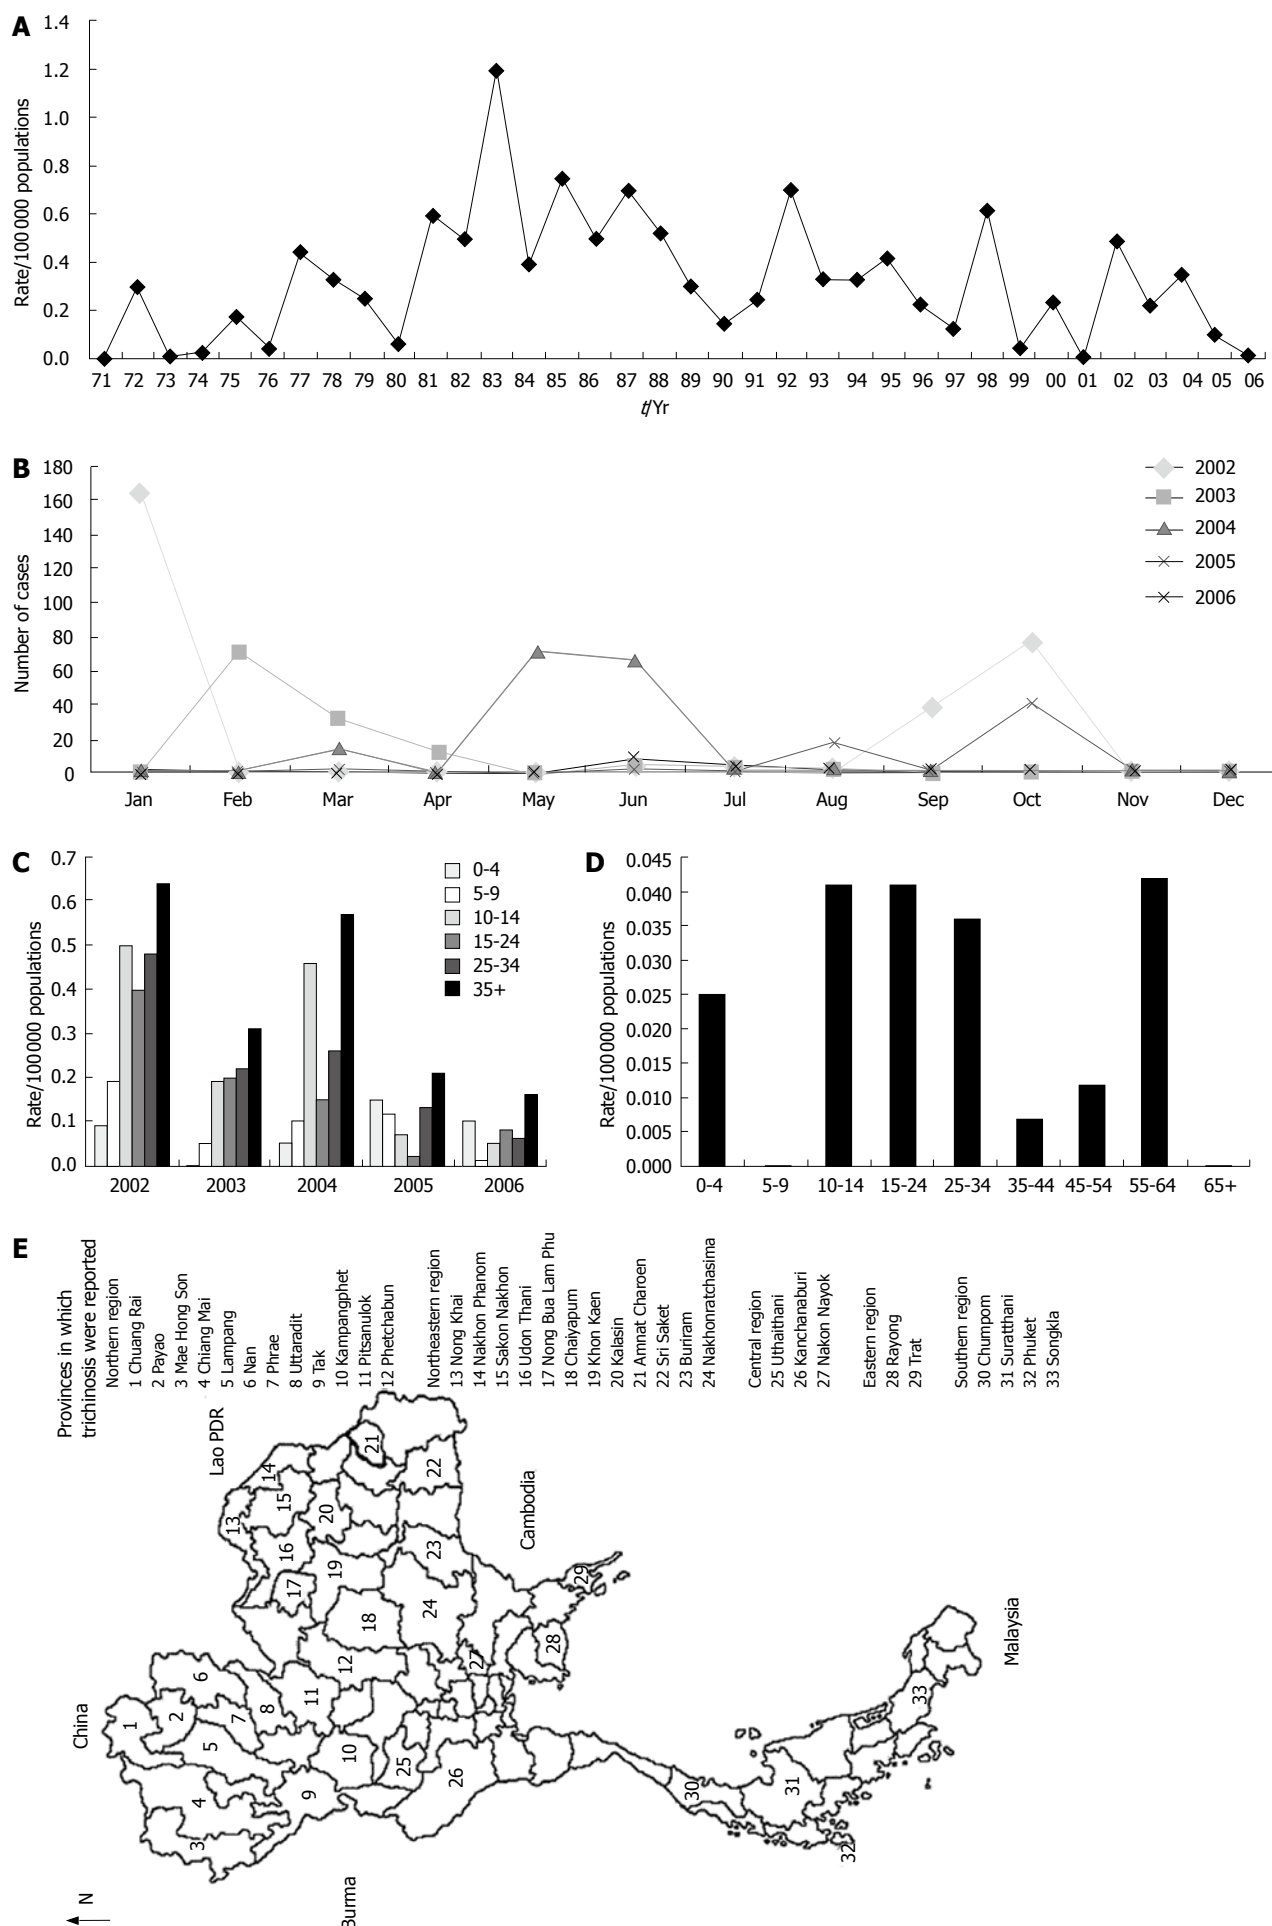

## REPORT CASES OF TRICHINOSIS PER 100 000 PER CAPITA BY AGE GROUP

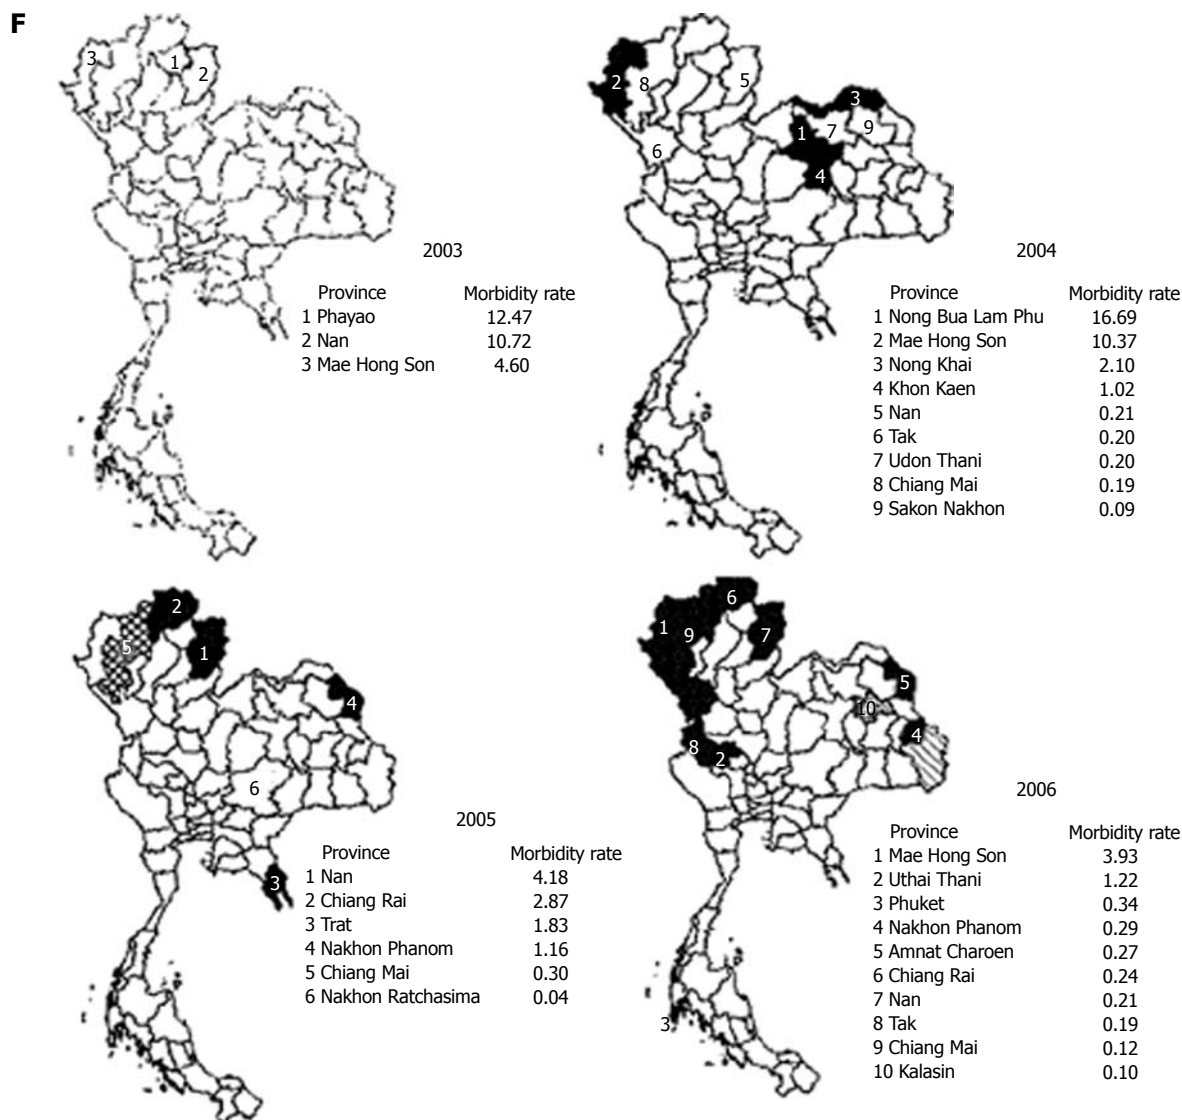

Previous research demonstrates variability in reports of trichinosis by age-group. Of 31 persons in an outbreak of trichinosis occurred in Chiang Rai Province, ranging from 9 to 72 years, one adult female died<sup>[8]</sup>. In Thailand, 8 cases of childhood trichinosis were reported in several studies<sup>[15]</sup>. Charkrit reported the youngest patient was about 1 year old<sup>[19]</sup>. Chotmongkol *et al* presented the progressive generalized muscle hypertrophy and weakness over a three-month period in a 49-year-old man infected with *T. spiralis*<sup>[17]</sup>. Kaewpitoon *et al* have reported that trichinosis cases are common in the 35-44 groups<sup>[4]</sup>. Since 2002, the distribution of human trichinosis cases by age groups has been collected by the annual epidemiological surveillance reports. Most patients are in the 35-44 groups, and many are over the age of 65. In 2002 and 2005, trichinosis cases were most frequently reported in the 35-44 groups, and this figure is very similar to previously reported research<sup>[4,17]</sup>. In 2006, the cases reported by the annual epidemiological surveillance varied considerably from reports of the past. Most, 66.67% patients were 15 to 44 years old. The youngest and oldest patients were 4 and 62 years old (Figure 1C). Reported cases of trichinosis per 100 000 people by age group in 2006, were similarly (0.036-0.042) across five age-groups as, that is, 10-14, 15-24, 25-34, 35-44 and 55-64 years old (Figure 1D). Infection occurs in men and women at the ratio of 1.7:1, 1:1.03, 1:1 and 1:1 in 2003, 2004, 2005 and 2006, respectively<sup>[18]</sup>.

## REPORT CASES OF TRICHINOSIS BY REGION, THAILAND

Trichinosis is more common in temperate than in tropical regions. The epidemiological surveillance reports of trichinosis have been conducted almost every year and data investigations reveal that outbreaks have occurred predominantly in rural areas. The annual epidemiological surveillance reports from 1962 to 2006 found consistently high numbers of cases in the north region. The north part of Thailand is responsible for 77.94% of all cases reported from 2002 to 2006. The northeast region was responsible for 21.61% of cases

**Figure 1** Reported cases of trichinosis in Thailand. **A:** Morbidity rate (per 100 000 populations) of trichinosis cases was reported by the Bureau of Epidemiology, Department of Disease Control, Ministry of Public Health, 1971-2006; **B:** Reported by month, 2002-2006; **C:** Reported per 100 000 populations by age-group, 2000-2006; **D:** Reported per 100 000 populations by age-group, 2006; **E:** Distribution by region during 1962-2006; **F:** Reported per 100 000 populations by Province, 2004-2006.

in 2004. In 2004, there were 124 reported cases in the northeast, representing the first time that a region other than the north had the highest number of cases. These results showed that trichinosis is a serious problem, particularly in the north and northeast regions of Thailand. Only small numbers of trichinosis cases were recorded in the central and south regions in 2005. The numbers of cases in other parts of Thailand were very few. In the central region, the infection rate was 0.3% of the total number of cases; the south region accounted for only 0.15% of cases. In 2006, most reported cases occurred in the north region (Figure 1E)<sup>[18]</sup>.

## REPORT CASES OF TRICHINOSIS PER 100 000 PEOPLE, BY PROVINCE

Most outbreaks that occurred during 1962 to 2006 were located in the north region. The most severely affected

areas in the north region were the highland provinces of Chiang Rai, Nan, Chiang Mai, Mae Hong, Son Payao, Lampang, Phrae, Uttaradit, Pitsanuloke, Phetchabun, Tak and Kamphangphet<sup>[8,12,19-21]</sup>. The first outbreak of trichinosis occurred in the Mae Sariang District, Mae Hong Son Province<sup>[5]</sup>. The second outbreak was in 1963 at Prao District, Chiang Mai Province. In April 1973, an outbreak of trichinosis occurred in Mae Sruay District, Chiang Rai Province. 31 persons were involved, and 1 adult female died. All trichinosis cases included a history of having consumed raw pork in the form of “lahb” and “nahm,” favorite dishes of north Thailand<sup>[8]</sup>. An epidemic of trichinosis involving 177 patients resulted in 13 deaths in Kok-Ta-Back Village, Nong-Pai District, Petchabun Province<sup>[12]</sup>. Takahashi *et al* (2000) reported 120 outbreaks from 1962 to 2000 involving nearly 6700 patients and 97 deaths. The highest numbers of cases were in Chiang Mai, Chiang Rai and Nan provinces, 1776, 1739 and 894 respectively. The numbers of cases

in other parts of Thailand were very few. The northeast region was responsible for the highest number of cases in some years mainly in 2004. Provinces involved were Non Bua Lam Phu, Nong Khai, Udon Thani, Sakon Nakhon, Nakhon Phanom, Amnat Charoen, Kalasin, Khon kaen, Chaiyapum, Nakhonratchasima, Buriram and Sri Saket. In the central region, Uthaithani, Kanchanaburi, Nakhon Nayok, Rayong and Trat provinces have been reported the number of trichinosis cases. In 1994, in the south of Thailand, an outbreak of trichinosis affecting 59 individuals resulted in 1 death in Chumphon Province. This was the first report of an epidemic of human infection caused by *T. pseudospiralis*<sup>[6]</sup>. At this time, Chumphon, Suratthani, Songkla and Phuket were the only provinces of the south region in which cases of trichinosis were observed. This is interesting because Phuket province is a popular destination for Thai and foreigner travelers.

The reported cases of trichinosis per 100 000 populations by province during 2003 to 2006 were classified by the bureau of the Epidemiology, Department of Disease Control, Ministry of Public Health, Thailand. In 2003, most trichinosis cases were reported from Payao, Nan and Mae Hong Son province, morbidity rate were 12.47, 10.72 and 4.60, respectively. The provinces with the highest rates of trichinosis cases in 2004 were Nong Bua Lam Phu, Mae Hong Son, Nong Khai, Khon Kaen, Nan, Tak, Udon Thani, Chiang Mai and Sakon Nakhon, 16.69, 10.37, 2.10, 1.02, 0.21, 0.20, 0.20, 0.19 and 0.09, respectively. Meanwhile, 2005 was comprised 6 provinces have been shown that the highest morbidity rate were Nan, Chiang Rai, Trat, Nakhon Phanom, Chiang Mai and Nakhon Ratchasima as 4.18 2.87 1.83 1.16 0.30 and 0.04, respectively. Recent, Mae Hong Son, Uthai Thani, Phuket, Nakhon Phanom, Amnat Charoen, Chiang Rai, Nan, Tak, Chiang Mai and Kalasin as 3.93, 1.22, 0.34, 0.29, 0.27, 0.24, 0.21, 0.19, 0.12 and 0.10, were the top ten leading rate of trichinosis cases in 2006 (Figure 1F)<sup>[18]</sup>.

## CONCLUSION

Studies of trichinosis in Thailand, since the first recorded outbreak in 1962 until 2006, show that most outbreaks occurred in the north of the country, an area in which popular, traditional dishes involve meat from pigs and wild boars, often eaten raw or under-cooked. Overall, more than 135 outbreaks have been reported during 1962-2006 involving 7340 patients and 97 deaths. Trichinosis is still a serious problem food-borne parasitic zoonoses in Thailand. No vaccines have been developed. Treatment exists for Trichinosis in humans if diagnosed promptly. Better prevention and control of trichinosis requires health education programs to improve the knowledge, attitude and behavior of people in the high-risk areas.

## Abstract

Hepatic steatosis affects 20% to 30% of the general adult population in the western world. Currently, the technique of choice for determining hepatic fat deposition and the stage of fibrosis is liver biopsy. However, it is an invasive procedure and its use is limited, particularly in children. It may also be subject to sampling error. Non-invasive techniques such as ultrasound, Computerized tomography (CT), magnetic resonance imaging (MRI) and proton magnetic resonance spectroscopy ( $^1\text{H}$  MRS) can detect hepatic steatosis, but currently cannot distinguish between simple steatosis and steatohepatitis, or stage the degree of fibrosis accurately. Ultrasound is widely used to detect hepatic steatosis, but its sensitivity is reduced in the morbidly obese and also in those with small amounts of fatty infiltration. It has been used to grade hepatic fat content, but this is subjective. CT can detect hepatic steatosis, but exposes subjects to ionizing radiation, thus limiting its use in longitudinal studies and in children. Recently, magnetic resonance (MR) techniques using chemical shift imaging have provided a quantitative assessment of the degree of hepatic fatty infiltration, which correlates well with liver biopsy results in the same patients. Similarly, *in vivo*  $^1\text{H}$  MRS is a fast, safe, non-invasive method for

## INTRODUCTION

In humans, adipose tissue is an important “energy bank” in which excess energy is stored and then released to meet the energy needs of the body. In the fed state and during periods of excess calorie intake, the excess energy is stored within adipose tissue as triglycerides. In the fasting state and during starvation, triglycerides within adipose tissue can be rapidly broken down by hormone-sensitive lipase to generate fatty acids. Oxidation of fatty acids releases more energy than that of carbohydrate, protein or triglycerides. Fatty acids are thus the most efficient “fuel” to meet the body's energy needs<sup>[1]</sup>.

In addition to playing an important role in energy homeostasis, adipose tissue is now well recognised as an endocrine organ<sup>[2,3]</sup>. It is known to produce and secrete a wide variety of bioactive peptides, known as adipokines. These include proteins, such as leptin, adiponectin, resistin, as well as the recently described visfatin and retinol binding protein 4<sup>[4-8]</sup>. In addition, proinflammatory cytokines, such as tumour necrosis factor alpha and interleukin-6, and acute phase reactants,

such as C-reactive protein are also secreted by the adipocyte. All of these adipokines may act at both a local (paracrine) and systemic (endocrine) level and contribute to the development of obesity-related disorders, such as insulin resistance, Type 2 diabetes and cardiovascular disease<sup>[2,3]</sup>.

Adipose tissue stores may become saturated, either due to failure to develop adequate adipose tissue mass (lipodystrophy), or to expand these stores sufficiently to accommodate increased energy intake. When this occurs, lipid starts to accumulate in non-adipose cells. Ectopic storage of lipids in organs, such as the liver, skeletal muscle and pancreas (the “lean body mass”) is thought to play a critical role in the development of insulin resistance and Type 2 diabetes<sup>[9]</sup>. The accumulation of ectopic fat has been shown to affect both renal and cardiovascular function and may contribute to the development of cardiovascular disease<sup>[10]</sup>.

Evidence to support the hypothesis that ectopic fat accumulation plays a crucial role in insulin resistance comes from the study of subjects with lipodystrophies. These subjects have insufficient adipose tissue mass and hence store excess energy as triglycerides within organs, such as liver and skeletal muscle. As a result, individuals may develop insulin resistance and are at increased risk of developing Type 2 diabetes<sup>[11-14]</sup>.

## RELEVANCE OF HEPATIC FAT ACCUMULATION

Fatty infiltration of the liver is not a new phenomenon. However, until the last few decades, fatty liver, particularly that associated with insulin resistance rather than alcohol excess—“non-alcoholic fatty liver disease”, was considered to be a relatively benign condition. This notion was challenged when several reports documented the development of liver failure in some patients following jejunal bypass operations for morbid obesity<sup>[15-17]</sup>. The liver histology in such patients was indistinguishable from that seen in alcoholic steatohepatitis<sup>[18]</sup>. Similar hepatic lesions were subsequently described in obese patients who had neither abused alcohol nor undergone bariatric surgery<sup>[19-21]</sup> and in patients with diabetes mellitus<sup>[22-24]</sup>. In 1980, Ludwig and colleagues introduced the term “non-alcoholic steatohepatitis” (NASH) to describe these histological findings in patients who did not consume alcohol<sup>[25]</sup>. A variety of other terms have been used to describe this entity with non-alcoholic fatty liver disease now being the preferred term.

Accumulation of fat within the liver is of particular importance in that, over time, it may lead to the development of steatohepatitis and ultimately cirrhosis, end-stage liver failure and hepatocellular carcinoma<sup>[26-29]</sup>.

## MECHANISMS OF HEPATIC FAT ACCUMULATION

The mechanisms leading to hepatic fat accumulation

remain poorly understood. The liver synthesizes triglycerides from free fatty acids. Free fatty acids are derived from lipolysis of triglycerides within adipose tissue, diet or *de novo* lipogenesis<sup>[1]</sup>. Once taken up by the liver, free fatty acids can either be oxidised in the mitochondria to form adenosine triphosphate (ATP), or esterified to produce triglycerides for storage, or incorporated into very low density lipoprotein (VLDL) particles. Triglycerides accumulate in the liver when their synthesis exceeds their export *via* VLDL<sup>[1,30,31]</sup>.

The development of non-invasive techniques for assessing hepatic fat content *in vivo* in humans has renewed interest in studying the mechanisms leading to hepatic fat accumulation. Ultrasound, computerized tomography (CT), magnetic resonance imaging (MRI) and proton magnetic resonance spectroscopy (<sup>1</sup>H MRS) have all played a prominent role in this.

## METHODS TO STUDY HEPATIC FAT

Currently, the gold standard for determining hepatic fat severity and morphology is a liver biopsy<sup>[31,32]</sup>. However, this procedure has several drawbacks, including discomfort, owing to its invasive nature, risk of infection, haematoma formation, or more significant internal bleeding, and biliary leakage. Furthermore, biopsies are subject to sampling error, because less than 1/50000th of the liver is available for histological analysis.

Non-invasive imaging techniques, such as ultrasound, Computerized tomography (CT), magnetic resonance imaging (MRI) and proton magnetic resonance spectroscopy can detect fatty infiltration of the liver, but unlike liver biopsy, they are limited in their ability to detect coexisting inflammation or fibrosis.

## NON-INVASIVE TECHNIQUES FOR ASSESSING HEPATIC FAT CONTENT

### Ultrasound

Hepatic ultrasound is a simple, non-invasive technique, which is widely used in clinical practice to detect fatty infiltration of the liver. As shown in Figure 1, hepatic steatosis causes increased echogenicity on ultrasound, so that liver appears brighter than the cortex of the ipsilateral kidney<sup>[33,34]</sup>.

Diffuse hepatic steatosis and diffuse fibrosis can have similar sonographic appearances and therefore it can sometimes be difficult to distinguish between them. Some groups have used the term “fatty fibrotic pattern” to describe this pattern of increased echogenicity, although the echo shadows tend to be coarser in the presence of pure fibrosis<sup>[35,36]</sup>.

In some cases, fatty infiltration of the liver may be patchy, rather than diffuse, in distribution. The non-uniformity may be so marked that the fat is deposited in one well-circumscribed region (focal fatty infiltration) or, alternatively, discrete areas of liver parenchyma remain uninvolved when the remainder of the liver is diffusely infiltrated with fat (focal fatty sparing). Both

**Figure 1** Ultrasound findings in hepatic steatosis. The steatotic liver is hyper-echoic, compared to the cortex of the right kidney. In addition, there is posterior attenuation of the ultrasound beam and reduced definition of the portal vein walls.

**Figure 2** CT findings in hepatic steatosis. In this contrast unenhanced scan, the liver appears darker than the spleen and the hepatic vessels appear bright. The increased brightness of the vessels relative to the liver parenchyma may erroneously suggest the use of contrast.

conditions may create diagnostic problems for the radiologist. For example, with focal fatty sparing, if the increased echogenicity of the majority of the liver is not appreciated, then the area of normal hepatic parenchyma may be misinterpreted as a pathological hypoechoic lesion<sup>[37]</sup>. If, however, the increased echogenicity of the remainder of the liver is appreciated, then the area of normal hepatic parenchyma may be helpful in making the diagnosis of fatty change<sup>[38]</sup>.

Several studies have assessed the sensitivity and specificity of ultrasound for detecting hepatic steatosis. In these, the sensitivity ranged from 60% to 94% and the specificity from 84% to 95%, respectively<sup>[35,39-41]</sup>. Another study combined fatty change with fibrosis and obtained a sensitivity of 98.7% and specificity of 94% for the “fatty fibrotic pattern”<sup>[42]</sup>. The sensitivity of ultrasound increases with increasing degrees of fatty infiltration. For example, in the presence of hepatic fat content of 10% to 19%, it has a sensitivity of 55%, which rises to 80% in the presence of > 30% fatty infiltration<sup>[43]</sup>. However, in the presence of morbid obesity (defined by a body mass index > 40 kg/m<sup>2</sup>), the sensitivity and specificity of ultrasound fall to 49% and 75%, respectively, possibly due to technical problems in performing ultrasound in such patients<sup>[44]</sup>.

Whereas ultrasound is a useful technique for detecting hepatic steatosis, particularly in severe cases, it is unable to provide a precise determination of hepatic fat content. Grading of hepatic fat content into broad categories (mild, moderate and severe steatosis) has been reported, using diagnostic criteria, based upon the visual assessment of hepatic echogenicity<sup>[35,41,42,45,46]</sup>. However, all of the above studies found the grading of hepatic fat content using ultrasound to be somewhat subjective. In addition, the most recent ones showed that ultrasound is very poor at discriminating small changes in hepatic fat content. For example, Fishbein and colleagues suggested from their study that an individual with hepatic steatosis undergoing a reduction of MRI hepatic fat fraction from 40% to 20% through successful intervention, would be unlikely to have a corresponding alteration in ultrasound appearance<sup>[45]</sup>.

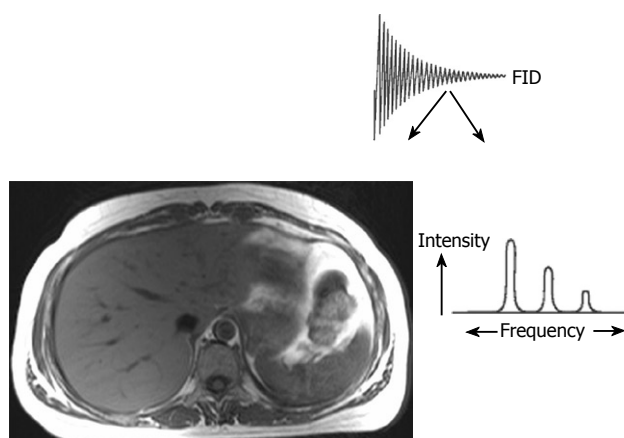

The operator dependency of ultrasound, its inability to precisely quantify hepatic fat content, and its inability to detect small changes in liver fat with time, all potentially limit its use in longitudinal clinical studies.

### Computerized tomography

Contrast-unenhanced Computerized tomography (CT) is the most accurate CT technique used to detect and characterise hepatic steatosis<sup>[47]</sup>. The CT diagnosis of hepatic steatosis is made by measuring the difference in liver and spleen attenuation values in Hounsfield units<sup>[48]</sup>. In individuals without hepatic steatosis, the mean attenuation value for the liver is at least 4 Hounsfield units greater than for the spleen<sup>[48]</sup>. However, in subjects with hepatic steatosis, the mean attenuation value for the liver is lower than that for the spleen, so the liver appears darker than the spleen, rather than brighter. This lower attenuation of the liver in hepatic steatosis is thought to be secondary to the accumulation of lipids (triglycerides and cholesterol) within the hepatocytes<sup>[49]</sup>. With severe hepatic steatosis, there is more marked contrast between the liver and intrahepatic vessels. The increased brightness of the vessels relative to the liver parenchyma may erroneously suggest the use of contrast (Figure 2)<sup>[36]</sup>.

Great care should be taken in diagnosing fatty infiltration of the liver on contrast-enhanced CT scans because contrast injection rate and timing of measurements can significantly influence the optimal liver-minus-spleen attenuation difference for diagnosing fatty liver<sup>[50,51]</sup>. It has been suggested that muscle, rather than spleen, may be a better qualitative standard of reference for diagnosing fatty liver on contrast-enhanced CT, and that fatty liver can be diagnosed if the liver has a lower attenuation value than muscle<sup>[52]</sup>. However, such a comparison works only if the degree of fatty infiltration is severe.

Although non-contrast-enhanced CT is very good for the qualitative diagnosis of macrovesicular steatosis of 30% or greater, there is conflicting evidence as to whether or not it can accurately quantify hepatic fat content. Some studies have demonstrated that

**Figure 3** Principles of magnetic resonance. The magnetic resonance (MR) signal or free induction decay (FID) may be converted by the mathematical process of Fourier transformation to form anatomical information (MR imaging) or localised biochemical information (MR spectroscopy). Modified from Taylor-Robinson SD Applications of magnetic resonance spectroscopy to chronic liver disease. *Clin Med* 2001; 1: 54-60 Copyright © 2001 Royal College of Physicians. Adapted by permission.

both the CT numbers for the liver and the ratio of CT numbers for the liver and the spleen show a good inverse correlation with the degree of steatosis seen on liver biopsy<sup>[47,53,54]</sup>. Nevertheless, it should be noted that a more recent study by Park and colleagues concluded that the diagnostic performance of unenhanced CT for quantitative assessment of macrovesicular steatosis is not clinically acceptable<sup>[55]</sup>. In addition, CT scanning has the drawback of exposing subjects to ionizing radiation. The above two factors limit its potential use in longitudinal studies and in children.

### **Magnetic resonance imaging and proton magnetic resonance spectroscopy**

**Principles of magnetic resonance imaging and spectroscopy:** The nuclear magnetic resonance (NMR) phenomenon was first reported by Bloch *et al* in 1946<sup>[56]</sup>. NMR techniques exploit the behaviour of certain atomic nuclei in an externally applied magnetic field. Magnetic resonance sensitive nuclei, such as hydrogen-1 ( $^1\text{H}$ ), carbon-13 ( $^{13}\text{C}$ ), nitrogen-15 ( $^{15}\text{N}$ ) and phosphorous-31 ( $^{31}\text{P}$ ) possess the quantum mechanical property of “spin”, a source of angular momentum intrinsic to nuclei with an odd mass number. When placed in a magnetic field they behave like magnetic dipoles, aligning parallel to or against the axis of the applied static magnetic field. When excited by irradiation with non-ionizing radiofrequency (rf) energy, this alignment of the nuclei is disturbed. During relaxation following excitation, the nuclei return to their original orientation, giving off a radiofrequency signal, which may then be detected by a receiver coil. This signal, known as the free induction decay (FID), can be resolved by a computer-based mathematical process known as Fourier transformation into either an image, providing anatomical information (MRI) or a frequency spectrum, providing biochemical information (MRS)<sup>[57,58]</sup>, as shown in Figure 3.

**Figure 4** In and opposed phase MR images of a liver illustrating the signal drop-off from an in-phase (A) to an opposed-phase image (B) in a patient with marked steatosis. ## **MAGNETIC RESONANCE IMAGING**

Nuclei from individual metabolites resonate at a given, but unique frequency, depending on the molecular structure of each compound. This is known as chemical shift and occurs because nuclei in different chemical environments experience slightly different magnetic field strengths. This variation in magnetic field strength results from the intrinsic “shielding” offered by the nearby electrons, which partially counteract the force of the main magnetic field. For example, the hydrogen nuclei in water (O-H bond) have less surrounding electrons than the hydrogen nuclei in lipid (C-H bond), so experience a slightly stronger magnetic field and, as a result, rotate at a slightly higher resonance frequency. The differences are extremely small and are typically measured using the dimensionless unit, parts per million (ppm)<sup>[59]</sup>.

Chemical shift MR imaging utilises this difference in resonance frequency of water and lipid to differentiate tissues containing only water from those containing both water and lipid<sup>[60]</sup>, as illustrated in Figure 4.

Applying this principle, Dixon developed a modified spin echo technique, now widely known as the Dixon method<sup>[61]</sup>. Using this technique, Lee and co-workers scanned the livers of five humans, two healthy volunteers with no evidence of liver disease and three patients with CT evidence of fatty infiltration of the liver<sup>[62]</sup>. In the subjects with CT evidence of hepatic fatty infiltration, there was a notable loss of signal

**Figure 5** Proton magnetic resonance spectra from three volunteers showing progressive degrees of hepatic fatty infiltration. Resonances from water and lipid (IHCL CH<sub>2</sub>) can be clearly seen. For each individual hepatic fatty infiltration was quantified using the equation: -Percentage fat = IHCL CH<sub>2</sub> peak area/Water peak area × 100. Shown are spectra from a liver with very mild fatty infiltration (1.0%), a liver with moderate fatty infiltration (10.2%), and a liver with severe fatty infiltration (74.9%). Adapted from Thomas *et al.* *Gut* 2005; 54: 122-127, with permission from the BMJ Publishing Group.

intensity on the out-of-phase images (because opposing signals from water and lipid tended to cancel each other out), and a less appreciable increase in signal intensity on the in-phase images. In contrast, in the healthy volunteers without hepatic steatosis, the signal intensity of the liver parenchyma was not altered between in-phase and out-of-phase images. They concluded that the Dixon method was capable of distinguishing fatty liver from normal liver, and that it might also be useful for the quantification of liver fat. Using the same technique, Heiken and colleagues scanned the livers of 35 subjects (12 healthy volunteers and 23 patients with CT evidence of fatty infiltration of the liver)<sup>[63]</sup>. They demonstrated the Dixon method to be a clinically useful technique for detecting and quantifying fatty infiltration of the liver and for differentiating non-uniform fatty infiltration from liver metastases<sup>[63]</sup>. However, this methodology has its limitations. It was time-consuming, and the quality of the images obtained was affected by respiratory and other motion artefacts, as well as by magnetic field inhomogeneities<sup>[61,64]</sup>.

Since these early studies, many researchers have developed modifications of the Dixon method with the aim to reduce these limitations. Levenson and colleagues used the technique to quantify hepatic fat in 16 subjects with a variety of liver abnormalities, and compared the imaging results with those from liver biopsies<sup>[65]</sup>. The results were reproducible and there was reasonably good correlation between the imaging and biopsy findings<sup>[65]</sup>. In pursuit of a quick, accurate, non-invasive evaluation of hepatic steatosis, Fishbein and co-workers developed a fast gradient echo technique, which allowed them to obtain images of the liver in both adults and children, using breath holding manoeuvres<sup>[66]</sup>. This technique not

only reduced the time taken for the scan, but had the advantage of reducing motion artefact due to respiration. Using the same scanning sequence, these authors compared hepatic MRI with ultrasound and liver biopsy in quantifying hepatic fat in 38 patients with a variety of liver diseases<sup>[45]</sup>. Both MRI and ultrasound assessment of steatosis severity correlated well with liver histology, but MRI was superior to ultrasound in detecting and quantifying minor degrees of hepatic steatosis. Several other groups have also demonstrated a good correlation between the severity of hepatic steatosis on MRI and liver biopsy<sup>[67-69]</sup>. Recently, Qayyum and colleagues studied 27 patients, 16 with cirrhosis, and compared two different MRI techniques in quantifying hepatic fat. Their preliminary results suggested that liver fat may be more accurately quantified with fat-saturated fast spin-echo MR imaging than with out-of-phase gradient echo MR imaging, especially in patients with cirrhosis<sup>[70]</sup>.

Further modifications continue to be made to the Dixon method for water and fat separation, such as the recently reported fast spin-echo triple-echo Dixon (FTED) technique, which enables both uniform water/fat separation and fast scanning with uncompromised scan parameters<sup>[71]</sup>. Thus, in the future, chemical shift MRI is likely to provide an accurate, safe and fast method of detecting and quantifying hepatic steatosis in both adults and children.

## PROTON MAGNETIC RESONANCE SPECTROSCOPY

Chemical shift magnetic resonance imaging enables the identification of tissues that contain a significant proportion of intracellular lipid. In contrast, proton magnetic resonance spectroscopy (<sup>1</sup>H MRS) facilitates the examination of the resonance frequencies of all hydrogen nuclei (protons) within a region of interest. Although the absolute differences in resonance frequencies in MRS are quite small, they can be separated out to form a spectrum. Frequency separation, and hence spectral resolution, is determined by the strength of the main magnetic field. The MR spectra are plotted on an axis of chemical shift. With MR spectroscopy, the concentration of any given molecule in a sample is represented by the area under the specific resonance peak within the spectrum. Quantification of hepatic fat using proton MR spectroscopy requires evaluation of the two dominant peaks within the unsuppressed MR spectrum, water at 4.7 ppm and lipid at 1.0-1.5 ppm<sup>[59]</sup>. Livers with fatty infiltration demonstrate an increase in the intensity of the lipid resonance peak as shown in Figure 5.

Since proton magnetic resonance spectroscopy allows direct measurement of the area under the lipid resonance, it can be used to provide a quantitative assessment of fatty infiltration of the liver. Allowance must be made for both T<sub>1</sub> and T<sub>2</sub> relaxation effects, which differ for lipid and water. A correction must also be made for unsaturated lipids, as a portion of the MR

signal from these molecules overlaps with the water resonance at 4.7 ppm<sup>[59]</sup>.

Allowing for these corrections, Longo and colleagues studied a population of subjects with non-alcoholic fatty liver disease and found the percentage hepatic lipid measurements using <sup>1</sup>H MRS correlated well with those obtained by CT and liver biopsy<sup>[54,72]</sup>. Thomsen and co-workers demonstrated similar results in patients with alcohol-induced fatty liver disease<sup>[73]</sup>. Since then, several other studies have shown <sup>1</sup>H MRS to be a fast, safe, non-invasive method for the quantification of hepatic fat content<sup>[74-78]</sup>. Recently, <sup>1</sup>H MRS has been used in a large United States population study to determine the prevalence of non-alcoholic fatty liver disease in the general adult population<sup>[79]</sup> and also in longitudinal clinical studies<sup>[80-84]</sup>. However, in most centres <sup>1</sup>H MRS remains largely a research tool, despite the fact that all commercially available MR scanners have MRS capabilities.

## CONCLUSION

Non-alcoholic fatty liver disease (NAFLD) is now recognized as the most common cause of chronic liver disease in the Western World<sup>[31]</sup>. Its prevalence will likely increase in the future in parallel with the predicted increase in obesity and Type 2 diabetes. Currently, the only proven treatments for this condition are lifestyle measures, such as dietary modification and exercise<sup>[82,85-87]</sup>.

Liver biopsy remains the gold standard investigation for determining hepatic fat deposition, but it is an invasive procedure and may be prone to sampling error.

Of the non-invasive imaging techniques used to detect fatty infiltration of the liver, ultrasound is the most widely used in clinical practice today. It will remain popular in the future due to its widespread availability and excellent tolerability. Magnetic resonance techniques using chemical shift imaging and *in vivo* <sup>1</sup>H MRS have an advantage over ultrasound in that they are able to detect small changes in liver fat content. They can be performed as an adjunct to whole body MRI, as part of the same examination, allowing a comparison to be made between hepatic fat content and whole body adipose tissue distribution in the same subject. Thus, in the future, as more technological advances are made and scanning times shorten further, it is anticipated that both techniques will be used much more widely, both in longitudinal clinical research studies, but also in clinical practice.

## ACKNOWLEDGMENTS

We are grateful to Jane Cox, Jeremy Cobbold, Marzena Wylezinska-Arridge and Adrian Lim for useful discussions. Studies performed at the Robert Steiner MRI Unit, MRC Clinical Sciences Centre, Hammersmith Hospital Campus, Imperial College London, are supported by Pfizer Global Research (Sandwich, UK), the British Medical Research Council and the United Kingdom Department of Health Research and

Development Initiative. Dr Mehta is currently supported by a fellowship from the Novo Nordisk UK Research Foundation.

Risk of colorectal neoplasm in patients with acromegaly: A meta-analysis. *World J Gastroenterol* 2008; 14(22): 3484-3489 Available from: URL: <http://www.wjgnet.com/1007-9327/14/3484.asp> DOI: <http://dx.doi.org/10.3748/wjg.14.3484>

## Abstract

**AIM:** To examine the risk of colorectal neoplasm in acromegalic patients by meta-analyzing all relevant controlled studies.

**METHODS:** Extensive English language medical literature searches for human studies, up to December 2007, were performed using suitable keywords. Pooled estimates [odds ratio (OR) with 95% confidence intervals (CI)] were obtained using either the fixed or random-effects model as appropriate. Heterogeneity between studies was evaluated with the Cochran *Q* test whereas the likelihood of publication bias was assessed by constructing funnel plots. Their symmetry was estimated by the adjusted rank correlation test.

**RESULTS:** For hyperplastic polyps the pooled ORs with 95% CI were 3.557 (2.587-4.891) by fixed effects model and 3.703 (2.565-5.347) by random effects model. The *Z* test values for overall effect were 7.81 and 6.984, respectively ( $P < 0.0001$ ). For colon adenomas the pooled ORs with 95% CI were 2.486 (1.908-3.238) (fixed effects model) and 2.537 (1.914-3.364) (random effects model). The *Z* test values were 6.747 and 6.472, respectively ( $P < 0.0001$ ). For colon cancer the pooled OR with 95% CI was identical for both fixed and random effects model (OR, 4.351; 95% CI, 1.533-12.354;  $Z = 2.762$ ,  $P = 0.006$ ). There was no significant heterogeneity and no publication bias in all the above meta-analyses.

**CONCLUSION:** Acromegaly is associated with an increased risk of colorectal neoplasm.

## INTRODUCTION

Acromegaly is a disease caused by excess secretion of growth hormone (GH), which is characterized by enlarged acral parts, coarse facial features, and visceromegaly. Acromegalic patients have a reduced life expectancy primarily due to cardiovascular, respiratory or cerebrovascular disease<sup>[1-3]</sup>. Acromegalics may also be at an increased risk for malignancies in several systems including the digestive tract, brain, kidney, breast and prostate<sup>[6-10]</sup>. Colon cancer incidence<sup>[6,7,10]</sup> and mortality rates<sup>[9]</sup> have been reported to be higher in acromegalics than expected. However, reported relative risks of colorectal cancer vary significantly depending on the study population and the study design. Moreover, the reported higher indices of colorectal neoplasia in acromegalics have not been a universal finding<sup>[11-13]</sup>. The main aim of this meta-analysis, therefore, was to examine the pooled risk of colorectal neoplasia (polyps and cancer) in acromegalic patients by meta-analyzing all relevant controlled studies. Secondary aims were to explore the possibility of heterogeneity between studies and to look for the existence of publication bias. This study is justified by the fact that, so far, no meta-analysis has been published examining the relationship between acromegaly and colorectal neoplasia.

## MATERIALS AND METHODS

### Data identification and extraction

We searched the MEDLINE/PUBMED and EMBASE databases up to December 2007 to identify all relevant English language medical literature for human studies under the search text terms; acromegaly AND (colon cancer OR colon polyps OR colorectal cancer OR colorectal polyps). We also performed a full manual search of all review articles, published editorials and of retrieved original studies. Data from each study were extracted independently by two authors (T.R and D.P) by using a predefined form, and disagreements were resolved by discussion and consensus.

### Selection criteria

Inclusion and exclusion criteria were delineated before the commencement of the literature search. Thus, eligible studies published as full articles were included in this meta-analysis if they met all of the following criteria: (1) written in the English language, (2) published as full articles and (3) a simultaneous control group was included.

Studies not meeting the aforementioned criteria, and in addition studies without data for retrieval, studies using historical control patients or autopsy data and duplicate publications were excluded. When two papers reported the same study the publication that was more informative was selected.

### Statistical analysis

Agreement in the selection of studies between the 2 reviewers was evaluated by the  $\kappa$  coefficient. We calculated the pooled odds ratios (ORs) and 95% confidence intervals (CI) and compared outcomes of individual studies by using the fixed<sup>[14]</sup> or the random effects model<sup>[15]</sup> as appropriate. Forest plots were constructed for visual display of OR (95% CI) of individual studies and pooled data. Heterogeneity between studies was evaluated with the Cochran  $Q$  test<sup>[16]</sup> and it was considered to be present if the  $Q$  test provided a  $P$  value of less than 0.10<sup>[16,17]</sup>. In the presence of significant statistical heterogeneity, sensitivity analyses were performed to search for the possible sources, such as sample size of each study, *etc.* These analyses were achieved by repeating the meta-analyses with exclusion of each individual study one at a time, in order to assess the overall effect of each study on the pooled ORs<sup>[18]</sup>. This indicates which particular studies are most influential and might help in the evaluation of the possibility that the conclusions result from the influence of a particular study. The likelihood of publication bias was assessed by constructing funnel plots<sup>[18]</sup> and their symmetry was estimated by the Begg and Mazumdar adjusted rank correlation test<sup>[19]</sup>.

All meta-analyses, sensitivity and meta-regression analyses in this study were performed by using suitable meta-analysis software (Comprehensive Meta Analysis-Version 2, Biostat Inc, Englewood, NJ, USA).

### Role of funding source

This was an investigator-initiated unfunded study. All

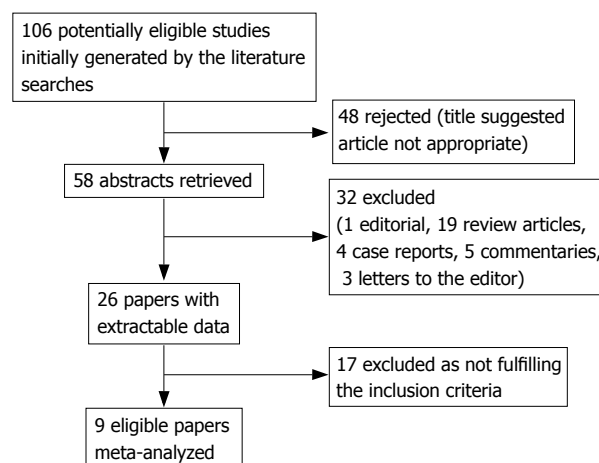

Figure 1 Flow diagram of the studies identified in this meta-analysis.

authors had access to the data and the statistical analysis report. Each author approved the final article and attests to the validity of the results.

## RESULTS

### Descriptive assessment and study characteristics

A flow chart describing the process of study selection is shown in Figure 1. Out of 106 titles initially generated by the literature searches, 48 were rejected as the title suggested that the articles were not appropriate. Of the remaining 58 abstracts, 32 were excluded for not having extractable data (editorials, review articles, case reports, commentaries and letters to the editor). Therefore, 26 papers remained candidates for eligibility. Of these, 17<sup>[6,8,9,11-13,20-30]</sup> were rejected on the basis of not fulfilling the inclusion criteria. Therefore 9 controlled studies remained eligible for meta-analysis<sup>[31-39]</sup>. Initial agreement between the reviewers for the selection of relevant articles was high ( $\kappa = 0.924$ , 95% CI, 0.851-0.997).

The main characteristics of the papers eligible for meta-analysis are shown in Table 1. The studies were conducted in different parts of the world; most were single centre studies and included 701 acromegaly patients and 1573 controls.

### Colon adenomas

Eight of the nine meta-analyzed studies<sup>[31-35,37-39]</sup> provided data concerning the frequency of colon adenomas in acromegaly patients and controls [149/641 (23.2%) *vs* 176/1,413 (12.45%)]. The pooled ORs (95%CI), by both the fixed and random effects model, were 2.486 (1.908-3.238) and 2.537 (1.914-3.364), respectively with  $Z$  test values for overall effect 6.747 and 6.472, respectively and  $P < 0.0001$  for both models (Figure 2). There was no significant heterogeneity ( $P = 0.371$ ) among these trials (Table 2). In addition there was no publication bias ( $P$  two tailed value 0.711, Table 2) as shown in the respective funnel plot (Figure 3).

### Colon hyperplastic polyps

Seven studies<sup>[31,33-38]</sup> provided data concerning the

Table 2 Heterogeneity and publication bias results of meta-analyzed studies, concerning the three types of colonic lesion examined, i.e. colon adenomas, hyperplastic polyps and colon cancer

Type of colonic lesion	Heterogeneity					Publication bias	
	Number of studies	Q-value	df (Q)	I <sup>2</sup>	P value	Kendall's tau	P value (two-tailed)
Adenomatous polyps	8	7.584	7	7.700	0.371	0.143	0.711
Hyperplastic polyps	7	7.447	6	19.433	0.281	0.143	0.764
Cancer	3	1.068	2	0.000	0.586	-0.333	1.000

**Figure 2** Forest plot showing individual and pooled ORs (95% CIs) and P values in studies comparing the colon adenoma prevalence in acromegaly patients and controls.

frequency of colon hyperplastic polyps in acromegaly

**Figure 3** Funnel plot of selected studies examining colon adenoma prevalence in acromegaly patients and controls. No evidence of publication bias found ( $P = 0.711$ , by adjusted rank correlation test). Similarly no evidence of publication bias was found for the other colon neoplasias studied, i.e. colon hyperplastic polyps and colon cancer (see results, Table 2).

patients and controls [128/573 (22.3%) *vs* 91/1236 (7.36%)]. The pooled OR (95% CI), by both the fixed and random effects model, were 3.557 (2.587-4.891) and 3.703 (2.565-5.347), respectively, with Z test values for overall effect 7.81 and 6.984, respectively and  $P < 0.0001$  for both models (Figure 4A). There was no significant

**Figure 4** Forest plot showing individual and pooled ORs (95% CIs) and *P* values in studies comparing the colon hyperplastic polyp prevalence (A) and the colon cancer prevalence (B) in acromegaly patients and controls.

heterogeneity among these trials ( $P = 0.281$ ) and no publication bias ( $P = 0.764$ , Table 2).

### Colon cancer

Three studies<sup>[34,37,38]</sup> provided data concerning the frequency of colon cancer in acromegaly patients and controls [14/304 (4.6%) *vs* 8/627 (1.2%), respectively]. The pooled ORs (95%CI), by both the fixed and random effects model, were identical [4.351 (1.533-12.354) for both] with *Z* test for overall effect = 2.762 and  $P = 0.006$  (Figure 4B). There was no significant heterogeneity among these trials ( $P = 0.586$ ) and no publication bias ( $P = 1$ ).

## DISCUSSION

The study on the association between acromegaly

and cancer risk has focused primarily on colorectal cancer, but the findings of previous studies are far from conclusive and the matter of colorectal cancer in acromegaly has been debated in the literature<sup>[40-44]</sup>.

The discrepant results in the literature prompted us to undertake a meta-analysis on control trials in order to assess whether patients with acromegaly are at an increased risk of developing colorectal neoplasia, because if this is the case, then in these patients an aggressive approach to endoscopic management should be applied. In addition, our study is justified by the fact that, so far, no meta-analysis has been published examining the relationship between acromegaly and colorectal neoplasia.

The pooled results in this study clearly showed that acromegalic patients are at a significantly increased risk of developing colorectal adenomatous and hyperplastic polyps as well as colorectal cancer compared with controls. This estimate is in agreement with the results of three larger epidemiological studies assessing the risk of colonic cancer in acromegaly<sup>[7,9,10]</sup>. According to these findings, therefore, it is beyond doubt that a suitable endoscopic approach, with early large bowel endoscopic screening and regular surveillance, is fully justified in acromegaly patients. Needless to say total colonoscopy is essential in acromegaly, as in several studies proximal colon pathology was found<sup>[13,33,34]</sup>. This requirement is made more difficult by the increased length and capacity of the acromegalic colon<sup>[13,42]</sup>. To overcome this and the prolonged colonic transit time in acromegalic patients, rigorous bowel preparation, in excess of that usually used, is needed<sup>[42]</sup>.

One possible weakness of this meta-analysis might be the inclusion of underpowered studies of small sizes. Another weakness might be the fact that five of the nine meta-analysed studies come from the same country, i.e. Italy. However, all possible weaknesses are compensated by the lack of heterogeneity among the meta-analysed studies and also by the lack of publication bias.

Why should acromegaly patients be at an increased risk of colorectal neoplasia? The answer to this question is difficult, but it seems that the increased risk for several cancers among acromegaly patients may be due to the elevated proliferative and anti-apoptotic activity associated with increased circulating levels of insulin-like growth factor- I (IGF- I). There is an increasing body of evidence suggesting that adults with high concentrations of IGF- I are at increased risk of colorectal cancer<sup>[45-47]</sup>. In some of these studies, high IGF binding protein-3 (IGFBP-3) levels were associated with a lower risk of cancer<sup>[45,46]</sup>. In acromegaly, GH excess increases serum IGF- I and, to a lesser extent, IGFBP-3 concentrations, with the IGF- I to IGFBP-3 ratio being greater as GH concentrations increase<sup>[48,49]</sup>. Thus, an elevated IGF- I to IGFBP-3 ratio is expected to increase cancer risk in acromegaly<sup>[45,50]</sup>. On the other hand, IGF- I receptors and mRNAs for IGF- I have been identified in human colorectal cells<sup>[51]</sup>. IGF- I is a known mitogen that may stimulate, by autocrine and paracrine actions, the proliferation of intestinal epithelial cells and their

migration<sup>[52]</sup>. In fact, increased proliferation of colonic epithelium, proportional to circulating IGF- I levels, has been demonstrated in acromegaly<sup>[53]</sup>. Moreover, IGF- I is able to stimulate the growth of colorectal cancer cells *in vitro*, whereas blockade of IGF- I receptors inhibits cell growth in the same model<sup>[51,54,55]</sup>.

In conclusion, this study showed that acromegalic patients are at an increased risk of colorectal adenomatous and hyperplastic polyps as well as colorectal cancer. Therefore, acromegaly should be characterized as a disorder carrying a high risk for the development of colorectal neoplasia where an aggressive approach to endoscopic management with early screening and regular surveillance is justified.

## COMMENTS

### Background

Patients with acromegaly may be at an increased risk for malignancies in several systems including the digestive tract. However, the reported higher indices of colorectal neoplasia in acromegalics have not been a universal finding.

### Research frontiers

We evaluated the risk of colorectal neoplasm in acromegalic patients by meta-analyzing all relevant controlled studies.

### Innovations and breakthroughs

We made a comprehensive search of studies dealing with colorectal neoplasm in acromegalic patients. The studies were analyzed to determine the risk of colorectal neoplasm in these patients.

### Applications

Based on this evaluation, we concluded that acromegalic patients are at an increased risk of colorectal adenomatous and hyperplastic polyps as well as colorectal cancer. Therefore, acromegaly should be characterized as a disorder carrying a high risk for the development of colorectal neoplasia where an aggressive approach to endoscopic management with early screening and regular surveillance is justified.

### Peer review

The authors explored the risk of colorectal neoplasm in acromegalic patients. It was concluded that acromegalic patients are at an increased risk of colorectal adenomatous and hyperplastic polyps as well as colorectal cancer.

were obtained from the sera of 8 patients, each patient had at least two isolates. One isolate from each individual was selected and subcloned into pHY106 vector, including 5 isolates with YVDD mutation and 3 isolates with YIDD mutation. All recombinant plasmids harboring HBV isolates were transfected into Huh7 cells. The results indicated that HBV genome carried in HBV replicons of clinical HBV isolates could effectively replicate and express in Huh7 cells. Adefovir, but not lamivudine, inhibited HBV replication both *in vitro* and *in vivo*, and *in vitro* inhibition was dose-dependent.

**CONCLUSION:** The novel method described herein enables individualized selection of anti-HBV agents in clinic and is useful in future studies of antiviral therapy for CHB.

Replication of clinical hepatitis B virus isolate and its application for selecting antiviral agents for chronic hepatitis B patients. *World J Gastroenterol* 2008; 14(22): 3490-3496 Available from: URL: <http://www.wjgnet.com/1007-9327/14/3490.asp> DOI: <http://dx.doi.org/10.3748/wjg.14.3490>

## Abstract

**AIM:** To establish a cell model harboring replicative clinical hepatitis B virus (HBV) isolates and evaluate its application in individualized selection of anti-HBV agents for chronic hepatitis B (CHB) patients.

**METHODS:** The full-length HBV genomic DNA from 8 CHB patients was amplified by polymerase chain reaction (PCR). All the patients were treated with lamivudine for at least seven months and finally became resistant to lamivudine. The amplified HBV DNA fragments were inserted into pHY106 vectors by *Sap* I digestion. The recombinant plasmids containing 1.1 copies of HBV genome were transiently transfected into Huh7 cell line, and the levels of HBsAg, HBeAg and intercellular HBV replicative intermediates were determined by ELISA and Southern blot analysis, respectively, with or without lamivudine and adefovir treatment. The antiviral treatment with adefovir was administered to the patients and analyzed in parallel.

**RESULTS:** A total of 25 independent HBV isolates

## INTRODUCTION

Hepatitis B virus (HBV) infection may lead to acute liver disease, chronic active hepatitis, liver cirrhosis, and hepatocellular carcinoma (HCC). Over 350 million people worldwide are estimated to be infected chronically by HBV and are, therefore, at risk of liver failure, cirrhosis, or HCC<sup>[1-4]</sup>. The principal treatment for chronic hepatitis B (CHB) involves the use of interferon alpha (IFN- $\alpha$ ) or nucleoside analogs.

Although the use of IFN- $\alpha$  and nucleoside analogs (such as lamivudine and adefovir) has improved the treatment of chronically infected HBV patients, an

effective reduction in virus load is only observed in less than 40% of treated patients<sup>[5-10]</sup>. The molecular basis for resistance to antiviral therapy is not clearly defined. However, studies have suggested that HBV genome mutations may play a direct role in the development of resistance to antiviral agents<sup>[11-15]</sup>.

*In vitro* analysis of clinical HBV isolates is difficult due to the lack of HBV cell culture model<sup>[16-19]</sup>. Fortunately, the lack of *in vitro* infectivity can be conquered by transfecting recombinant plasmids encoding over-length HBV genome into human liver cell lines. Following transfection, HBV pre-genomic and messenger RNA are transcribed from the plasmids and progeny virus is replicated and released from cells. The present study is to develop a more efficient method for selecting anti-HBV agents using a highly efficient HBV expression vector. It is supposed to be useful for future studies on resistance surveillance and novel drug discovery.

## MATERIALS AND METHODS

### Patients

Eight patients with CHB were selected according to the diagnostic criteria of CHB<sup>[20]</sup>, and the infection of hepatitis A, C, E and G viruses, human immunodeficiency virus, cytomegalovirus and the use of alcohol were excluded. All patients were treated with lamivudine for more than seven months, and were found to be resistant to lamivudine treatment in the Department of Infectious Diseases of Union Hospital of Tongji Medical College, Huazhong University of Science and Technology, from January 2005 to August 2005. All the patients were HBsAg and HBeAg positive, with HBV DNA levels above 10<sup>6</sup> copies/mL and elevated serum ALT ( $\geq 1.5$  times that of the upper normal limit) at the time of sample collection. Access to the materials complied with the Helsinki Declaration and approved by the local ethics committee, and the informed consents were obtained from all the patients.

### Plasmids and bacteria

HBV cloning and expression vector pHY106 was kindly provided by Dr. Lu MJ (Institute of Virology, Duisburg-Essen University, Germany), which contains a cytomegalovirus (CMV) promoter upstream of a short, recombinant HBV sequence that allows the in-frame insertion of a full-length HBV genome by *Sap* I digestion (Figure 1). The HBV replicon, pHBV1.3, containing 1.3-fold full length genome of HBV (*ayw* subtype), was conducted in our laboratory as described previously<sup>[21]</sup>. Plasmid pUC19 and *E.coli* JM109 strain were maintained in our laboratory and stored at -80°C.

### Cell culture

Human hepatoblastoma cell line, Huh7, was maintained in MEM medium supplemented with 10% fetal bovine serum (FBS) at 37°C in a moist atmosphere containing 5% CO<sub>2</sub>.

### Primers design

Primers were designed according to Gunther's method<sup>[22]</sup>, P1 (1803-1821): 5'-CCGGAAGCTTGAGCTCTTC-TTTTTCACCTCTGCCTAATCA-3' and P2 (1841-1822): 5'-CCGGAAGCTTGAGCTCTTCAAA AAGTTGCATGGTGCTGG-3' for amplifying HBV full-length genome. The italics denoted *Hind* III, *Sac* I and *Sap* I sites for inserting HBV genome into pUC19 and PHY106.

### Amplification of full-length HBV genomic DNA

HBV DNA was isolated from 200  $\mu$ L sera using QIAamp Blood Kit (Qiagen Co., Germany) according to manufacturer's instructions. Polymerase chain reaction (PCR) amplification of full-length HBV genomes was performed using primers P1 and P2 according to the methods of Gunther *et al.*<sup>[22]</sup>. If the initial PCR reactions were negative, a second round of PCR was performed under identical conditions using 5  $\mu$ L of 1:10 dilution of the first round reaction products as template.

### Construction of recombinant plasmids harboring full-length HBV genome

Following PCR amplification, PCR product was purified using a QIAquick Gel Kit (Qiagen Co., Germany) according to manufacturer's instructions. Then PCR products and plasmid pUC19 were digested with the restriction enzyme *Sac* I, and the 3.2 kb PCR products were inserted into the linear pUC19 vector (Figure 2). Recombinant plasmids were identified by restriction enzyme cleavage and termed as pUC19-HBV1.0.

### Construction of HBV replicons harboring 1.1-fold length HBV genome

pUC19-HBV1.0 was cleaved with the restriction enzyme *Sap* I, and a 3.2 kb fragment was recovered and subcloned into pPHY106 vector (Figure 2). Recombinant plasmids were identified by *Hind* III and *Nsi* I digestion and termed as pPHY106-HBV1.1. HBV polymerase gene of pPHY106-HBV1.1 was analyzed by sequencing.

### Replication of clinical HBV replicon in Huh7 cell line

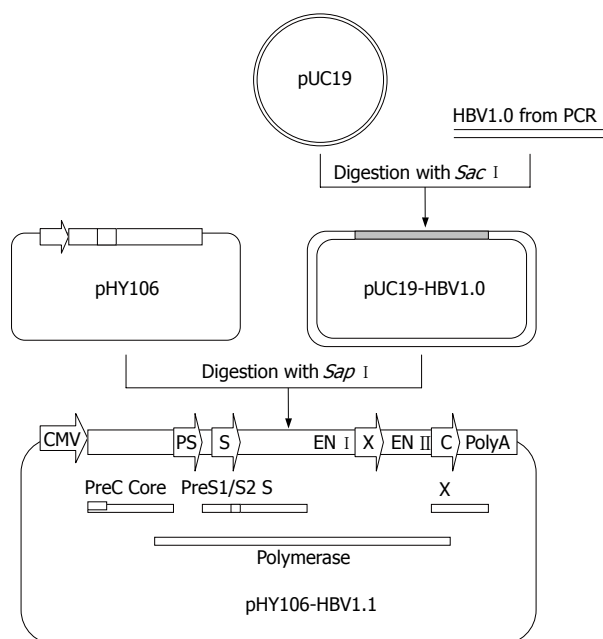

The plasmid pPHY106-HBV1.1 was transiently transfected into Huh7 cells, and the replication of clinical HBV replicons was measured. Huh7 cells were seeded with  $5 \times 10^5$ /well and cultured in six-well plates. Sixteen hours later, the cells were transfected with 5  $\mu$ g of plasmid pPHY106-HBV1.1 using 5  $\mu$ L lipofectamine reagent (Invitrogen Co., USA) according to the manufacturer's instructions. Following transfection, cultures were fed with fresh media and incubated for 96 h. The levels of HBsAg, HBeAg and HBV DNA in supernatant were determined by ELISA and quantitative PCR everyday. Meanwhile, the total cellular DNA was isolated and HBV replicative intermediates were detected by Southern blot hybridization.

### Southern blot analysis of HBV replicative intermediates

Five  $\mu$ g of total DNA of transfected cells was separated

**Figure 1** The schematic map of HBV expression vector of pHY106.

**Figure 2** Construction of replicons of clinical HBV isolates using pHY106. Full-length HBV genomes from PCR application can be digested with *Sap* I and inserted into *Sap* I-digested pHY106 to produce HBV replicon. HBV open reading frames (ORFs) for the pre-core (PC), core, preS1 (PS1), preS2 (2) surface (S), polymerase, and X genes are indicated by square frame. Promoter sequences for the preS (PS), surface (S) and core (C) genes are indicated by arrows.

on 1.5% agarose gels, and blot onto Hybond-N nylon membranes (Amersham Bioscience Inc, UK) using standard Southern blot procedures. Membranes were hybridized with a  $^{32}$ P-labeled full-length HBV DNA fragment and viral DNA was analyzed using a storage phosphor system (Cyclone, Packard Bioscience Co.).

#### Antiviral treatment in Huh7 cells transfected with clinical HBV replicons

Plasmid pHY106-HBV1.1 was transiently transfected into Huh7 cells as described above. The next day, cells were fed with fresh medium containing 0.01, 0.1, 1 and 10  $\mu$ mol/L of adefovir (Gilead Sciences, USA) and 0.01, 0.1, 1 and 10  $\mu$ mol/L of lamivudine, respectively, for 72 h, after which intracellular HBV replicative intermediates were isolated and quantified as described above.

**Figure 3** Identification of recombinant expression plasmids by restriction endonuclease digestion analysis. M: 1 kb DNA ladder marker; Lane 1-8: Recombinant plasmids digested with *Hind* III and *Nsi* I.

#### Statistical analysis

Data were presented as mean  $\pm$  SD error of the mean (SEM). Statistical significance of differences between the measured parameters was determined by Mann-Whitney's test. Statistical analyses were performed using the SPSS13.0 software. The values were statistically significant at  $P < 0.05$ .

## RESULTS

#### Amplification and cloning of full-length clinical HBV isolates

Using the method of Gunther *et al*, full-length HBV DNA was amplified from the sera of 6 patients following a single round of PCR. For the other two cases, a second round of PCR was performed to amplify HBV full-length genome successfully. In general, it was more difficult to amplify full-length HBV genome from patients with low levels of viremia. The PCR products were cloned into pUC19 vector, and a total of 25 independent HBV clones were obtained from the sera of the 8 patients and each patient had at least two clones.

#### Construction of HBV replicons harboring 1.1-fold length HBV genome

One clone was selected from each patient, and was subcloned into pHY106 vector. The directions of inserted clones were identified by digestion with restriction enzyme *Hind* III and *Nsi* I (*Nsi* I is a single restriction site at nt1064 of HBV genome). If HBV clones were forwardly inserted, the recombinant plasmid should be cleaved into two fragments with a molecular weight of 5400 bp and 920 bp (Figure 3). Polymerase gene of 5 HBV isolates showed YVDD mutation and the other 3 isolates showed YIDD mutation.

#### Replication of clinical HBV replicons in Huh7 cell line

Eight of the HBV isolates cloned into the PHY106 vector were analyzed for their ability to replicate *in vitro*. Recombinant plasmids were transfected into Huh7 cells and allowed to replicate for 96 h, after which HBsAg, HBeAg and HBV DNA were detected, and intracellular replicative intermediates were extracted and analyzed by Southern blot hybridization. A marked variation was observed in the levels of HBsAg, HBeAg, HBV DNA and intracellular replicative intermediates among

pHBV1.3 is positive control; pHY106 is negative control.

Figure 4 Analysis of intracellular replication of clinical HBV isolates. HBV isolates were cloned into the vector pHY106 and transfected into Huh2 cells. Seventy-two hours after transfection, intracellular replicative intermediates were isolated and analyzed by Southern blot. Double-stranded (DS) and single-stranded (SS) intermediates are indicated. Lane 1-8: eight replicons of clinical HBV isolates; Lane 9: pHY106 negative control.

individual clones (Tables 1 and 2, Figure 4). The HBsAg and HBeAg levels rapidly reached to a plateau within 72 h. Further incubation did not increase the concentration of HBsAg and HBeAg in the culture supernatants. There was also a consistency of the HBsAg, HBeAg and HBV DNA levels in supernatants (Tables 1 and 2).

Figure 5 Antiviral susceptibility of an HBV isolate cloned from a patient with lamivudine resistance. An HBV isolate amplified from the sera of patients failing in lamivudine therapy was cloned into the pHY106 vector and analyzed *in vitro*. Lane 1-4: transfected cells treated with 0.01, 0.1, 1 and 10 μmol/L of adefovir; Lane 5-8: transfected cells treated with 0.01, 0.1, 1 and 10 μmol/L of lamivudine.

**Antiviral treatment in Huh7 cells transfected with clinical HBV replicons**

A cell-based antiviral assay was used to test the lamivudine and adefovir susceptibility of the 8 clinical isolates that replicated efficiently in cell culture. The results indicated that adefovir but not lamivudine, efficiently inhibited the replication of clinical HBV isolates *in vitro*, furthermore, the inhibition effect depended upon the concentration of adefovir. The viral replication was completely inhibited in the transfected cells treated with 10 μmol/L adefovir (Figure 5).

**Antiviral treatment in vivo**

All chronic HBV infected patients who had resistance to lamivudine were treated with adefovir for 6 mo. These patients were sensitive to adefovir therapy, and their HBV viral load in sera dropped at least  $10^3$ - $10^5$  copies/mL. Together with the results of antiviral test of adefovir *in vitro* as described above, it indicated that antiviral susceptibility of clinical HBV isolates was well coincident between *in vivo* and *in vitro*.

**DISCUSSION**

HBV contains a 3.2-kb, circular, double-stranded DNA genome and causes acute and chronic hepatitis B, cirrhosis, and eventually HCC<sup>[23]</sup>. Investigation of the expression and replication of the HBV genome as well as the full viral life cycle is hampered by the lack

of an *in vitro* tissue culture system in which HBV is propagated<sup>[16-19]</sup>. The HBV cell model system has been the subject of many studies in the last four decades. Unfortunately, no study has reported the identification of an appropriate tissue culture system to propagate HBV. This has greatly hindered the progress of HBV studies in many fields, such as virology, molecular biology, immunology and antiviral therapy. In an attempt to overcome this obstacle, several researchers transduced HBV genome into human hepatocyte *via* plasmids, in which HBV gene could replicate, express, and even assemble infectious virions<sup>[21,24-26]</sup>. Because the HBV genome is very dense and genes overlap with each other, HBV genome was inserted into plasmids in a head-to-tail linkage manner.

Recently, many groups have transfected over-length HBV genome into hepatocytes for viral replication and anti-HBV studies<sup>[21,24-26]</sup>. It is well known that the longest HBV transcript is a 3.5 kb mRNA; therefore, several plasmids carrying HBV multiple genomes were constructed, such as 2.0 copies and 1.3 copies of HBV genome, these over-length HBV genome contains complete HBV replication units, such as Enh I, Enh II, DR1, DR2, the transcription origin site of viral pre-genome, promoters and ORFs. Although these artificially constructed HBV replicons played an important role in anti-HBV studies, they were not suitable for the individualized selection of antiviral agents. Recently many scientists working in HBV fields considered that HBV replicated as quasi-species *in vivo* and individual species are likely to vary<sup>[27,28]</sup>. HBV genome mutation is mostly caused by immune and drug pressures, for example, CHB patients treated with lamivudine, when mutation appeared in polymerase gene of HBV, will be resistant to lamivudine therapy. As a result, HBV replicon can be used for the individualized selection of antiviral agents *in vitro* based on clinical HBV isolates.

In this study, we established a novel method to assess *in vitro* replication of clinical HBV isolate and investigated its application for selecting antiviral agents for CHB patients. We employed pHY106 vector to construct HBV replicons of clinical isolates. The pHY106 contains a CMV promoter, followed by a 15 nucleotide HBV sequence encoding the pre-core initiation site (plus the next two amino acids of the pre-core protein), a short heterologous linker sequence that contains two *Sap* I sites, and finally a 180 nucleotide region that encodes the carboxy terminus of the HBV X gene (five amino acids) and the polyadenylation signal for HBV mRNA. Following digestion of pHY106 and full-length HBV genomes with *Sap* I (Figure 2), HBV genomes can be inserted in-frame, resulting in the generation of replication-competent HBV clones, 95% of which are derived from patient virus (Figure 2). The CMV promoter upstream of the pre-core initiation site allows efficient transcription of the 3.5 kb pre-genomic RNA after transfection of liver cell lines. The minimal 5' and 3' sequence derived from the wild type HBV

strain in pHY106 is highly conserved among published HBV isolates. Thus, HBV isolates cloned into the pHY106 vector should be representative of patient virus with little or no genotypic changes.

We obtained 8 clinical HBV replicons from CHB patients with lamivudine resistance, and found that these replicons were not susceptible to lamivudine treatment *in vitro* because of YMDD mutation of polymerase gene. Sequence analysis of clinical HBV isolates with established drug resistant mutations will provide useful information for selecting the existing or novel antiviral agents or the combination of antiviral agents for further treatment. At least four major mutational patterns are associated with lamivudine resistance (rtM204I, rtL180M + rtM204I, rtL180M + M204V, and rtV173L + rtL180M + M204V)<sup>[29]</sup>. Many mutations enhance viral replication, e.g., the pre-core mutation G1896A has been shown to greatly enhance the replication capacity of HBV encoding the rtM204I (but not rtM204V) lamivudine resistant mutation<sup>[30]</sup>. Adefovir demonstrated an excellent therapeutic effect for CHB patients who failed in lamivudine therapy<sup>[31-35]</sup>. Together with the results of antiviral treatment of adefovir *in vitro* and *in vivo*, our results confirmed that adefovir inhibited the replication of HBV with lamivudine resistance *in vitro* and *in vivo*, and indicated that antiviral susceptibility of clinical HBV isolates was well coincident between *in vivo* and *in vitro*. Therefore, the antiviral treatment *in vitro* will provide useful information for individualized selection of antiviral agents *in vivo*.

Several antiviral agents including lamivudine, adefovir and entecavir are available for CHB treatment, and several novel antiviral agents for CHB treatment are being developed. *In vitro* analysis of drug susceptibility based on clinical HBV isolates is useful for personalized selection of the existing or novel antiviral agents or combinations of antiviral agents for treatment. However, there are still some problems to be resolved. Firstly, HBV replicates as quasi-species *in vivo*, and the replication capacity of individual species are likely to vary; therefore the predominant HBV isolate should be selected in this study. Secondly, the replication of HBV *in vitro* is significantly different from that of *in vivo*, and the influence of the difference between *in vitro* and *in vivo* on antiviral agent selection should be considered. Finally, despite the use of a high fidelity DNA polymerase for HBV genome amplification, artificial mutation may occur in HBV genome, and the replication of HBV isolates may be affected.

Our study described a novel strategy and method for developing an *in vitro* system for selection of antiviral agents based on clinical HBV isolates, and evaluated the application in individualized selection of antiviral agents for chronic hepatitis B patients. The results indicated that *in vitro* analysis of drug susceptibility based on clinical HBV isolates is useful for individualized selection of antiviral agents for patients with CHB.

## COMMENTS

### Background

Hepatitis B virus (HBV) is the leading cause of chronic hepatitis. Antiviral treatment of chronic hepatitis B (CHB) relies on interferon alpha and nucleoside analogs that inhibit activity of HBV polymerase. However, resistance of HBV to antiviral nucleoside analogs, caused by mutation of HBV polymerase gene, has become a major clinical problem. Moreover, the lack of reliable *in vitro* infection system and convenient models has hindered the new treatment options. Therefore, establishment of new strategies for studying *in vitro* the drug susceptibility of clinical isolates of HBV is extremely important for antiviral therapy for CHB patients.

### Research frontiers

The phenotypic assays have first been developed for monitoring drug susceptibility of human immunodeficiency virus viral populations. Some of them are used currently in clinical practice to monitor drug resistance. As compared with the human immunodeficiency virus phenotypic assay, the development and clinical use of the HBV phenotypic assay are still at an early stage. This study demonstrated the relevance of this type of assay for longitudinal monitoring of the drug susceptibility status of the viral population isolated from clinical samples.

### Innovations and breakthroughs

This study describes a novel strategy and method for the cloning of HBV genomes isolated from CHB patients into plasmidic vectors and the basis of another phenotypic assay capable of assessing HBV drug susceptibility *in vitro* and evaluates the effects of antiviral agents in circulating viral isolates from chronic HBV.

### Applications

This work may help determine the drug susceptibility of HBV quasi-species to antivirals and select antiviral agents for CHB patients.

### Peer review

In this study the authors established a novel method to assess *in vitro* replication of clinical HBV isolate and investigated its application for selecting antiviral agents for CHB patients. It will be very useful in future studies of antiviral therapy for CHB.

**CONCLUSION:** This study confirms that patients with PSC-IBD have a particular disease phenotype independent of the initial disease location. Although their disease is less active and they use more 5-aminosalicylates, they present a higher risk of colorectal cancer.

## Abstract

**AIM:** To investigate the phenotype of inflammatory bowel disease associated with primary sclerosing cholangitis (PSC-IBD).

**METHODS:** Data from 75 PSC-IBD patients evaluated in our tertiary center between 1963 and 2006 were collected and compared to 150 IBD patients without PSC, matched for sex, birth date, IBD diagnosis date and initial disease location regarding ileal, different colonic segments, and rectum, respectively.

**RESULTS:** While PSC-IBD patients received more 5-aminosalicylates (8.7 years/patient *vs* 2.9 years/patient,  $P < 0.001$ ), they required less immunosuppressors (24% *vs* 46% at 10 years;  $P < 0.001$ ) and less intestinal resection (10% *vs* 44% at 10 years,  $P < 0.001$ ). The 25-year cumulative rate of colectomy was 25.1% in PSC-IBD and 37.3% in controls ( $P = 0.004$ ). The 25-year cumulative rate of colorectal cancer was 23.4% in PSC-IBD *vs* 0% in controls ( $P = 0.002$ ). PSC was the only independent risk factor for the development of colorectal cancer (OR = 10.8; 95% CI, 3.7-31.3). Overall survival rate without liver transplantation was reduced in PSC-IBD patients (67% *vs* 91% in controls at 25 years,  $P = 0.001$ ).

## INTRODUCTION

The association of primary sclerosing cholangitis (PSC) with ulcerative colitis (UC) was first described by Smith and Loe in 1965<sup>[1]</sup>. The association with Crohn's disease (CD) was suggested by Atkinson and Carroll in 1964<sup>[2]</sup>, but was found less common than with UC. PSC may appear many years after proctocolectomy for colitis, and onset of IBD can be seen many years after liver transplantation for complicated PSC<sup>[3-7]</sup>. There is no evident correlation between the severity of UC and that of the associated PSC<sup>[4,5]</sup>.

Backwash ileitis, rectal sparing and low disease activity seem to characterize IBD when associated to PSC<sup>[8,9]</sup>. These characteristics may be partly linked as a proximal colonic disease and is usually less symptomatic than a distal one. Another crucial point regarding colitis is the increased risk of colorectal carcinoma. The two major risk factors for this complication are long duration of disease and the extent

of colitis. Recently, family history of sporadic colorectal cancer, active inflammation within the colonic mucosa and presence of PSC have been shown to increase the risk of colorectal cancer or dysplasia<sup>[10-14]</sup>. In a meta-analysis involving 116 studies<sup>[15]</sup>, the cumulative probability of cancer in UC patients regardless of disease extent or PSC association was 18% at 30 years. In a study from Broomé *et al*<sup>[16]</sup>, the cumulative risk of colorectal neoplasia (cancer or dysplasia) after 25 years of disease duration was 50% in the PSC-IBD group and 10% in the group of patients with UC without PSC. Nevertheless, conflicting results have been published<sup>[17-20]</sup>, but these studies had different sample size, end points and comparison groups. Moreover, patients with PSC may be misdiagnosed for IBD due to usual quiescent colitis in this sub-group of patients.

The patients with PSC associated UC are more likely to have extensive disease or pancolitis than those without PSC<sup>[8]</sup>. Moreover, the rectum seems to be less involved by inflammatory lesions<sup>[8]</sup>. Thus, comparing the colorectal cancer risk of PSC-UC patients with that of all coming UC patients without PSC may be debatable. Moreover, CD can also be associated with PSC, and there is no reason to restrain this comparison exclusively to UC patients. Besides the disease duration, the extent of disease is the most important matching criteria for comparing the colorectal cancer risk of PSC-IBD patients to IBD patients without PSC.

The aim of this study was to describe the clinical setting and outcome, in particular the risk of neoplasia, of a cohort of PSC associated IBD patients and to compare them to a group of IBD patients without PSC matched for disease location and extent at diagnosis. The patients were not matched for the type of IBD (i.e. CD or UC) because we considered that PSC-IBD patients represent a third IBD phenotype which have to be regarded without presumption<sup>[8]</sup>.

## MATERIAL AND METHODS

### Patients

Patients in this study were obtained from the MICISTA Registry, a tertiary clinical database of all IBD patients evaluated by the same staff of physicians at Rothschild Hospital (1974-2002) and then at Saint-Antoine Hospital (since 2003 to present time). The registry was built during the year 1994, with data before 1994 collected retrospectively. Data were collected prospectively in patients entering the database after 1994. There were 51 patients with additional diagnosis of PSC in the MICISTA registry ( $n = 51$  out of 5274, 0.97%). In addition, PSC-IBD patients followed in the Hepatology Department of the Saint-Antoine Hospital in the same period were also included ( $n = 24$ ). In all patients, diagnosis of PSC was defined by the following criteria: persistently elevated serum gamma glutamyl transferase (GGT) or alkaline phosphatase levels for at least 3 mo, characteristic radiographic appearance of sclerosing cholangitis and/or histologic features consistent with PSC on liver biopsy and absence of conditions associated with secondary sclerosing cholangitis<sup>[21]</sup>. The diagnosis of CD, UC, indeterminate colitis (IC) or

unclassified IBD (IBDu) were based on Lennard-Jones criteria and Montreal classification<sup>[22,23]</sup>.

### Matching

Controls were chosen randomly within the MICISTA registry to match to the identified cases (2 controls for one PSC case). In order to focus the analysis on colorectal cancer risk, we chose the following matching criteria: gender, birth year ( $\pm 2.5$  years), IBD diagnosis calendar year ( $\pm 2.5$  years) and initial disease location. Digestive tract was divided into the following seven segments: upper gastrointestinal tract, jejunum, ileum, caecum and ascending colon, transverse and descending colon, sigmoid colon, and rectum. Controls were matched to case considering each gastrointestinal tract segment.

### Data collection

Data concerning demographic information, IBD clinical settings (duration, initial and cumulative extent, year-by-year disease activity (assessed prospectively over one year according to a score taking into account flares: score 0 to 3, hospitalisations: score 4, excision surgery: score 5) from 1995 to 2005, extra intestinal lesions, medical and surgical treatment), morphological examination results (endoscopy, radiology), histopathology findings (digestive and liver biopsies) and outcome information (including colorectal neoplasia, colectomy, PSC complications and death) were abstracted from medical files. Colorectal neoplasia included flat low or high grade dysplasia and adenocarcinoma. Low and high grade dysplasia occurring in non-flat lesion was not taken into consideration.

### Statistical analysis

Comparisons between the two groups were made using the Student's *t* test or Mann Whitney test when appropriate. A *P* value under 0.05 was considered significant. The cumulative risks for colorectal neoplasia, CRC, treatment by immunosuppressors, ileal or colonic surgery and colectomy were calculated using Kaplan-Meier survival curves. The calculation of the cumulative risk for colorectal neoplasia and CRC were done after censoring observations at the time of proctocolectomy or death or at the end of follow up. Risk factors for colorectal neoplasia and CRC were established on the entire population of the study (composed by the two groups). Seventeen variables were tested by univariate analysis using the log rank test. Those variables with *P* values below 0.20 were further tested in a logistic multivariate regression model using a backward stepwise procedure (Cox model). In addition, two therapeutic variables assessing a prolonged treatment with aminosaliclates and immunosuppressors (treatment of more than two years) was entered in the model. The final step retained independent factors with *P* values below 0.05 in a 2-tailed test. Results are given as odds ratios (OR)  $\pm$  95% confidence intervals (CI).

## RESULTS

### Characteristics of the cases and controls

Seventy five IBD patients with concomitant PSC were

Table 1 Demographical and clinical characteristics of the two groups

	PSC-IBD ( <i>n</i> = 75)		IBD without PSC ( <i>n</i> = 150)		<i>P</i>	
Male (%)	53.3		53.3		1	
Age at IBD diagnosis (yr) (mean + SD)	27.8 (14)		28.5 (14)		0.75

Death	8.50%	

PSC-IBD: Inflammatory bowel disease associated with primary sclerosing cholangitis; UDCA: Ursodeoxycholic acid; ERCP: Endoscopic retrograde cholangiopancreatography; MRCP: Magnetic resonance cholangiopancreatography.

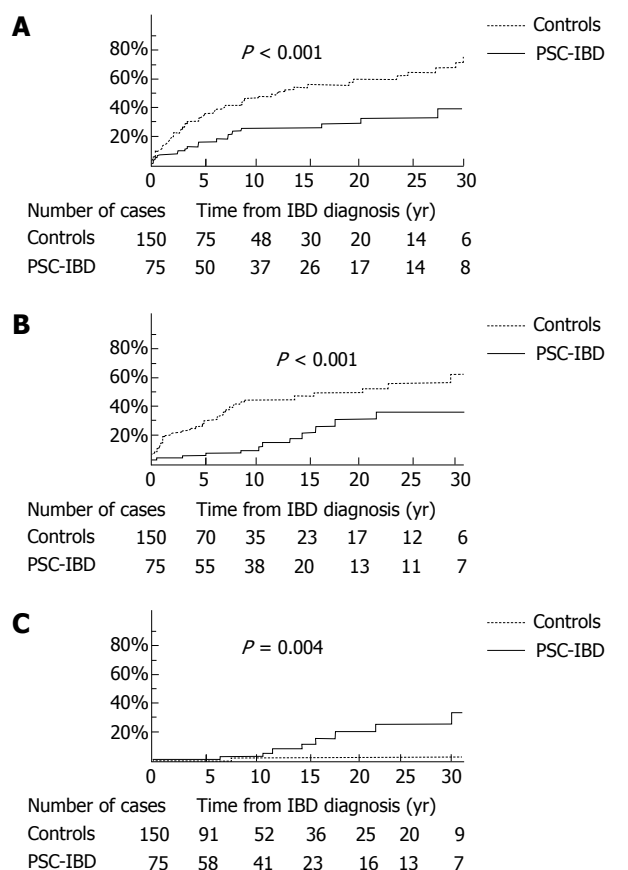

identified and were matched to 150 IBD patients without PSC. Demographic and clinical characteristics

of the two groups are described in Table 1. The mean follow up was longer in the PSC-IBD group. Rectal sparing and ileal involvement were observed in 20% and 19% of PSC-IBD patients (cumulative topography). Systemic manifestations were equally reported in the two groups. The final IBD diagnosis differs between the two groups. Final diagnosis of CD was made more often in the control group than in the PSC-IBD group ( $P = 0.05$ ). Although UC was finally diagnosed in the same proportion in the two groups, the proportion of IBD unclassified was significantly higher in the PSC-IBD group. PSC-IBD patients were significantly less likely to be current smokers (whether before or after IBD diagnosis) than controls without PSC.

Characteristics of patients with PSC and IBD are presented in Table 2. The mean time from onset of IBD to discovery of associated PSC was  $8 \pm 15.6$  years. 94.7% of PSC-IBD patients received ursodeoxycholic acid (UDCA), and the mean delay between PSC diagnosis and UDCA treatment was 13.5 mo. Thirteen patients underwent orthotopic liver transplantation (17.3%).

### IBD severity

**IBD year-by-year activity:** In controls, IBD was active during 351 out of 739 patient-years (47.5%) and hospitalization was required in 90 patient-years (12.2%), whereas PSC-IBD patients exhibited active IBD in

**Figure 1** Cumulative probability of colorectal cancer or dysplasia (A), cumulative incidence of immunosuppressors use (B), cumulative incidence of colonic or ileal surgical resection (C), from the IBD diagnosis date in cases (those with inflammatory bowel disease -associated with primary sclerosing cholangitis) vs controls (those with IBD without PSC).

143 out of 529 patient-years (27%;  $P < 0.001$ ) and hospitalization in 30 patient-years (5.7%;  $P < 0.001$ ).

**Medical treatment:** PSC-IBD patients received significantly more 5-ASA (8.5 years/patient *vs* 3.0 years/patient in controls,  $P < 0.0001$ ). In the PSC-IBD group, 48.6% of the patients required systemic steroids or immunosuppressors, as compared to 85.3% in the control group ( $P < 0.001$ ; OR = 0.15; 95%CI, 0.07-0.31). In fact, in the PSC-IBD group and in the control group, 21.6% and 38% of patients, respectively, had at least once enteral nutrition or systemic steroid therapy ( $P = 0.014$ ; OR = 0.5; 95% CI, 0.2-0.9). Moreover, 27% of PSC-IBD patients *vs* 47.3% of controls received immunosuppressors ( $P = 0.004$ ; OR = 0.4; 95%CI, 0.2-0.8). Finally, cumulative incidence of immunosuppressors use at 10 years after the diagnosis of IBD was 24% in the PSC-IBD group and 46% in the control group ( $P < 0.001$ , Figure 1A).

**Surgery requirement:** A colonic or a small bowel surgical resection was performed more frequently in the control group than in the PSC-IBD group (36.7% *vs* 17.3%;  $P = 0.003$ ). The cumulative incidence was also lower. At 10 years, 10% of patients from the PSC-IBD group and 44% from the control group underwent surgical resection ( $P < 0.001$ , Figure 1B). This difference

between the two groups was essentially due to colonic resection difference as cumulative incidence of small bowel resection was not different between the two groups (log rank test:  $P = 0.14$ ), whereas cumulative incidence of colonic resection showed major differences (log rank test:  $P = 0.0004$ ). Cumulative incidence of colectomy was significantly lower in the PSC-IBD group than in the control group (25.1% *vs* 37.3% at 25 years;  $P = 0.004$ ). The most common indication of colectomy was failure of medical treatment in both groups (55.9% in the control group and 62.5% in the PSC-IBD group;  $P = 0.7$ ). In the PSC-IBD group, the second indication was colorectal neoplasia (37.5%). In the control group the second and third indications were fulminant colitis (38.2%) and colorectal neoplasia (5.9%), respectively.

**Overall survival:** Six deaths were observed in the PSC-IBD group and five in the control group. Global actuarial survival rate at 25 years was similar in the two groups: 91.2% in the control group and 88.4% in the PSC-IBD group ( $P = 0.4$ ). Nevertheless, when censoring observation at liver transplantation, the survival was shorter in PSC-IBD group with a 25-year survival rate of 91.2% in control group and 67.6% in PSC-IBD group ( $P < 0.001$ , Figure 2). In the PSC-IBD group, causes of death were most of the time (5/6) related to chronic liver disease complications including cholangiocarcinoma (2 cases), hepatocellular carcinoma (1 case), decompensated cirrhosis (1 case), and immediate post transplantation complication in one case. Death was of cardiac origin in the last case. In the control group, causes of death were never related to IBD and were due to tuberculosis, lung cancer, ischemic cardiac events and septic shock.

### Colorectal neoplasia risk

**Colorectal dysplasia or cancer risk:** Crude incidence of colorectal neoplasia (dysplasia and cancer) was higher in the PSC-IBD group ( $n = 10$ , 13.3%) than in controls ( $n = 2$ , 1.3%). The cumulative rate of colorectal neoplasia was also higher in PSC-IBD group (25.6% *vs* 1.5% in control group at 25 years;  $P = 0.004$ ; Figure 2). When restricted to cancer only, results were similar with colorectal cancer observed in 10.7% of patients in the PSC-IBD group *versus* 0.7% in the control group, and cumulative rates of colorectal cancer of 23.4 and 0% at 25 years in cases and controls, respectively ( $P = 0.002$ ). The mean IBD duration at cancer diagnosis was 209 mo  $\pm$  93 mo in PSC-IBD group, whereas the only case of colorectal cancer in control group was diagnosed 534 mo after the IBD onset. Nevertheless, duration of the colitis in PSC-IBD patients may be underestimated due to the mild course of the disease.

UDCA exposition were 78.3  $\pm$  23.7 mo and 71.2  $\pm$  8.2 mo in PSC-IBD patients with and without neoplasia, respectively ( $P = 0.75$ ). When taking into account only carcinoma, UDCA exposition were 74.6  $\pm$  25.9 mo and 71.8  $\pm$  8.1 mo in PSC-IBD patients with and without colorectal cancer, respectively ( $P = 0.91$ ).

None of the patients with colorectal cancer had

**Figure 2** Overall survival from IBD diagnosis date in cases (those with inflammatory bowel disease associated with primary sclerosing cholangitis) vs controls (those with chronic ulcerative colitis). Follow up was censored for those who underwent orthotopic liver transplantation.

a familial history of colorectal cancer. Among the 8 colorectal cancers diagnosed in PSC-IBD group (6 PSC-UC and 2 PSC-CD patients), 7 had neither nodal involvement nor metastasis and were treated by proctocolectomy. The remaining patient had a nodal invasion and was treated with adjuvant chemotherapy (5FU and folinic acid). For one patient who underwent a proctocolectomy for uncontrolled active UC, colon cancer was unexpectedly diagnosed on histological examination of the colon. The only case of cancer diagnosed in the control group was localized (T4N0M0) and required colectomy with no adjuvant treatment. The 8 colorectal cancers in PSC-IBD group were located in the right colon, whereas the only case of colorectal cancer in the control group was located in the left colon. Among the 8 cases of colorectal cancer in the PSC-IBD group, 3 patients underwent orthotopic liver transplantation (2 liver transplantations after colorectal cancer diagnosis). Until the end of follow up, no death related to colon cancer was observed.

**Risk factor of neoplasia and colorectal cancer:** The univariate analyses for the risk of colorectal neoplasia and colorectal cancer were established on the entire population of the study and the variables tested are described in Table 3. Five variables were further tested in the multivariate regression model: initial sigmoid colon involvement, extraintestinal manifestations, association with PSC, treatment with 5-ASA for more than two years, and treatment with immunosuppressors for more than two years. After analysis, the only independent variable associated with colorectal neoplasia was association with PSC (OR = 6.9; 95% CI, 3.2-14.9). Similarly, PSC was the only independent variable associated with colorectal cancer (OR = 10.8; 95% CI, 3.7-31.3).

## DISCUSSION

In the present study, PSC-IBD patients had a less active IBD than patients without PSC, and PSC was the only independent risk factor for CRC (Odds Ratio 10.8). Our study was performed in a large cohort and displays a methodological design to address the role of PSC as a risk factor of colorectal cancer in IBD. This case-control study involves 75 PSC-IBD patients. Each case was matched to two IBD controls without PSC. Initial

**Table 3** Univariate analysis for the risk of colorectal neoplasia *n* (%)

	Neoplasia ( <i>n</i> = 12)	No neoplasia ( <i>n</i> = 213)	Log rank <i>P</i>
Male gender	8 (66.7)	112 (52.6)	> 0.20
Age at IBD diagnosis below 16 yr	3 (25)	52 (24.4)	> 0.20
Age at IBD diagnosis below 40 yr	9 (75)	165 (77.5)	> 0.20

PSC	10 (83.3)	65 (30.5)	0.004

IBD: Inflammatory bowel disease associated; PSC: Primary sclerosing cholangitis; CD: Crohn's disease.

disease location accounts for a matching criterion. This matching procedure was chosen to limit confounding factors which could bias colorectal neoplasia risk evaluation. It is, therefore, noticeable that the cumulative disease location was not statistically different between the two groups. In a study from the Mayo Clinic published in 2005<sup>[8]</sup>, a trend to an increase of colorectal neoplasia was observed, but the two groups compared had different rates of pancolitis : 87% in the PSC-IBD group *vs* 54% in the control group ( $P < 0.001$ ). Thus, in this study, the trend observed could be due to the difference in colitis extent. In our study, this bias has been avoided by the matching procedure. Moreover, in the study of Loftus *et al*<sup>[8]</sup>, matching criteria included the year of first visit at the Mayo clinic  $\pm 10$  years and the IBD duration before the first visit at the Mayo clinic  $\pm 5$  years, meaning that two matched patients could have a difference of 15 years regarding the IBD diagnosis date. In our study, this difference was at maximum of 5 years. Finally, our study is the only one to use the birth date as a matching criterion.

The increased risk of colorectal cancer in PSC-IBD patients has been discussed in the literature. Although some studies did not retrieve an excessive risk<sup>[17-20]</sup>, many recent studies are in agreement with our results<sup>[14-16]</sup>. The fact that 33% of patients in the study by definition had PSC could hold back others factors. Nevertheless, our multivariate analysis showed that PSC remained an independent factor. In our study, cumulative incidences of colorectal neoplasia and cancer in the control group were low compared to recent data of the literature. In the study of Rutter *et al* focusing on ulcerative colitis<sup>[24]</sup>, the cumulative incidences of colorectal neoplasia and cancer were higher than in our control group (7.7% and 2.5% *vs* 1.5% and 0% at 20 years). Furthermore, in our

IBD group without PSC, CD was finally diagnosed in 40% of the cases and cumulative incidence of colectomy was higher than in the study of Rutter *et al*<sup>[24]</sup> (22.2% *vs* 9.5% at 20 years). High colectomy rates could play a protective role regarding colonic neoplasia. Indeed, in a middle 1980's study on UC<sup>[25]</sup>, with high colectomy rate (31% at 18 years), the cumulative incidence of colorectal cancer was closer to our results (1.4% at 18 years). More recently, in a population based cohort study from Copenhagen county<sup>[26]</sup>, the overall cumulative probability for development of CRC in UC patients was 1.1% at 20 years with an overall cumulative colectomy probability after 20 years of 27.9%.

To assess IBD activity in the two groups, we took into account the number of active patient-years and the requirement of medical or surgical treatment. Our results pointed out a less active disease in PSC-IBD patients. Ten years after IBD diagnosis, 46% of the patients from the control group had required immunosuppressors (*versus* only 24% in the PSC-IBD group). The lesser severity of PSC associated IBD was also reflected by a lower surgery rate. Moreover, in the control group colectomy was indicated in 94.1% for uncontrolled active disease (with more than one third of severe acute colitis), whereas in PSC-IBD group, colectomy was performed for this indication in only 62.5% of cases (with no case of severe acute colitis). Five-aminosalicylates might prevent colorectal cancer in IBD<sup>[27]</sup> and difference between the two study groups regarding the 5-ASA consumption could have skew our conclusions on colorectal neoplasia and cancer risk. In fact, PSC-IBD patients received more 5-ASA than controls and despite larger use of 5-ASA, this assumed protective factor did not decrease the risk of colorectal neoplasia in this group. The larger use of 5-ASA in PSC-IBD patients can be explained by their weak IBD activity. While patients with PSC-IBD have often a quiescent IBD course and carry on their 5-ASA treatment lengthily, IBD patients without PSC can have a more active disease requiring immunosuppressors. Until recently, 5-ASA was not known to have a preventive effect on colorectal cancer risk in IBD<sup>[27]</sup>, and patients in this situation stopped their 5-ASA treatment.

The reasons of the increased risk of colorectal neoplasia in PSC-IBD patients are still not well understood. The role of endogenous bile acids has been hypothesized, but remains speculative. The high frequency of colorectal cancer and of several other cancers in PSC patients suggest that other factors are involved in the carcinogenesis<sup>[28,29]</sup>. Moreover, two recent studies have suggested that UDCA treatment decrease the colorectal neoplasia risk in PSC-IBD patients<sup>[30, 31]</sup>. As a consequence, it may be hypothesized that our PSC-IBD patients could have presented a higher rate of colorectal neoplasia in the absence of UDCA treatment.

In our patients with PSC, as in other series<sup>[8]</sup>, the most frequent presentation was pancolitis. On the contrary, rectal sparing and backwash ileitis were retrieved in only 20% and 19%, respectively, whereas it was seen more often in several studies (52% and 51%,

respectively, in the recent study by Loftus *et al*<sup>[8]</sup>). In our study, current smoker status was less frequent in PSC-IBD group than in control group. This has already been described and is probably emphasized by a strong association between PSC and UC compared to CD<sup>[32,33]</sup>, and by the protective effect of smoking regarding the onset of UC and PSC<sup>[19,34-36]</sup>.

In our study, most of the deaths in PSC-IBD patients were related to complications of a chronic liver disease. In both groups, death was directly linked neither to an IBD complication nor to a colorectal neoplasia or cancer.

In conclusion, this study confirms that PSC-IBD patients have a higher risk of colorectal neoplasia and cancer than IBD patients without PSC, despite a lower disease activity and a larger use of 5-ASA. It demonstrates that this higher risk is unrelated to disease location or extent. It suggests that a factor directly linked to PSC may increase the risk of neoplasia. Our finding strongly support that these patients require a close colorectal neoplasia tracking by endoscopy, and may be by other methods.

## COMMENTS

### Background

Inflammatory bowel disease associated with primary sclerosing cholangitis (PSC-IBD) may have a distinct IBD phenotype, with a low activity and a high risk of colorectal cancer. However, lower activity may be due to more proximal disease location and rectal sparing, and the high risk of colorectal cancer to the high frequency of pancolitis.

### Research frontiers

IBD patients with colonic involvement have an increase risk of colorectal neoplasia. Some studies suggest that PSC-IBD patients might have an increased risk of colorectal neoplasia compared to patients with IBD alone. However, no previous studies comparing colorectal cancer risk between PSC-IBD and IBD patients and using rigorous matching criteria are available.

### Innovations and breakthroughs

In this study, we confirmed that patients with PSC-IBD have a particular disease phenotype, with a high rate of pancolitis and a lower disease activity compared to IBD matched controls without PSC. Despite a weaker disease activity and a higher use of 5-aminosalicylates, we showed that PSC-IBD patients have a higher risk of colorectal cancer. Contrariwise to previous studies, we used a matching procedure taking into account the disease extent and the diagnosis date. Thus we avoided these major biases.

### Applications

This study confirms that PSC-IBD patients have a higher risk of colorectal neoplasia and cancer than IBD patients without PSC, despite a lower disease activity and a larger use of 5-aminosalicylates. It demonstrates that this higher risk is unrelated to disease location or extent. It suggests that a factor directly linked to PSC may increase the risk of neoplasia. These results strongly support that PSC-IBD patients require a close colorectal neoplasia tracking by endoscopy, and may be by other methods.

### Peer review

The paper by Sokol and co-workers investigated disease activity and cancer risk in inflammatory bowel disease associated with primary sclerosing cholangitis. This paper is interesting and it has clearly stated aims, the sample size and the overall designs of the study are fair, the results adequate to provide experimental evidence and to support valid conclusions. The authors conclusions support previous literature about increased risk of colon cancer in PSC-IBD patients, compared to patients with PSC alone.

phased-array MRI gave an accuracy of 74.50% (21 out of 34). The sensitivity and specificity was found to be 61.76% and 80.88%, respectively. By using ERUS in the detection of lymph node metastases, an accuracy of 76.47% (18 out of 34) was obtained. The sensitivity and specificity were found to be 52.94% and 84.31%, respectively.

**CONCLUSION:** ERUS and phased-array MRI are complementary methods in the accurate preoperative staging of rectal cancer. In conclusion, we can state that phased-array MRI was observed to be slightly superior in determining the depth of transmural invasion (T stage) and has same value in detecting lymph node metastases (N stage) as compared to ERUS.

### Abstract

**AIM:** To compare the diagnostic accuracy of pelvic phased-array magnetic resonance imaging (MRI) and endorectal ultrasonography (ERUS) in the preoperative staging of rectal carcinoma.

**METHODS:** Thirty-four patients (15 males, 19 females) with ages ranging between 29 and 75 who have biopsy proven rectal tumor underwent both MRI and ERUS examinations before surgery. All patients were evaluated to determine the diagnostic accuracy of depth of transmural tumor invasion and lymph node metastases. Imaging results were correlated with histopathological findings regarded as the gold standard and both modalities were compared in terms of predicting preoperative local staging of rectal carcinoma.

**RESULTS:** The pathological T stage of the tumors was: pT1 in 1 patient, pT2 in 9 patients, pT3 in 21 patients and pT4 in 3 patients. The pathological N stage of the tumors was: pN0 in 19 patients, pN1 in 9 patients and pN2 in 6 patients. The accuracy of T staging for MRI was 89.70% (27 out of 34). The sensitivity was 79.41% and the specificity was 93.14%. The accuracy of T staging for ERUS was 85.29% (24 out of 34). The sensitivity was 70.59% and the specificity was 90.20%. Detection of lymph node metastases using

### INTRODUCTION

In recent years, the treatment of rectal carcinoma has been improved by the introduction of new surgical techniques and neoadjuvant therapies. Surgery is still the method of choice for the treatment of rectal carcinoma. The depth of tumor infiltration into the rectal wall and involvement of the regional lymph nodes are the major factors in determining prognosis<sup>[1,2]</sup>. Therefore, assessment of the invasion depth (T stage) and lymph node involvement (N stage) are vital components of preoperative staging. The three main techniques currently used are computed tomography (CT), endorectal ultrasonography (ERUS), and magnetic resonance

imaging (MRI) using various coils. Positron emission tomography (PET) is useful adjunct to systemic and regional staging, especially of a recurrent rectal cancer, but is rarely used as part of loco-regional staging of rectal cancer preoperatively<sup>[3,4]</sup>. The utility of ERUS and MRI for preoperative local staging of rectal carcinoma has been widely demonstrated<sup>[5-7]</sup>. In our study, we compared the ability of ERUS and pelvic phased-array MRI for preoperative local staging of rectal carcinoma. The imaging results obtained by both examinations were correlated with the histopathological gold standard evaluations of the surgical specimens.

## MATERIALS AND METHODS

Between June 2005-July 2007, 34 consecutive patients (15 male and 19 female), with a mean age of 58.7 (ranging from 29 to 75 years) who had biopsy proven rectal carcinoma were included in this study. All of the patients had underwent colonoscopic examination in which a biopsy procedure was also performed preoperatively. Following histopathological analysis of the endoscopic biopsy specimens, patients were diagnosed as having rectal adenocarcinoma. Patients who previously underwent chemotherapy or radiotherapy were excluded from the study. Regarding the location of the rectal tumors, the rectum is considered starting from the anal verge and extending to the rectosigmoid junction. Five cancers (14.71%) were in the upper third of the rectum, 17 cancers (50%) were in the middle third of the rectum and 12 cancers (35.29%) were in the lower third of the rectum.

Fifty patients (44.12%) underwent an abdomino-perineal resection and 19 patients (55.88%) a low-anterior resection. Following surgery, operative specimens were analysed by a pathologist (D.S.) who was unaware of ERUS and MRI results. The sections were evaluated microscopically in terms of determining the depth of transmural tumor invasion and lymph node metastases according to TNM criteria<sup>[8]</sup>.

### ERUS

ERUS examinations were performed by an experienced colorectal endoscopist (A.B.) on this area using a B-K Falcon 2101 ultrasound machine with a 7 and 10 MHz rotating superficial endoprobes. All patients were given enema the day before the examination. Informed consents were obtained from all of the patients prior to the examination.

Endorectal ultrasound was carried out with the patients in the left lateral decubitus position without needing any sedation. The tip of the transducer was covered with a latex balloon filled with degassed water.

The bowel wall is represented in five sonographic layers as a result of differences in acoustic impedance<sup>[9]</sup>. Beginning with the lumen, the five layers are: (1) hyperechoic layer from the interface between mucosa and ultrasound probe; (2) hypoechoic layer produced from the mucosa and muscularis mucosae; (3) hyperechoic layer corresponding to the submucosa; (4) hypoechoic layer corresponding to the muscularis propria; and

(5) hyperechoic layer being the interface between the muscularis propria and perirectal fat/serosa<sup>[9,10]</sup>.

Ultrasonographic staging of tumor depth is denoted by the prefix "u". The ultrasonographic staging corresponds to the TNM classification: (1) uT1, tumor confined to mucosa and submucosa; (2) uT2, tumor infiltrating muscularis propria; (3) uT3, tumor invading perirectal fat; and (4) uT4, tumor infiltrating surrounding organs<sup>[11]</sup>.

The sonographic criteria for identifying involved lymph nodes consist of size greater than 5 mm, mixed signal intensity, irregular margins and spherical rather than ovoid or flat shape.

### MRI

MRI examinations of the same patient group were performed by means of a 1.5 tesla superconducting magnet (GE, Signa, Milwaukee, Wisconsin, USA). All patients gave informed consent for the examination.

During the examination a pelvic coil was used which is a wrap-around surface coil around the pelvis. Patients did not undergo rectal air insufflation, nor did they receive bowel preparation or intravenous contrast. The patients were placed in head - first supine position in the magnet. We did not perform T1 weighted images. The imaging protocol included T2 weighted images obtained by acquiring a non-breath hold FSE sequence by using the following parameters: TR: 3700 ms; TE: 105 ms; Echo train length: 16; Matrix size: 512 × 256; Section thickness: 4 mm; Field of view: 26 cm × 26 cm. T2 weighted images were obtained in axial, sagittal and coronal planes.

A single specialized radiologist (A.M.H.) who was blinded to the ERUS examination results evaluated these images. The layers as showed by MRI are defined as follows: (1) mucosa; thin, low-signal intensity line; (2) submucosa; thicker, higher-signal intensity; (3) muscularis propria; low signal; (4) perirectal fat; high signal layer; and (5) mesorectal fascia; fine, low-signal intensity layer enveloping the perirectal fat and rectum<sup>[10]</sup>.

This fascia represents the plane of dissection during total mesorectal excision and the tumor proximity to within 1 mm of this fascia was taken as a marker of tumor involvement of the circumferential resection margin.

T2 weighted images are more useful for evaluating the rectal wall layers and revealing involvement of other pelvic structures. On these images both the depth of transmural tumor invasion (T staging) and lymph node involvement (N staging) were assessed.

The depth of tumor invasion (T stage) and lymph node involvement (N stage) were classified according to the TNM classification<sup>[8]</sup>. In this staging system: (1) T1 tumors are confined to mucosa and submucosa; (2) T2 tumors invade muscularis propria; (3) T3 tumors extend to mesorectal fat; (4) T4 tumors show adjacent organ invasion. N0: No nodal involvement; N1: One to three regional nodes positive for tumor; N2: Four or more regional nodes positive for tumor.

Spiculation from the tumor margin was considered to indicate malignant tumoral infiltration and, therefore, as

in the Maastricht study<sup>[12]</sup>, spiculated lesions (i.e. showing perirectal strandings) were classified as T3 disease.

Any discrete hypointense lesion detected in the mesorectal fat was interpreted as a lymph node. Lymph nodes of 5 mm diameter or greater were reported as nodal metastases while those lesser than 5 mm diameter were considered to be uninvolved<sup>[13]</sup>.

### Statistical analysis

The overall accuracy, sensitivity, specificity, positive predictive value and negative predictive value were calculated for ERUS and MRI to predict transmural tumor invasion and lymph node involvement using the histopathological findings as the gold standard.

## RESULTS

All tumors could be detected by both ERUS and MRI. The histopathological evaluation of resected tumors revealed adenocarcinoma for all of the patients. Mean histological tumor size was 3.7 cm (range 1.5-6.8 cm). The pathological T stage of these adenocarcinomas was: pT1 in 1 patient, pT2 in 9 patients, pT3 in 21 patients and pT4 in 3 patients. The pathological N staging of these tumors was: pN0 in 19 patients, pN1 in 9 patients and pN2 in 6 patients.

### T staging

Comparison of T staging results obtained with phased-array MRI and ERUS with the pathology is summarized in Tables 1 and 2.

Regarding MRI, one patient with pT3 tumor was understaged as T2 tumor. In 4 patients with pT2 tumors, MRI overestimated as T3 tumors and in 2 patients with pT3 tumors, MRI overestimated as T4 (Figure 1A, C and D). In the remaining cases, with

**Figure 1** A: MRI demonstrates a large tumor passing through the muscularis propria and invading the mesorectal fatty tissue within very close proximity to the mesorectal fascia; lymph nodes are also present; The MRI prediction was a T4 tumor; B: This was predicted as a T3 tumor by ERUS examination; C: Macroscopic specimen shows that the tumor has already filled all the mesorectal fatty tissue but the mesorectal fascia is still intact; D: Pathological examination reveals that this is a T3 stage tumor.

**Figure 2** A: ERUS shows the tumor invading the muscularis propria which can be regarded as a T2 tumor. A lymph node is also seen; B: MRI clearly demonstrates that the tumor is confined to the muscularis propria and does not invade the mesorectal fatty tissue. Lymph nodes are also seen; C: Macroscopic specimen reveals the tumor does not extend to the mesorectal fat; D: Pathology confirms that this is a T2 stage tumor.

a pT1 tumor in 1 patient, pT2 tumor in 5 patients (Figure 2B, C and D), pT3 tumor in 18 patients (Figure 3B, C and D) and pT4 tumor in 3 patients, MRI correctly assessed the stage of transmural tumor invasion. The accuracy of T staging was 89.70% (27 out of 34). The sensitivity was 79.41% and the specificity was 93.14%. MRI correctly predicted invasion in 23 patients and no invasion in 6 patients, thus the overall accuracy in terms of discriminating between pT1-pT2 and pT3-pT4 tumors was found to be 85.29% with a 95.8% sensitivity and 60% specificity. The positive and negative predictive values were calculated as 85.19% and 85.7%, respectively. With ERUS, 4 patients were understaged. In 3 patients with

**Figure 3** A: ERUS examination shows the tumor extend to the mesorectal fat by passing beyond the muscularis propria. A lymph node is also seen; B: MRI defines the tumor as violating the muscularis propria and extending to the mesorectal fatty tissue. Lymph nodes are seen; C: Operation specimen confirms mesorectal invasion; D: Pathology specimen demonstrates tumor cells invading the mesorectum which is indicative of a T3 tumor.

**Figure 4** A: ERUS shows perirectal fat invasion of the tumor and predicts it as T3; B: MRI demonstrates that the tumor is not invading the mesorectal fatty tissue and is confined to the rectum which is considered as a T2 tumor. The lymph nodes are also present in the mesorectal fatty tissue; C: Operation specimen reveals that the tumor does not extend beyond the muscularis propria; D: Pathology confirms that this is a T2 stage tumor.

pT3 tumors, ERUS staged as T2 and in 1 patient with pT4 tumor, ERUS staged as T3. In 6 patients, overestimation did occur where 5 pT2 tumors were overestimated as T3 (Figure 4A, C and D) and 1 pT1 tumor was overestimated as T2.

In the remaining 4 cases with pT2 (Figure 2A, C and D), 18 with pT3 (Figure 3A, C and D) and 2 with pT4 tumors, ERUS correctly predicted the T staging.

The accuracy of T staging was 85.29% (24 out of 34). The sensitivity was 70.59% and the specificity was 90.20%. ERUS was correctly predicted invasion in 21 patients and no invasion in 5 patients, thus the overall

**Table 3** Phased-array MRI and ERUS in detecting lymph node metastases

	Pathology

MRI	6	1	11	2
ERUS	6	4	12	4

accuracy of ERUS in terms of discriminating between pT1-pT2 and pT3-pT4 tumors was found to be 76.47% with a 87.5% sensitivity and 50% specificity. The positive and negative predictive values were calculated as 80.77% and 62.50%, respectively.

### N staging

Comparison of N staging results obtained with phased-array MRI and ERUS with the pathology is summarized in Table 3. Detection of lymph node metastases using phased-array MRI gave an accuracy of 74.50% (21 out of 34). The sensitivity and specificity were found to be 61.6% and 80.88%, respectively. By using ERUS in the detection of lymph node metastases, an accuracy of 76.47% (18 out of 34) was obtained. The sensitivity and specificity were found to be 52.94% and 84.31%, respectively. Overstaging and understaging of phased-array MRI and ERUS in terms of predicting T and N stage are summarized in Table 4.

## DISCUSSION

Treatment options for rectal cancer depend on the stage at presentation<sup>[1]</sup>. Since staging of rectal cancer with digital rectal examination is unreliable, preoperative staging is mostly based on imaging<sup>[14]</sup>. Accurate staging is particularly important because stage 1 tumors are best treated with surgery alone, whereas stage 2 and 3 tumors require preoperative chemoradiotherapy<sup>[15]</sup>.

CT, ERUS and MRI are the imaging modalities predominantly utilized in the preoperative staging of rectal cancer. CT is unable to differentiate the different layers of the rectal wall and has lower overall predictive accuracy than ERUS and MRI. Initially, preoperative local staging of rectal carcinoma using body coil MRI was only 60% accurate in predicting the transmural tumor invasion<sup>[16]</sup>.

This poor result can be attributed to the use of body coil which suffers from low spatial resolution. But in the

recent years, the advent of endorectal MRI has made it possible to generate images with high signal-to-noise ratio (SNR) near the coil with better identification of the rectal wall. The reported accuracy ranging between 81% and 89%<sup>[17,18]</sup> compares favorably with that of ERUS. However, endorectal MRI does have the same limitations as ERUS. Major pitfalls include poor resolution of pelvic structures surrounding the rectum due to the small field of view, and failure to insert the coil in patients with stenosing tumors.

MRI with a pelvic phased-array coil provides slightly lower resolution of the rectal wall compared to the endorectal coil, but allows the entire pelvis to be imaged, and thus, more distant spread can be assessed. In addition, this coil is noninvasive and useful for all rectal tumors regardless of site and size.

ERUS can distinguish the different anatomic layers of the bowel and thus, it appears to have advantages over both CT or MRI in assessing mural penetration and is invaluable in assessing patients considered for local resection. However, it is highly operator dependent, has poor patient acceptability, has limited depth penetration and can not be performed in stenotic tumors or tumors in the upper rectum<sup>[19,20]</sup>. The assessment of the mesorectal fascia is also hampered by its limited field of view.

Kwok *et al*<sup>[21]</sup> concluded that ERUS was the most accurate technique for assessing wall penetration. However, in studies that compared MRI with an endorectal coil with ERUS, the former was found to be as effective as ERUS for assessing T stage and was more effective in assessing nodal involvement. They concluded that MRI using an endorectal coil was the most accurate technique for predicting the pathological stage of rectal cancer.

The meta-analysis of Bipat *et al*<sup>[22]</sup>, also found that ERUS was the best technique for assessing local invasion, but stressed its limitations: operator dependency, no assessment of stenotic tumor, inability to visualize with a rigid probe, tumors located in the upper rectum, inability to detect lymph nodes outside the range of the transducer, and inability to visualize mesorectal fascia. The authors emphasized that none of the techniques were able to identify involved lymph nodes with satisfactory accuracy.

Overall accuracy in the ERUS assessment of tumor depth ranges from 63%-96% with an average of 81.8% in 2718 patients<sup>[9,11,20]</sup>. In a review of cross-sectional studies investigating tumor depth in 873 patients, the overall accuracy was 85%, with sensitivity ranging from 84% in T1 to 76% in T4<sup>[23]</sup>.

Overstaging of tumor depth frequently occurs as a result of perineoplastic inflammation as ultrasound can not clearly differentiate between inflammatory and neoplastic tissue<sup>[11,24]</sup>. Similarly, preoperative biopsy causes hemorrhage and obliteration of sonographic layers<sup>[11]</sup>.

Phased-array coils or pelvic coils have improved spatial resolution with improved signal-to-noise ratio<sup>[7]</sup>, without the technical limitations of endorectal MRI<sup>[25]</sup>. They have the advantage of having a larger field of view of the mesorectal fascia. The role of circumferential

resection margin as an important prognostic indicator of local recurrence is evident and several MRI studies have shown a high accuracy in this regard<sup>[12,25,26]</sup>. Beets-Tan *et al*<sup>[12]</sup> used contrast-enhanced thin section MRI on a 1.5 tesla scanner with a quadrature phased-array spine coil and reported that the depth of transmural tumor invasion and mesorectal fascia involvement were predicted correctly in 83% and 100% of their patients, respectively. Although contrast enhancement may be helpful for differentiating reactive changes from true tumor invasion, they reported that MRI could not be used to distinguish reliably between fibrosis with and fibrosis without tumor cells.

On the other hand, Tatli *et al*<sup>[27]</sup> in their study using gadolinium-enhanced combined pelvic- phased array and endo-rectal coil MRI, surgical treatment groups (stage 1 vs stage 2/3) were accurately predicted in 33 out of 39 patients (85%). Overall, a 93% sensitivity, 86% specificity, and 88% accuracy were achieved in the identification of mesorectal fat invasion.

Brown *et al*<sup>[28]</sup> conducted a prospective study that found correct invasion depth assessment attained in 100% of their cases. Judging from the excellent results reported by this group who were able to differentiate between desmoplastic spiculation and true invasion, the best technique may be the one described by these authors and involves more precise image acquisition and administration of effective contrast material. Thus, thin section MRI performed on a 1.5 tesla scanner with a phased-array coil in general can be considered to provide moderate to good accuracy in the prediction of invasion depth and good accuracy in the prediction of mesorectal fascia involvement. These data are comparable to accuracy rates of 82%-88%<sup>[23,29]</sup> obtained with ERUS for the prediction of invasion depth.

Although overall T stage accuracies by MRI are similar to that of ERUS, MRI has higher accuracies when assessing T3 and T4 tumors as compared to early T stages (T1 and T2)<sup>[25,26]</sup>. When directly compared to ERUS for a T3 tumor, Blomqvist *et al*<sup>[30]</sup> had 11 false positives with ERUS compared to 8 for MRI. On the other hand, Akasu *et al*<sup>[31]</sup> in their series found that, two third of staging errors in invasion depth resulted from overstaging and were most common with pT2 tumors.

This data is consistent with our study in which most staging errors arised from overstaging with both modalities and these were mostly pT2 tumors (4 pT2 cases were overestimated by MRI and 5 pT2 cases were overestimated by ERUS).

Recent studies confirmed that ERUS can accurately stage the depth of tumor invasion particularly in T1 and T2 tumors<sup>[20,22,32,33]</sup>, whereas MRI seems superior in more locally advanced disease<sup>[25,26]</sup>.

Although our patient population is too small to make a final statement, we found that phased-array MRI had slightly better accuracy (89.70%), sensitivity (79.41%) and specificity (93.14%) as compared to ERUS (85.29%, 70.59% and 90.20%, respectively) for detecting the depth of transmural tumor invasion.

Also we obtained better results by phased-array MRI

in terms of predicting early T stages (6 out of 10) as compared to ERUS (4 out of 10).

The preoperative assessment of regional lymph node status forms part of the overall staging of any rectal tumor. The overall accuracy of assessing lymph node involvement ranges between 59% and 95%<sup>[17]</sup>. Nearly all published MR imaging studies of rectal cancer have used size as a criterion for predicting nodal involvement<sup>[17,34]</sup>, although there is no particular size cut-off that can be used to discriminate between benign and malignant lymph nodes.

Brown *et al*<sup>[35]</sup> confirmed that in mesorectal lymph nodes greater than 3 mm, morphological criteria such as an irregular border and mixed signal intensity is definitely a better predictor of lymph node status than size alone. More recent studies suggest that multiple criteria should be used to improve accuracy<sup>[18]</sup>.

Regarding the detection of lymph node metastases, we obtained an accuracy of 74.50% with phased-array MRI and 76.47% with ERUS. Sensitivity was slightly better with MRI than ERUS (61.76% and 52.94% respectively).

ERUS and phased-array MRI are complementary methods for accurate preoperative staging of rectal cancer. Neither ERUS nor MRI can accurately stage tumoral invasion for all T stages. Nodal staging, although better defined with phased-array MRI, is limited for both of the methods<sup>[10]</sup>.

In conclusion, in this study comparing those two modalities we can state that phased-array MRI is slightly superior in determining the depth of transmural tumor invasion (T stage) and has same value in detecting lymph node metastases (N stage) as compared to ERUS.

## COMMENTS

### Background

The preoperative staging of rectal cancer is very important in terms of planning appropriate therapy and determining prognosis. Therefore, the assessment of transmural tumor invasion depth and detection of lymph node metastases are of major importance for which purpose authors have investigated the accuracy of most recently used imaging techniques, namely endorectal ultrasonography (ERUS) and phased-array magnetic resonance imaging (MRI).

### Research frontiers

ERUS and MRI using various coils are currently used imaging modalities for the preoperative staging of rectal carcinoma. The utility of these techniques for staging of rectal carcinoma has been demonstrated well in the literature and both are regarded very useful. In this prospective study, authors' aim was to determine the diagnostic accuracy of each technique in the same cohort of patient population and then to postsurgically compare the obtained results to find out which modality was more effective in the preoperative staging of rectal cancer.

### Innovations and breakthroughs

The results suggested that phased-array MRI is slightly superior to ERUS in determining the transmural tumor invasion depth whereas both techniques seem to yield similar values in detecting lymph node metastases.

### Applications

Based on this study, authors can state that ERUS and phased-array MRI can be used for the preoperative staging of rectal carcinoma and both techniques are accurate determinants of the T and N stages of tumors in most cases. They can also be applied as complementary methods for accurate preoperative staging of rectal cancer.

### Terminology

Pelvic phased-array MR technique provides a full evaluation of rectal wall layers

with a large field of view compared with the standard MR techniques. It uses the pelvic phased-array coil which is a wrap-around surface coil around the pelvis. This coil has the advantages of the surface coil by obtaining higher signal but with greater coverage than a single surface coil and improved homogeneity resulting in higher spatial resolution images.

### Peer review

This is a very clear text, well presented and well written, the compared effectiveness of MRI and endoscopic ultrasound is compared in 34 patients having a colorectal cancer, with have a pathology control. The results are very clear and important.

nodes were lower in the treated than in the model group ( $P < 0.05$ ,  $P < 0.01$  or  $P < 0.01$ ). NF- $\kappa$ B protein expression was negative in all groups. Comparing P-selectin and caspase-3 expression levels among all three groups, there was no marked difference between the model and treated group.

**CONCLUSION:** Dexamethasone can protect mesenteric lymph nodes. The mechanism may be by reducing the content of inflammatory mediators in the blood and inducing lymphocyte apoptosis.

### Abstract

**AIM:** To study the influence and mechanisms of dexamethasone on mesenteric lymph node of rats with severe acute pancreatitis (SAP).

**METHODS:** The SAP rats were assigned to model, treated or sham-operated groups. The mortality, pathological changes of mesenteric lymph nodes, expression levels of NF- $\kappa$ B, P-selectin, Bax, Bcl-2 and caspase-3 protein and changes in apoptotic indexes in lymph nodes were observed at 3, 6 and 12 h after operation. The blood levels of endotoxin, superoxide dismutase (SOD), malondialdehyde (MDA), and endothelin-1 (ET-1) in blood were determined.

**RESULTS:** SOD content, expression of Bax protein and apoptotic index were significantly higher in the treated group than in the model group at different time points ( $P < 0.05$  or  $P < 0.01$ ). Other blood-detecting indexes and histopathological scores of mesenteric lymph

### INTRODUCTION

Severe acute pancreatitis (SAP) with a high incidence of complications and high mortality has been a difficult disease in medical research for many years. Recent studies have confirmed that the release of manifold inflammatory mediators is an important part of the inflammatory cascade reaction. Apart from anti-inflammatory and anti-allergic activity, dexamethasone can improve microcirculation and inhibit enzyme and inflammatory mediators. Dexamethasone has sound therapeutic effects on SAP<sup>[1]</sup>. The mesenteric lymph nodes are very important for the protection of abdominal organs from infection, and perform an important role in maintaining immune balance.

In this experiment, the influence of dexamethasone on changes in inflammatory mediator levels in the

blood, pathological changes of mesenteric lymph nodes, and on changes in expression level of NF- $\kappa$ B, P-selectin, Bax, Bcl-2 and caspase-3 proteins, as well as on apoptotic index, has been observed. This is to explore the protective mechanism of dexamethasone on SAP complicated with mesenteric lymph node injury. This study is believed to be the first to apply tissue microarrays for histopathological determination of mesenteric lymph node disease severity. With advantages such as time and energy saving and high efficiency, tissue microarrays can significantly improve pathological study efficiency.

## MATERIALS AND METHODS

### Materials

Clean grade, healthy male Sprague-Dawley (SD) rats weighing 250-300 g were purchased from the Experimental Animal Center of the Medical School, Zhejiang University. Sodium taurocholate and sodium pentobarbital were purchased from Sigma (USA). Dexamethasone (injection) was purchased from Zhejiang Xinchang Pharmaceutical Company (China). Malondialdehyde (MDA), superoxide dismutase (SOD) assay kits were purchased from Nanjing Jiancheng Bioengineering Research Institute (China), with calculation units of nmol/mL and U/mL, respectively. The serum Endothelin-1 ELA kit (ET-1) was purchased from Cayman Chemical Company (Catalog Number: 583151, USA) and the calculation unit for content was ng/L (or pg/mL). The NF- $\kappa$ B, Bax, Bcl-2 and P-selectin antibody were purchased from Santa Cruz (Santa Cruz, CA). Caspase-3 antibodies was purchased from NeoMarkers. The DNA *in situ* nick end-labeling (TUNEL) kit was purchased from Takara (Japan).

### Animal grouping and rat SAP model preparation

Ninety clean grade, healthy male SD rats were prepared into the SAP models and randomly divided into the model and treated groups (45 rats each). Another 45 were selected to be the sham-operated group. Next, the above groups were randomly divided into 3, 6 and 12-h groups, with 15 rats in each group. The treated group was injected with dexamethasone *via* the tail vein: 0.5 mg/100 g body weight, single dose, 15 min after successful preparation of the SAP model. The sham operation consisted of abdominal opening, pancreas and duodenum turning over, and finally abdominal closure. The sham-operated and model groups were injected with saline *via* the tail vein 15 min after the operation. SAP preparation was as follows. The rats were anesthetized by intraperitoneal injection of 2% sodium pentobarbital (0.25 mL/100 g). In the model group, we identified the duodenal papilla inside the duodenum duct wall, and then used a No. 5 needle to drill a hole in the mesenterium avascular area. After inserting a segmental epidural catheter into the duodenum cavity *via* the hole, it was inserted into the biliary-pancreatic duct, in the direction of the papilla, in a retrograde position. This was followed by retrograde transfusion of 3.5% sodium

Table 1 Pathological score standard of lymph node

Score	Observation indexes
1	Follicle Germinal center dilated, lymphatic sinus dilated, sinus cell hyperplasia or only lymphatic sinus dilated, sinus cell hyperplasia
2	Follicle Germinal center dilated, lymphatic sinus dilated, sinus cell hyperplasia, spotty necrosis in mantle zone and Germinal center or only lymphatic sinus dilated, and sinus cell hyperplasia, infiltration of neutrophil, eosinophile granulocyte and plasmocyte
3	Follicle Germinal center dilated, lymphatic sinus dilated, sinus cell hyperplasia, spotty necrosis in mantle zone and Germinal center, infiltration of neutrophil, eosinophile granulocyte and plasmocyte

taurocholate 0.1 mL/100 g by microinjection pump at the speed of 0.2 mL/min, and then the hole in the duodenum lateral wall was sutured<sup>[2-6]</sup>.

### Survival rate and pathological changes

Rat mortality was measured at 3, 6 and 12 h after operation, and survival was calculated. We observed the pathological changes in the mesenteric lymph nodes. After euthanasia with sodium pentobarbital, we collected mesenteric lymph node samples from the rats. The lymph node pathological score was determined according to a set of standards developed by Zhang (Table 1).

### Observation index

The levels of plasma endotoxin, and serum SOD, MDA and endothelin-1 (ET-1) were determined from blood taken from the heart. The above indexes were all detected according to the manufacturers' instructions.

### Tissue microarrays and staining

Prepared tissue microarrays of mesenteric lymph node and adopted SP (streptavidin-peroxidase) method for immunohistochemical staining, observed the NF- $\kappa$ B, Bax and Bcl-2 protein expression respectively. TUNEL Staining was carried out as follows<sup>[7]</sup>. NF- $\kappa$ B, P-selectin, Bax, Bcl-2 and Caspase-3 protein expression: We applied tissue microarrays to prepare microarray sections of mesenteric lymph node; Adopted SP (streptavidin peroxidase) method for immunohistochemical = staining. We observed protei expression in mesenteric lymph nodes under light microscope, as follows: (-) < 10% positive cells; (+) 10%-20% positive cells; (++) 20%-50% positive cells; and (+++) > 50% positive cells. We applied the tissue microarrays to prepare the microarray sections of mesenteric lymph node. TUNEL staining was used to visualize the number of apoptotic cells in the lymph node tissue microarrays, and the apoptotic index (%) was calculated.

### Statistical analysis

Statistical analysis was conducted by using SPSS 11.5 software (SPSS, USA). The Kruskal-Wallis test or analysis of variance was applied for comparison of the three groups. The Bonfferoni test was also applied.  $P \leq 0.05$  was considered statistically significant.

**Table 2** Comparison of different indexes level in blood (*M* (*Q<sub>R</sub>*))

Index	Sham-operated group (h)			Model group (h)			Treated group (h)		
	3	6	12	3	6	12	3	6	12
Endotoxin (EU/mL)	0.02 (0.01)	0.02 (0.01)	0.02 (0.01)	0.04 (0.02)	0.06 (0.03)	0.06 (0.02)	0.03 (0.01)	0.04 (0.01)	0.04 (0.02)
MDA (nmol/mL)	9.9 (9.9)	13.2 (6.6)	13.2 (9.9)	29.7 (6.6)	33.0 (9.9)	29.7 (14.9)	19.8 (9.9)	26.4 (13.2)	26.4 (13.2)
SOD (U/mL)	105.6 (8.3)	103.6 (6.2)	99.2 (16.2)	76.6 (13.0)	73.0 (24.5)	77.6 (12.6)	90.8 (13.4)	91.9 (11.6)	88.7 (13.7)
ET-1 (ng/L)	14.05 (1.78)	14.53 (2.082)	14.78 (2.28)	17.97 (5.57)	19.21 (7.02)	18.31 (5.06)	13.64 (1.54)	13.86 (2.64)	13.66 (2.47)

## RESULTS

### Survival

In the model group, the mortality was 0, 0 and 13.33% (2/15) at 3, 6 and 12 h, respectively. The sham-operated and treated groups showed 100% survival, while there was no significant difference between the model and treated groups.

### Comparison of serum MDA, SOD and ET-1 levels

Serum MDA was significantly higher in the model and treated groups than in the sham-operated group at all time points ( $P < 0.01$ ). Serum MDA in the treated group was significantly lower than in the model group at 3 and 6 h ( $P < 0.01$ ) (Table 2).

Serum SOD in the model and treated groups was significantly lower than in the sham-operated group at different time points ( $P < 0.01$ ). Serum SOD in the treated group was significantly higher than in the model group at different time points ( $P < 0.01$ ) (Table 2).

Serum ET-1 differed significantly between the treated and sham-operated groups at various time points ( $P < 0.05$ ), and the level in the model group significantly higher than that in the sham-operated group at various time points ( $P < 0.01$ ). Serum ET-1 in the treated group was significantly lower than that in the model group at 3 and 12 h ( $P < 0.01$ ), and the level in the treated group was significantly lower than that in the model group at 6 h ( $P < 0.01$ ) (Table 2).

### Pathological changes in lymph nodes, seen by light microscopy

The mesenteric lymph nodes in the sham-operated group had normal morphology and structure. In the model and treated groups, swollen lymph nodes, dilated follicular germinal centers and expanded lymphatic sinuses were seen in most cases. Sinus cell hyperplasia and spotty necrosis in the mantle zone and germinal center of the lymph nodes were clearly visible, and neutrophil and plasmocyte infiltration was seen in a few cases. There were no marked differences in the pathological changes between the model and treated groups, but spotty necrosis in the mantle zone and germinal centers, as well as inflammatory cell infiltration only occurred in a few rats in the treated group.

**Figure 1** Tissue microarrays of mesenteric lymph nodes were prepared and stained for immunohistochemistry ( $\times 200$ ). (A) NF- $\kappa$ B expression in the treated group (6 h); (B) Bax protein expression in the sham-operated group (3 h); (C) Bax protein expression in the treated group (12 h); (D) Bcl-2 protein expression in the treated group (3 h).

### Comparison of lymph node pathological scores

The pathological score in the model group was significantly higher than in the sham-operated group at different time points (6 h,  $P < 0.05$ , 3 and 12 h,  $P < 0.01$ ). The score in the treated group was significantly higher than in the sham-operated group at 12 h ( $P < 0.01$ ). The pathological score was significantly lower in the treated group than in the model group at 6 h ( $P < 0.05$ ) (Table 3).

### Changes in lymph node expression of NF- $\kappa$ B, P-selectin, Bax, Bcl-2 and caspase-3

Expression of NF- $\kappa$ B was negative in all groups at all times (Figure 1A). Lymphocytes were stained positively for P-selectin. There was no significant difference in staining in any of the groups. Lymphocytes were stained positively for Bax. Expression of Bax was significantly higher in the treated group than in the model group at 12 h ( $P < 0.01$ ). There was no marked difference in the other groups (Tables 3 and 4, Figure 1B and C). Lymphocytes were stained positively for Bcl-2. There was no significant difference among any of the groups at different time points (Tables 3 and 4, Figure 1D).

### Comparison of caspase-3 expression level of lymph node

Lymphocytes were stained positive for caspase-3. There was no significant difference between the sham-operated and model groups at all time points. Caspase-3 expression in the sham-operated group was significantly lower than in the treated group at 12 h ( $P < 0.05$ ). There was no significant difference between the model and treated groups at all time-points (Tables 3 and 4).

### Comparison of apoptotic index in lymph nodes

The apoptotic cells in lymph nodes were the lymphocytes. Apoptotic cells appeared in three rats in the sham-operated group at 6 h, with an apoptotic index between

**Table 3** Comparison of different pathological indexes in the lymph node ( $M(Q_R)$ )

Indexes	Sham-operated group (h)			Model group (h)			Treated group (h)

10 and 20 per 10000 cells. Apoptotic cells appeared in four rats in the model group at 12 h, with an apoptotic index between 6 and 50 per 10000 cells. Apoptotic cells appeared in three, eight and nine rats at 3, 6 and 12 h, respectively, with an apoptotic index between 2 and 160 per 10000 cells in treated group. There was no significant difference among any of the groups at 3 h. The apoptotic index was significantly higher in the treated group than in the model group at 6 h ( $P < 0.05$ ). The apoptotic index was significantly higher in the treated group than in the sham-operated group at 12 h ( $P < 0.01$ ) (Table 4 and Figure 2).

## DISCUSSION

At present, the pathogenesis of SAP has not been fully elucidated<sup>[7,8]</sup>. We are attracted to the barrier function of mesenteric lymph nodes during the onset and progression of SAP<sup>[9]</sup>. The normal mesenteric lymph node barrier can effectively prevent intestinal bacteria and endotoxin entering the body and maintain homeostasis<sup>[10-12]</sup>, while the function of the lymphocytes in the mesenteric lymph nodes reflects the function of the whole intestinal immune barrier<sup>[13]</sup>. If the function of the immune barrier is injured, the mesenteric lymph nodes are damaged and permeability of mucous membrane of small intestine is increased<sup>[14]</sup>, which reduces their capacity to phagocytose ectopic bacteria and endotoxin. The excessive release of inflammatory mediators during SAP is the main cause of mesenteric lymph node injury. According to the results of this experiment, after inducing SAP, the level of inflammatory mediators such as ET-1 and MDA in the blood was significantly higher in the treated group than in the sham-operated group, and the level of

inflammatory mediators was positively correlated with the severity of mesenteric lymph node injury.

Endotoxin can invade the body and cause gut-origin endotoxemia, increase permeability of mesenteric lymph nodes, and promote invasion of intestinal bacteria and endotoxin. As one of the important common mediators in inflammatory mediator cascade reaction of inflammatory reaction<sup>[15-17]</sup>, Nitric oxide (NO) can be regarded as an index of SAP. However, some researchers<sup>[18]</sup> believe that a small amount of endogenous NO can protect the body from ischemia-reperfusion injury, and prevent any increase in intestinal vasopermeability induced by endotoxemia and bacteria translocation.

NF- $\kappa$ B is a transcription factor that participates in the regulation of expression of inflammatory molecules. Its activation is a key initial step in the inflammatory reaction<sup>[19-21]</sup>. However, NF- $\kappa$ B was found to be negative in this experiment, which indicates that there is no direct relation between inflammatory reactions in the mesenteric lymph nodes and NF- $\kappa$ B. This study also showed that dexamethasone decreased the level of inflammatory mediators. It was demonstrated that dexamethasone exerted its anti-inflammatory effect by lowering the level of several inflammatory factors in the serum, inhibiting their production, and blocking the cascade reaction of the inflammatory mediators. P-Selectin is a member of the family of cell adhesion molecules. However, the content is very low and its expression is significantly increased with acute inflammation<sup>[22,23]</sup>. It is also an important indicator of inflammation<sup>[22,24]</sup>. In this study, there was no marked difference in P-selectin expression. Therefore, we suppose that P-selectin expression is not related to lymph node injury.

**Figure 2** TUNEL staining, showing the pathological changes in the mesenteric lymph nodes ( $\times 400$ ). (A) In the sham-operated group (6 h), there were no apoptotic cells; (B) In the model group (12 h), several apoptotic cells appeared; (C) treated group (6 h); (D) apoptotic cells were increased in the treated group (12 h).

Apoptosis also plays an important role during the onset, progression and prognosis of AP. It has been found<sup>[25,26]</sup> that when necrosis and apoptosis coexist and necrosis prevails, inducing apoptosis results in body protection. Both necrosis and apoptosis are mechanisms of death for injured cells<sup>[27]</sup>. Unlike necrosis, apoptosis does not release harmful substances in lysosomes or cause intense inflammatory reactions<sup>[28]</sup>. The present study showed that expression of Bax protein was significantly higher in the treated group than in the model group at 12 h. The expression of Bcl-2 protein was reduced. Bcl-2 expression was positively correlated with apoptosis level of mesenteric lymph nodes, and negatively correlated with SAP severity. The expression of Bax and Bcl-2 proteins was not significant in the model group at any time, with less apoptosis, which indicates that dexamethasone can protect lymph nodes by increasing Bax protein, inhibiting Bcl-2 protein, and inducing apoptosis of mesenteric lymph nodes. The apoptotic index was significantly higher in the treated group than in the model group, while the pathological score was significantly lower in the treated group than in the model group, which indicates that dexamethasone can promote the apoptosis of mesenteric lymph nodes and protect the lymph nodes. The massive apoptosis of lymph node cells certainly inhibits excessive inflammation, and protects several organs from SAP-related lymph node injury. Caspase-3 is one of the important proteases that can induce apoptosis, and is also the final effector in the caspase cascade effect, which is involved in apoptosis. Moreover, it has a pivotal position in the process of stopping the protease cascade. Caspase-3 is a marker of apoptosis and it is also involved in the process. It can destroy a variety of protease complexes in cells with the digestive way, activate intranuclear nuclease to cause DNA schizolysis, form DNA fragments, undermine cell calcium pump function, and lead to intracellular calcium overload<sup>[29,30]</sup>. Inhibiting caspase-3 activity can reduce the occurrence of

apoptosis<sup>[31]</sup>. In this study, there was no marked difference in caspase-3 expression level in the model and treated groups; therefore, we suppose that caspase-3 expression is not related to severity of lymph node injury.

Núñez *et al.*<sup>[32]</sup> found that apoptosis occurs with high concentrations of NO. Increasing NO in serum can alleviate the inflammatory reaction of AP. Apoptosis during SAP is the result of complex action of various factors whose relationships form a network structure. Since 1952, when Stephensen *et al.*<sup>[33]</sup> first reported the therapeutic effect of glucocorticoids on AP, many empirical studies have confirmed that glucocorticoids can improve survival of animals with pancreatitis<sup>[33-35]</sup>, although the precise mechanism is unclear. As a long-acting glucocorticoid, dexamethasone can be applied extensively in a clinical setting. It can regulate inflammatory mediators<sup>[36,37]</sup>, improve microcirculation<sup>[38]</sup>, eliminate OFR (oxygen free radical)<sup>[39]</sup>, and inhibit NF- $\kappa$ B<sup>[40,41]</sup>. There have now been several studies on the mechanism of dexamethasone in SAP, but there has still been no study on the effect of dexamethasone on mesenteric lymph nodes. We are of the opinion that a few apoptotic lymphocytes in lymph nodes mean that the function of lymphocytes has been slightly injured. However, the significance of lymphocyte apoptosis is that its immunological function is severely inhibited, which can have a protective effect.

Since it was first reported by Kononen *et al.*<sup>[42]</sup> in 1998, tissue microarray has been extensively used<sup>[43-45]</sup>, but there have been no reports on its application in the study of pancreatitis. In this experiment, the diameter of microarray tissue was only 2 mm. Super sensitive SP immunohistochemistry and TUNEL technique were used. The observation indexes of this experiment are satisfactory. This study demonstrates that tissue arrays of 2.0 mm diameter have advantages such as reliability, savings in time, energy and reagents, and convenient control<sup>[46,47]</sup>. This study provides a new theoretical basis for the application of tissue microarray in the pathological examination of AP.

## COMMENTS

### Background

The normal mesenteric lymph node barrier can effectively prevent intestinal bacteria and endotoxin entering the human body and maintain homeostasis. The function of lymphocytes in the mesenteric lymph nodes reflects the function of the whole intestinal immune barrier. If the function of the immune barrier is injured, the mesenteric lymph nodes will be damaged, which reduces the capacity for phagocytosis of ectopic bacteria and endotoxin. The excessive release of inflammatory mediators during SAP is the main cause of mesenteric lymph node injury.

### Research frontiers

SAP has a high incidence of complications and high mortality, and has been a difficult disease in medical research for many years. Recent studies have confirmed that the release of many inflammatory mediators is an important reason for the inflammatory cascade reaction. Apart from anti-inflammatory and anti-allergic activity, dexamethasone can improve microcirculation and inhibit enzymes and inflammatory mediators. Dexamethasone has sound therapeutic effects on SAP. In this study, the influence of dexamethasone on changes in content of inflammatory mediators in blood, pathological changes of mesenteric lymph nodes, and changes of expression of NF- $\kappa$ B, P-selectin, Bax, Bcl-2 and caspase-3 proteins, as well as apoptotic index, was investigated, to explore the

protective mechanism of dexamethasone on SAP complicated with injury of mesenteric lymph nodes.

### Innovations and breakthroughs

This study applied tissue microarrays for histopathological examination of mesenteric lymph nodes, which is believed to be the first report of the pathological category for severity of lymph nodes around the world.

### Applications

With advantages such as time and energy savings and high efficiency, tissue microarrays can significantly improve study efficiency. We applied tissue microarrays to pathological detection and obtained good results.

### Terminology

NF- $\kappa$ B is a transcription factor that participates in regulating expression of inflammatory molecules. Its activation is a key initial step in the inflammatory reaction. NF- $\kappa$ B can regulate the expression of inflammatory mediators.

### Peer review

This is a very interesting study. The authors studied the influences and mechanisms of dexamethasone on mesenteric lymph nodes in rats with SAP. It is believed to be the first report of the pathological classification of severity of lymph node injury around the world.

Prevalence of Barrett's esophagus in patients with moderate to severe erosive esophagitis. *World J Gastroenterol* 2008; 14(22): 3518-3522 Available from: URL: <http://www.wjgnet.com/1007-9327/14/3518.asp> DOI: <http://dx.doi.org/10.3748/wjg.14.3518>

### Abstract

**AIM:** To investigate the proportion of patients with moderate-severe erosive esophagitis (EE) who will have Barrett's esophagus (BE) after healing of inflammation.

**METHODS:** Patients with EE of Los Angeles (LA) class B, C and D who underwent follow-up endoscopy documenting complete mucosal healing.

**RESULTS:** A total of 86/169 patients were suspected of having BE (38 before healing and 48 after healing of EE) and, 46/86 eventually had the histological confirmation. At index esophago-gastro-duodenoscopy (EGD), BE was suspected in 38/169 (22%), and ultimately, histologically confirmed in 20 of these. In 11 patients where biopsies were performed in the presence of inflammation, BE was detected in 2 and missed in 5 (including 2 dysplasias). In 131/169 patients (77.5%), BE was not suspected at index EGD. After healing of EE though, 48 patients had suspicion of BE who underwent biopsies, and in 26 of these histology was positive for BE. The length of inflammation had a linear correlation with the length of BE ( $P = 0.01$ ). Out of multiple variables to predict BE, only the suspicion at index endoscopy was statistically significant ( $P = 0.01$ ).

**CONCLUSION:** BE was seen in 46/169 (27%) patients with EE of LA class B, C and D. The length of EE can predict the length of underlying BE segment.

### INTRODUCTION

Gastroesophageal reflux disease (GERD) affects 10-20 percent population in Western nations and may be complicated by erosive esophagitis (EE), Barrett's esophagus (BE), and esophageal adenocarcinoma among others<sup>[1]</sup>. In a large population-based cohort study, the estimated incidence of esophagitis was 2.4 per 1000 patient-years<sup>[2]</sup> and the importance of this complication rests in its potential for masking underlying BE, a condition clearly associated with adenocarcinoma<sup>[3]</sup>. BE appears to have a higher prevalence in middle-aged to elderly men<sup>[4-6]</sup>. In one study involving a population of veteran patients, the prevalence of BE was 13% in the setting of typical gastro-esophageal reflux symptoms<sup>[7]</sup>. The current opinion, once EE is found on endoscopy, is to provide effective anti-secretory therapy to eliminate the confounding factor (both visual and histological) of esophagitis, in order to correctly diagnose BE and any associated dysplasia. However, this practice is not universally accepted by the gastroenterology physicians due to limited data on the prevalence of BE in patients with EE<sup>[8]</sup>. We aimed to investigate the prevalence of BE in a group of patients with moderate-severe EE, after achieving complete healing on follow-up endoscopy.

## MATERIALS AND METHODS

### Patients

Records of all esophago-gastro-duodenoscopies (EGDs) performed at our institution between January 1998 and June 2006 were retrospectively reviewed from our endoscopy database. Our standardized, electronic report protocol contains all the essential elements included in the analysis (length of EE, Los Angeles classification of EE, length of suspected BE segment, size of hiatus hernia, *etc*). Other required information was obtained from patient's electronic medical records. All EGDs were either performed independently by a board certified, faculty gastroenterologist or by an in-training fellow under direct supervision of a faculty member. Photo documentation was obtained in all cases. Our department mandates completion of all elements of endoscopy reporting and adherence to the standardized biopsy protocol. In addition, patients with EE of class C and D are routinely (irrespective of the suspicion of BE) followed endoscopically, while class B patients undergo a follow-up EGD only if a normal Z-line cannot be clearly identified. For follow-up purposes, patients are routinely given written instructions at the conclusion of the initial visit in addition to a mailed letter, and a reminder phone call by the department clerk the day before their follow-up appointment. The patient population using our department's services comprises of 80% Caucasians, 15% Hispanics and 5% African-Americans.

LA classification of EE defines class A as one or more mucosal breaks confined to the mucosal folds, each no longer than 5 mm; class B, at least one mucosal break > 5 mm, confined to the mucosal folds, not contiguous between the tops of 2 folds; class C, at least one mucosal break contiguous between the tops of 2 or more mucosal folds but not circumferential ( $\leq 75\%$  of the luminal circumference) and class D, one or more circumferential mucosal breaks (comprising > 75% of esophageal luminal circumference). Inclusion criteria: all patients with EE of LA classes B, C, or D, who after receiving intensive anti-secretory therapy using double dose proton pump inhibitors (institutional formulary restricted to the use of omeprazole, lansoprazole and rabeprazole) had achieved complete mucosal healing, documented on at least one follow-up EGD. Exclusion criteria: patients with EE of LA class A, those without EGD follow up, those who failed to achieve complete mucosal healing after PPI therapy, those with known BE, and those with an EGD performed at our institution prior to the index examination. Demographic data including age, race, sex, and body mass index were noted. At index EGD length and LA class of EE, presence/absence of hiatus hernia and its estimated size were recorded. If biopsy specimens were obtained at index procedure due to suspected BE, the results of these were noted and compared with results of biopsies taken at follow-up endoscopy. Finally, if BE was endoscopically suspected, its length, and results of four quadrant biopsies taken at 2 cm intervals (a uniform practice in our department), when applicable, were documented.

For non-circumferential BE (tongue like salmon colored projections above the esophago-gastric junction), the mucosal sampling was obtained in a similar fashion from the involved area. BE was suspected endoscopically by the presence of salmon-colored columnar-appearing mucosa in the tubular esophagus, and confirmed by the presence of specialized intestinal metaplasia containing goblet cells, on histology. BE was labeled as short segment (SSBE) or long segment (LSBE) based on the length of the columnar appearing mucosal segment of < 3 cm, or  $\geq 3$  cm, respectively. The presence of any grade of dysplasia on histology was recorded. This study was approved by our institutional review board (IRB).

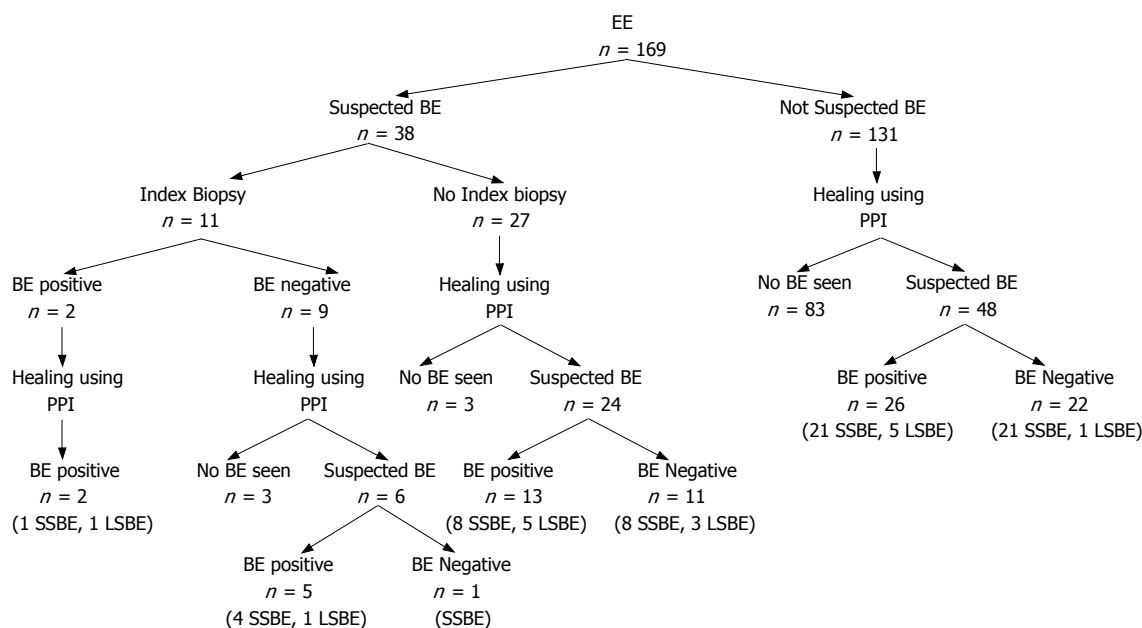

### Statistical analysis

Continuous variables were reported as mean  $\pm$  standard error of the mean (SEM). Categorical data were listed as percentages (%). For continuous outcomes, analysis of variance (ANOVA) was used to determine differences between groups. Logistic regression was performed to identify variables predictive of BE. These variables included age, length and severity of EE at index endoscopy, size of hiatus hernia, body mass index, and suspicion of BE at index endoscopy. Also, linear regression was used to determine predictors of the length of BE found after healing. A two-tailed  $P < 0.05$  was considered statistically significant.

## RESULTS

A total of 546 patients had the endoscopic diagnosis of EE at our institution between January, 1998 and June, 2006. Of these, 377 were excluded from the study (EE class A,  $n = 168$ ; prior EGD or history of BE,  $n = 91$ ; EE class B with visibly normal Z-line,  $n = 68$ ; failure to follow up,  $n = 18$ ; incomplete healing,  $n = 18$ ; insufficient documentation,  $n = 14$ ). After excluding above, 169 patients met the inclusion criteria of LA class B (36/169, 21.3%), C (83/169, 49.1%), or D (50/169, 29.6%) EE, and subsequently demonstrated complete healing on at least one follow-up EGD (mean duration: 12 wk; range: 2-52 wk; only 2 patients underwent FU EGD at 52 wk). The indications for the index EGD varied as listed in Table 1. The demographic information of the study population is listed in Table 2. The characteristics of the excluded patients were similar to the patients included in the study. Patients initially diagnosed with EE were mostly (98%) Caucasian men, and those diagnosed with BE were all men. The average age, BMI, and size of hiatus hernia were similar between BE and non-BE groups (Table 2). A hiatus hernia was more prevalent in patients diagnosed with BE than non-BE patients (90.2% *vs* 72.6%, respectively;  $P < 0.001$ ). The mean length of EE segment in the study population was  $4.44 \pm 0.35$  cm; the mean length of EE in class B was  $2.94 \pm 0.56$  cm; class C,  $3.83 \pm 0.38$  cm and class D,  $6.30 \pm 0.77$  cm. Interestingly, the mean length of EE segment increased as the severity of LA class increased (D > B/C;  $P = 0.002$ ).

A total of 86/169 (50.9%) patients were suspected

of BE (either before or after healing of EE), and 80 of these who underwent repeat biopsies, histological confirmation was obtained in 46 (57.5%). Histological confirmation of BE in patients with suspected LSBE was 12/16 (75%) and in patients with suspected SSBE was 34/64 (53.1%).

In 38 (22.5%) patients, BE was visually suspected at index EGD and in 11 of these biopsies were performed during the same procedure. Interestingly, BE could initially be confirmed only in 2 of these 11; however, after healing, 6 still had suspicion of BE and repeat biopsies confirmed specialized intestinal metaplasia in 5 of them (two patients also had a low grade and a high grade dys-

**Table 2** Demographic information of the patients undergoing index endoscopy (n = 169)

Patient demographics	BE group (n = 46)	Non BE group (n = 123)

plasia each). In the remaining 27 with suspicion of BE at index EGD who did not undergo index biopsies, 24 were still suspected of BE after healing of EE, and in 13/24 histology was positive for BE on repeat biopsies (Figure 1).

A total of 131 EE patients were not suspected of having BE at index EGD. After healing of EE though, BE was suspected in 48/131 (who underwent biopsies). Of these, 26 were histologically confirmed as having BE (Figure 1).

Overall, 46/169 (27%) from the study population had BE confirmed by histology. The breakdown by LA class included 8 (17.4%) from B (6 SSBE, 2 LSBE), 25 (54.3%) from C (20 SSBE, 5 LSBE) and 13 (28.3%) from class D (8 SSBE, 5 LSBE) EE. This represented 22.2% of all patients from class B, 30.1% from C and 26% from class D esophagitis.

Logistic regression performed to identify variables that could predict the presence of BE (including age, BMI, length and severity of EE, size of hiatus hernia, and suspicion of BE at index) found only "suspicion of BE at index" to be significant. Patients in whom BE was

**Figure 2** In patients with EE the length of inflammation had a linear relationship with the length of BE segment.

suspected at index EGD were 4.5 times more likely to have histological confirmation than those in whom it was not suspected at index EGD ( $P = 0.01$ ). Linear regression was also performed and it was found that the length of EE correlated with the length of BE (found after healing of esophagitis); there appeared to be a linear relationship between these two variables ( $P = 0.009$ ) as shown in Figure 2.

## DISCUSSION

BE is an important, potentially pre-malignant complication of gastro-esophageal reflux disease. The major reason to evaluate patients with longstanding GERD is to recognize BE<sup>[9]</sup>. The possible role of GERD induced EE leading to BE has not been clearly established, but possible cellular injury and subsequent healing with columnar epithelium has been hypothesized<sup>[10]</sup>. On the other hand, this is also possible that the pathogenic mechanisms for the two entities (i.e., EE and BE), are different, but are often seen together due to shared patient characteristics and risk factors. Interestingly though, BE has also been identified in up to 25% of asymptomatic or minimally symptomatic individuals<sup>[11]</sup>.

In a multi-center study of non-veteran patients (60% men, 78% Caucasians) presenting for colonoscopy, the prevalence of BE was 6.8% in those with or without the symptoms of heartburn, and rose up to 15% if they had EE on the endoscopy<sup>[12]</sup>. In this study, patients with minor grades of esophagitis were not re-evaluated after medical therapy. In a study by Hanna *et al*<sup>[13]</sup>, 176 patients with EE but without apparent BE were followed for a mean of 11 wk while on a standard dose of PPI. At follow-up 116 (67%) showed complete healing of EE. Of these, 32 (27.6%) were suspected of having BE, but histology was confirmatory only in 16 (50%). Overall, BE was seen in 21 cases (12%), most of which had short-segment BE. In contrast, our study shows 27% prevalence of BE in association with higher grades of EE (some requiring more than one follow-up endoscopy to document complete healing). Again, in the study by Hanna *et al*, patients with visually suspected BE were excluded, and furthermore, 33% of their patients did

not achieve complete healing at follow up EGD and biopsies. These two factors could have accounted for the relatively low proportion of BE patients in their study. Interestingly, in our study, if we exclude patients with suspected BE (left arm of Figure 1) at index EGD, the prevalence of BE in the remaining patients (right arm of Figure 1) drops to 19.84% with most of these having SSBE (80.76%). In our study, the histological confirmation rate for BE was 18.18% (2/11) when biopsies were performed in the presence of inflammation and 56.4% (44/78) when performed after complete healing of EE. In two patients, BE with dysplasia was missed when biopsies were taken in the presence of inflammation. This does raise additional concerns that sampling for BE can be more difficult in those with EE and the potential for missing dysplastic areas could be higher. In our study, a significant number of patients with class B esophagitis did not undergo a follow-up EGD, as endoscopists felt confident that BE was not present.

In our analysis, as the severity of EE increased, so did the average length of erosions. Our data also suggest that the length of BE (if found at follow-up) can be predicted by the length of inflammation seen at the index examination. The strongest predictor for the presence of BE was the suspicion of it at index endoscopy. When visual diagnosis of BE was made, the final diagnosis of BE could be established only in 53% (46/86); although a sampling error cannot be ruled out, similar findings have also been reported by other investigators<sup>[14,15]</sup>. It will be interesting to see if newly available mucosal enhancing techniques (chromoendoscopy, high definition/magnification, narrow band imaging or confocal endomicroscopy) with the ability of targeted biopsies could increase the yield of diagnosing BE with or without the presence of EE.

The limitations of this study include the retrospective nature of the analysis and the fact that the patient population comprises mostly of older men who are at increased risk of EE<sup>[16]</sup> and BE<sup>[17]</sup>. Therefore, these data might not be applicable to populations who have higher preponderance of women and relatively younger patients. Furthermore, in the study, the possibility of higher inter-observer variability of EE grading cannot be ruled out.

In conclusion, BE was seen in 27% of patients with moderate-severe grades of EE. Esophageal inflammation can mask underlying BE or dysplasia, and make biopsies less accurate. The length of EE at index endoscopy may predict the length of BE at follow-up endoscopy. Therefore, it is suggested that follow-up endoscopy be performed, and evaluation for potential BE made once complete endoscopic healing of moderate-severe EE is achieved.

## COMMENTS

### Background

Gastro-esophageal reflux disease may be complicated by erosive esophagitis (EE) and Barrett's esophagus (BE). BE is clearly associated with esophageal adenocarcinoma.

### Research frontiers

To investigate whether patients with moderate-severe EE are at increased risk of BE and whether the presence of inflammation affects detection of underlying BE.

### Innovations and breakthroughs

Present study shows higher prevalence of BE with advanced grades of EE, once complete healing of inflammation is achieved. There is potential for missing Barrett's and even dysplasia if biopsies are obtained in the presence of active inflammation.

### Applications

BE appeared to be more prevalent in patients with moderate-severe EE. Endoscopic biopsies (if needed) at a follow-up examination should only be performed once complete mucosal healing is documented.

### Peer review

This is an interesting study, where the length of EE at index endoscopy may predict the length of BE at follow-up endoscopy. It will be some value for clinical practice.

### Abstract

**AIM:** To investigate the effect of 5-aminosalicylic acid (5-ASA) suppositories on rectal band ligation-induced pain.

**METHODS:** Sixty patients were randomized into two treatment groups.

**RESULTS:** Our results showed that there was no difference between 5-ASA suppository group and the control group for pain control.

**CONCLUSION:** 5-ASA may be an alternative treatment for hemorrhoids; however, it does not affect the rectal band ligation-induced pain.

### INTRODUCTION

Patients with hemorrhoids most often consult a physician only after their symptoms become unbearable. Hemorrhoids are frequently occurring inflammatory processes involving the hemorrhoid plexus<sup>[1]</sup>. Treatments of this inflammatory process remains a difficult problem in some cases, despite the large number of conservative methods available, such as injection sclerotherapy, rubber band ligation (RBL), cryotherapy, infrared photocoagulation, bipolar diathermy galvanic generator and laser application<sup>[2]</sup>. RBL, which is an easy and inexpensive procedure, is used to treat second-degree hemorrhoids, and surgery is often necessary for third and fourth degree hemorrhoids<sup>[3]</sup>.

Although RBL is a well-established treatment of choice for symptomatic internal hemorrhoids, fatalities following RBL have been reported<sup>[4-6]</sup>. Following this treatment some patients experience pain which may be accompanied by itching. Post-RBL pain has been reported at a frequency of 8.3% in the literature<sup>[7]</sup>. These complaints usually start on the day of treatment and may last several days.

The aim of this study was to investigate the effect of 5-aminosalicylic acid (5-ASA) suppositories (250 mg BID) on RBL-induced pain.

### MATERIALS AND METHODS

#### Patients

The study was designed as a double-blind, randomized trial of 24 mo duration. One hundred and seven patients (44 males and 63 females) volunteered to take part in the study after receiving a full explanation of the nature and purpose of the trial.

Before the start of the trial, and after three weeks of treatment, patients were assessed both clinically and rectoscopically. Endoscopic examination assessed the degree of hemorrhoids<sup>[8]</sup>, and determined whether or not anal fissure was present.

Sixty patients with second degree symptomatic hemorrhoids were included in this study. All patients' histories were obtained, and complete physical examination, digital rectal examination, and rigid rectoscopy were performed. Both groups consisted of 30 patients and none of these patients suffered from other systematic disease nor were they pregnant.

All the patients were prescribed the standard fiber diet and warm sitz baths (29°C/daily, twice). All patients underwent rectal band ligation for a single hemorrhoid cushion. One group was started on 5-ASA 500 mg BID P.R. and the control group received suppositories with placebo (glycerin). Patients were asked to score their pain on postprocedure day 1 and day 2. The scale used scored no pain as 0, mild pain as 1 and severe pain as 2.

### Statistical analysis

The Statistical Package for Social Sciences (SPSS) version 10.0 for Windows was used to analyze the data. The Pearson Chi-square, McNemar and the Student-*t* test were used whenever appropriate. Differences were considered significant if  $P < 0.05$ .

## RESULTS

There were 30 patients in each group; 14 males and 16 females in the 5-ASA group (mean age,  $31.86 \pm 10.75$  years), and 9 males and 21 females in the control group (mean age,  $32.73 \pm 9.58$  years). There were no statistically significant differences between the two groups according to sex and age.

Twenty-five patients (15 in the 5-ASA group and 10 in the control group) also presented with anal fissure. There were no statistical differences between the two groups ( $P > 0.05$ ).

All patients showed clinical and endoscopic evidence of active hemorrhoid disease and complained of pain in the perianal region. In addition, some patients had bleeding, mucus in stool, tenesmus, itching or pain in the perianal region during defecation.

Table 1 shows the differences on RBL-induced pain between groups 1 and 2. With regard to RBL-induced pain, we could not find any significant differences for either of the groups on the first ( $P = 0.390$ ) or on the second day ( $P = 0.601$ ). Although there was pain in 33% of 5-ASA group patients on the first day, that ratio increased to 90% on the second day. However, that difference was not statistically significant ( $P = 0.290$ ).

In the control group, 20% of patients did not have pain on the first day, and 93.3% had no pain on the second day. This difference was statistically not significant ( $P = 0.490$ ).

We did not find any statistical difference between two groups according to sex ( $P = 0.441$  for 5-ASA group;  $P = 0.080$  for control group) between the first day and the second day ( $P = 0.233$  for 5-ASA group;  $P = 0.523$  for control group). When we compared first day pain after RBL between fissure (+) and (-), it was statistically significant for both groups ( $P = 0.005$  for the 5-ASA group;  $P = 0.007$  for the control group). On the other hand, there were no differences among the groups on the second day ( $P = 0.189$  for the 5-ASA group;  $P = 0.103$  for the control group).

If we compare the pain scores between the two groups who had fissures (+), there were no differences ( $P = 0.665$  for the first day of treatment;  $P = 0.659$  for the second day of treatment).

Table 1 Comparison of pain in each group one and two days after RBL *n* (%)

Pain (score)	Group1 (day 1)	Group 1 (day 2)	Group 2 (day 1)	Group 2 (day 2)	<i>P</i> (day 1)	<i>P</i> (day 2)
No (0)	10 (33)	27 (90)	6 (20)	28 (93.3)	0.390	0.601
Mild (1)	13 (43)	2 (6.7)	18 (60)	2 (6.7)		
Severe (2)	7 (23)	1 (3.3)	6 (20)	0		

## DISCUSSION

Pain is the main symptom for second degree internal hemorrhoids. The exact etiopathogenesis of hemorrhoids-induced pain remains unknown. It is known that spasm of the internal sphincter is believed to be responsible for the discomfort after hemorrhoidectomy<sup>[8]</sup>. Furthermore, RBL behaves like hemorrhoidectomy presenting with similar pain. However, incarceration of smooth muscle fibers and mucosa in the transfixed vascular pedicle and epithelial denudation of the anal canal may also constitute the reason for pain<sup>[9]</sup>. A proper technique of ligation dictates that rubber bands are placed well above the dentate line. Sharp pain immediately after installment of a band denotes encroachment on the pain-sensitive area adjacent to the dentate line and necessitates removal of the band<sup>[10]</sup>. Theories for such pain include the band being placed in the receptive field of an aberrant somatic cutaneous nerve of the internal sphincter being drawn into the band, causing spasm and pain<sup>[11]</sup>. Other possible causes of pain include pressure sensation caused by edema of the hemorrhoid bundle and also, foreign body sensation of the band on the rectal mucosa.

Therefore, a number of substances with anti-inflammatory (corticosteroids), anesthetic (xylocaine) or vasoconstrictive action, are currently in use with various degrees of success, 5-ASA is a powerful anti-inflammatory agent, which has been extensively used in patients with inflammatory bowel disease as an alternative topically applied corticosteroid<sup>[12]</sup>. It reduced the intensity of all symptoms evaluated, probably *via* its anti-inflammatory activity, and decreased significantly the congestion of the hemorrhoid plexus<sup>[11]</sup>. On the other hand, there is only one study published which has investigated the reduction of pain by an agent post-RBL. It showed that hydrocortisone-cinchocaine-framycetin suppositories, which are effective for inflammation, showed no significant difference in decreasing the severity of pain<sup>[13]</sup>.

Neiger and Widaver showed that 5-ASA, given in the form of suppositories three times daily for two weeks, was very effective in eliminating the clinical symptoms in patients with hemorrhoids. Our results showed that 5-ASA, in the form of 250 mg suppositories given twice daily, is an effective drug in the symptomatic treatment of hemorrhoids irrespective of their degree of severity, without causing any significant side effects<sup>[14]</sup>.

It is known that edema is one of the results of inflammation. Despite the fact that 5-ASA is effective against inflammation, in our study it failed to decrease

the severity of pain. Our results may be interpreted in two ways: 5-ASA may not affect the pain induced by hemorrhoids, or there may not be any correlation between pain and inflammation or edema.

However, we showed that anal fissures had a potential effect in inducing RBL pain in patients with hemorrhoids. We decided that if a patient with hemorrhoids had anal fissure, the priority treatment should be applied to the anal fissure for decreasing the severity of pain symptoms.

In conclusion, 5-ASA may be an alternative treatment for hemorrhoids, but it is not effective in RBL-induced pain.

## COMMENTS

### Background

Post Rectal Bant Ligation (RBL) pain has been reported at a frequency of 8.3% in the literature.

### Research frontiers

5-aminosalicylic acid (5-ASA) decreases the inflammation of proctitis. Inflammation is one of the reasons of RBL-induced pain.

### Innovations and breakthroughs

Anal fissures have a potential effect in inducing RBL pain in hemorrhoids patients. We decided that if a hemorrhoid patient had anal fissures, the priority treatment should be applied to the anal fissure for decreasing the severity of pain symptoms. 5-ASA may be an alternative treatment for hemorrhoids.

### Applications

Although 5-ASA decreases the inflammation of proctitis, it is not effective in RBL-induced pain.

### Peer review

These results may be interpreted in two ways: 5-ASA may not affect the pain induced by hemorrhoids, or there may not be any correlation between pain and inflammation or edema.

### Abstract

**AIM:** To establish the role of *FHIT* in the pathogenesis hepatocellular carcinoma (HCC).

**METHODS:** We examined genomic alterations, as well as, mRNA and protein expression patterns from the *FHIT* gene, in 48 surgically resected hepatocellular carcinoma (HCC) tissues. Additionally, *p53* mutations were analyzed.

**RESULTS:** Aberrant *FHIT* transcripts were detected in 11 of 48 surrounding non-tumor liver tissues and 27 of 48 HCC samples (22.9% vs 56.3%,  $P = 0.002$ ). No point mutations were identified within the open reading frame region of *FHIT*. Loss of heterozygosity (LOH) of the *FHIT* locus was detected in 4 of 42 informative cases for D3S1300, and 3 of 29 informative cases for D3S1313. Reduced expression of *FHIT* protein (Fhit) was observed in 8 (16.7%) of 48 HCC samples, with complete loss of Fhit in only 1 case. There were no associations with abnormal transcripts, LOH, and Fhit expression. *p53* mutations were identified in 9 of the 48 HCC cases. However, none of the cases displayed a G to T transversion at *p53* codon 249.

**CONCLUSION:** Aberrant *FHIT* transcripts were more common in HCC tissues as compared to non-cancerous liver tissues. However, Fhit expression was lost or reduced in a minor fraction of HCC tissues, while it was strongly expressed in non-cancerous liver tissues.

### INTRODUCTION

Hepatocellular carcinoma (HCC) is currently the fifth most common cancer worldwide and the fourth leading cause of cancer-related deaths. The number of new cases is estimated as more than 500 000 per year, accounting for 4% of all newly diagnosed cancers<sup>[1]</sup>. More than 80% of HCC cases occur in developing countries, especially in South-East Asia and sub-Saharan Africa, but the incidence is increasing in economically developed regions, including Japan, Western Europe, and the United States<sup>[1-2]</sup>. The overall prognosis of HCC is poor, because many patients at presentation are already in an advanced and unresectable state, and will have a median survival time of less than 6 mo<sup>[3]</sup>. High mortality may be partially attributable to the fact that the nanocapsular part of the liver lacks sensory fibers, leading to symptoms presentation only in the advanced HCC<sup>[3]</sup>. Therefore, only a small proportion of patients are eligible for liver resection, which results in a 5-year survival rate of about 40%<sup>[4]</sup>. However, even following surgical resection, recurrence rates can be as high as 50% at 2 years<sup>[4]</sup>.

Hepatocarcinogenesis is a multistep process involving different genetic alterations that ultimately lead to the malignant transformation of hepatocytes.

Numerous genetic and epigenetic alterations contribute to the activation of carcinogenic pathways in HCC<sup>[4]</sup>. Whereas most studies on the mechanisms of tumorigenesis have focused on genetic changes, various epigenetic changes have been increasingly identified in HCC<sup>[4]</sup>. The short arm of human chromosome 3 is one of the most common sites of chromosomal abnormality in malignant diseases<sup>[5-8]</sup>. One candidate is the fragile histidine triad (*FHIT*) gene, located on 3p14.2, spanning the FRA3B common fragile site<sup>[9-10]</sup>. The *FHIT* gene is composed of 10 exons encompassing 1.8 Mb genome regions, of which only exons 5 to 9 code for protein. It encodes a small mRNA of 1.1 kb, and a small protein of 16.8 kDa<sup>[9]</sup>. Studies on the functional aspects of *FHIT* have been reported that this gene is a bona fide tumor suppressor gene<sup>[11]</sup>. The *FHIT* gene and its protein have may be involved in the regulation of cell proliferative and apoptotic processes<sup>[11]</sup>. Down-regulation of *FHIT* inhibits apoptosis and *FHIT* protein (Fhit) interacts with a number of key proteins involved in cancer progression, including *p53*<sup>[11-12]</sup>. Coexpression of *FHIT* and *p53* synergistically inhibits the proliferation of various tumor cell lines. These synergistic effects may occur because of stabilization of *p53* related to Fhit-mediated downregulation of MDM2<sup>[12]</sup>. Altered transcripts and allelic loss of the *FHIT* gene are frequently identified in premalignant and malignant lesions of various tumors<sup>[13-18]</sup>. Moreover, loss or reduction of Fhit expression has been found in most tumors including HCC<sup>[10-14,19-22]</sup>.

To establish the role of *FHIT* in the pathogenesis of HCC, we examined genomic alterations, as well as, mRNA and protein expression in surgically resected HCCs and their associated non-cancerous surrounding liver tissues. We also investigated the possible associations between *FHIT* abnormalities and *p53* mutations.

## MATERIALS AND METHODS

### Patients

HCC samples and their corresponding non-cancerous liver tissues were obtained from 48 patients who had undergone surgical resection at Ulsan University Hospital in South Korea. Written informed consent was obtained from all patients participating in this study, and the study was approved by the Institutional Review Boards at Ulsan University Hospital. All cancer samples were obtained from within the tumor. Matching surrounding non-cancerous liver tissues were obtained as far as possible from the tumors. All specimens were frozen immediately after surgical resection, and stored at -70°C. HCC diagnosis was based on histologic confirmation or elevated serum AFP (> 400 ng/mL) with radiologic findings, or at least two coincident radiologic findings (contrast-enhanced dynamic computer tomography (CT), contrast-enhanced dynamic magnetic resonance imaging (MRI), and Doppler ultrasonography compatible with HCC.

Postoperative follow-up included a dynamic CT/MRI study every 3 mo, and laboratory testing of the serum

AFP level every 1 to 3 mo at our outpatient clinic. In the case of suspected HCC recurrence, further examinations, including angiography and lipiodol CT, were performed. If necessary, ultrasound-guided biopsy was conducted to confirm the diagnosis. Bone scintigraphy or chest CT was performed when clinically indicated. The follow-up period was defined as the interval from the date of surgical resection of HCC until the date diagnosis of the recurrence, or the date of death, or the end of follow-up.

### Reverse transcription polymerase chain reaction (RT-PCR) and sequencing of *FHIT* gene transcripts

Total RNA and DNA were isolated from the HCCs and corresponding non-cancerous tissues, using the TRIZOL reagent (Gibco BRL Life Technologies, Gaithersburg, MD, USA). cDNA was synthesized by reverse transcriptase from 1 µg of total RNA. One ul of the RT reaction was used to amplify the *FHIT* cDNA as described by Ohta *et al.*<sup>[9]</sup>. To amplify *FHIT* exons 3-10, a nested PCR was carried out in 10-µL final volume with 30 ng of primers (5U2-3D2 and 5U1-3D1, according to Ohta *et al.*<sup>[9]</sup>). The first round of PCR amplification was performed in 10 uL of reaction mixture comprising 1 µmol/L primers 5U2-3D2 and 5U1-3D1, 200 µmol/L each dNTP, 1 × PCR buffer, 2.5 U of ampliTaQ, and 0.5 µL of the synthesized cDNA mixture under the following reaction conditions: denaturation for 10 min at 95°C, 34 cycles of 30 s at 95°C, 30 s at 56°C, and 45 s at 72°C, and a final extension step for 10 min at 72°C. After 10-fold dilution of the amplified product 10-fold in DW, 2 µL of aliquots were subjected to a second round of PCR amplification using nested primers, 5U1 and 3D1, under the above conditions. Each nested RT-PCR assay was repeated at least twice with the original extracted RNA for confirmation. All reactions were performed at least twice and the integrity of the RNA samples verified. To confirm the presence of mRNA and rule out nonspecific amplification, 25 cycles of *β-actin* cDNA were preformed after RT, both with and without the RT enzyme. PCR products were directly sequenced using primer 5U1 and 3U1 with an automated Applied Biosystem Model 3730 DNA sequencer (Perkin-Elmer, Foster City, CA, USA). For sequence analysis of abnormal *FHIT* transcripts, the PCR products were resolved in 1.5% ethidium bromide agarose gel. Bands were excised from gels, and PCR products were purified using the QIAquick PCR purification kit (QIAGEN Inc., Valencia, CA, USA). PCR products excised from gels were directly sequenced using the sequencing primers described by Zekri *et al.*<sup>[18]</sup>.

### Microsatellite polymorphism analysis

To investigate the allelic loss of *FHIT* gene, a PCR-based approach was performed utilizing primers that amplify two polymorphic microsatellite markers internal to and flanking the *FHIT* gene. The microsatellite marker D3S1300 is located in intron 5 of the *FHIT* gene, whereas marker D3S1313 is slightly telomeric to *FHIT*. The 10 µL PCR mixture contained 1 × Gold Buffer, 0.8 µL 25 mmol/L MgCl<sub>2</sub>, 0.8 µL 10 mmol/L

dNTP, 1  $\mu$ L 5  $\mu$ mol/L concentrations of each primer pair, 0.5  $\mu$ L 0.25 unit Amplitaq Gold, and 2  $\mu$ L of the 10 ng extracted DNA. 1  $\mu$ L of diluted PCR product was mixed with 9  $\mu$ L of loading buffer (formamide: Ro  $\times$  500 size standard, 1:39). The mixture was denatured at 95°C for 5 min, chilled on ice, and loaded on an ABI PRISM 3100 automatic sequencer. The data were analyzed using the GeneScan and Genotyper software (Perkin-Elmer/Applied Biosystems). Constitutional homozygosity was regarded as uninformative. For informative cases, allelic loss was scored as positive if the signal of one allele was lost or reduced to at least 50% in tumor DNA, compared with the corresponding normal allele. All samples were run twice to confirm the presence or absence of allelic imbalance.

### Western blotting analysis

Protein concentration was measured using the BCA protein assay (Pierce, Rockford, IL). Ten micrograms of lysate protein was separated by SDS-PAGE using a 12% polyacrylamide gel and electroblotted onto a Hybond ECL (Amersham Pharmacia Biotech). After blockage of nonspecific binding sites for 1 h with 5% nonfat milk in TPBS (PBS and 0.1% Tween 20), the membrane was incubated at room temperature for 2 h with rabbit anti-FHIT antibody (Zymed Laboratories, South San Francisco, CA, USA) at a dilution of 1:500. The membrane was washed three times with TPBS, incubated further with horseradish peroxidase (HRP)-conjugated goat anti-rabbit antibody (New England Biolabs, Beverly, MA, USA) at room temperature, and then washed three times with TPBS. Membranes were developed with the ECL chemiluminescence system (Amersham Pharmacia Biotech). The intensity of Fhit expression in HCC tumors was compared with that in non-cancerous surrounding liver tissues.

### p53 mutation analysis

The primers used were oligonucleotides complementary to the sequence flanking the exon/intron junctions of exons 5-9. The sequence of the primers is as follows: exon 5, 5'-CTGACTTTCAACTCTG-3' (forward) and 5'-AGCCCTGTCGTCTCT-3' (reverse); exon 6, 5'-CTC TGATTCCTCACTG-3' (forward) and 5'-ACCCAGTTGCAAACC-3' (reverse); exon 7, 5'-TGCTTGCCACAGGTCT-3' (forward) and 5'-ACAGCAGGCCAGTGT-3' (reverse); exon 8, 5'-AGGACCTGATTTTCCTTAC-3' (forward) and 5'-TCTGAGGCATAACTGC-3' (reverse); and exon 9, 5'-TATGCCTCAGATTCAC-3' (forward) and 5'-ACTTGATAAGAGGTCC-3' (reverse). The same primers sets were used for DNA sequencing. PCR was carried out in a 20- $\mu$ L reaction contained; 50 ng DNA, 10  $\times$  PCR buffer, 200  $\mu$ mol/L each of dNTP, 5 pmol of each primer and 1 U of Taq DNA polymerase. PCR conditions were as follows: 95°C (10 min) for 1 cycle, 95°C (40 s), 63°C (40 s; for exons 4, 5, and 7-9) or 67°C (40 s; for exon 6), 72°C (40 s) for 40 cycles, and a final extension step of 72°C (10 min). PCR products were separated by electro-

phoresis and visualized with 1.5% ethidium bromide. Samples without the DNA template were included in all assays as negative controls. PCR products were purified using the QIAquick PCR purification kit (QIAGEN Inc., Valencia, CA, USA), and they were sequenced by the dideoxychain termination method with the Big Dye Terminator cycle sequencing kit (Perkin-Elmer Corporation, Foster City, CA, USA). Cycle sequencing was performed for 25 cycles of denaturation (96°C, 30 s), annealing (50°C, 15 s), and extension (60°C, 4 min), according to the Big Dye Terminator protocol. After spin column purification with Centri-Sep columns (Perkin-Elmer Corporation), samples were analyzed with the automated Applied Biosystem Model 3730 DNA sequencer (Perkin-Elmer, Foster City, CA, USA).

### Statistical analysis

All continuous variables were compared using the Mann-Whitney test, or the one-way analysis of variance (ANOVA). Categorical variables were compared using the Fisher's exact test. All data were analyzed using the statistical package SPSS (version 14.0: SPSS Inc., Chicago, IL, USA). In all cases, a 2-tailed *P* value of less than 0.05 was considered statistically significant.

## RESULTS

### Patient characteristics

The baseline characteristics of the 48 patients were shown in Table 1. The patients included 35 men and 13 women with a mean age of 50 years (range 28-71 years). HBV was the most common etiology, accounting for 38 (79%) of the 48 cases. Antibody to HCV was identified in three cases. Seven patients were negative for HBV and HCV. Alpha-fetoprotein (AFP) level ranged from 1.0 to 240 000 ng/mL with a median level of 202 ng/mL. Twelve (25%) of the 48 patients had normal AFP levels (< 11 ng/mL), whereas 20 (41.7%) patients had AFP levels of > 400 ng/mL. Preoperative diagnosis of HCC was based on histologic confirmation in 28 cases, or elevated serum AFP (> 400 ng/mL) with radiologic findings, or at least two coincident radiologic findings compatible with HCC in the remaining 20 cases. In 22 of the 48 patients, cirrhosis was observed in the surrounding non-cancerous liver tissue, and chronic hepatitis was identified in parenchyma surrounding the tumors in the remaining 26 cases. According to the Child-Pugh classification at the time of operation, 19 patients were class A (CPT 5-6), 3 were class B. Based on UICC TNM staging<sup>[23]</sup>, 5 patients were stage I, 41 stage II, and 2 stage III. Small HCC was defined as a single tumor < 5 cm, or 2-3 tumors < 3 cm without invasion of major veins larger than sub-segmental branches. These criteria are similar to those applied to define early stage HCC in the BCLC (Barcelona Clinic Liver Cancer) staging scheme<sup>[24]</sup>. Tumors exceeding these limits were regarded as advanced HCC. At initial diagnosis, 26 patients had small HCC, while 22 patients were advanced HCC. The mean tumor size was

5.8 ± 3.9 cm. Among the 46 patients with solitary tumors, a diameter of 3 cm or less was observed in 11 (23.9 %), between 3 cm and 5 cm in 15 (32.6%), and greater than 5 cm in 20 (43.5%). There were no tumors with positive lymph nodes or macroscopic vascular invasion by HCC. Of these HCCs, 8 were at grade I, 13 at grade II, 20 at grade III and 5 at grade IV according to the Edmondson and Steiner's grade<sup>[25]</sup>. Microscopically, vascular and tumor capsular invasions were detected in 13 (27%) and 5 (10%) patients, respectively.

### RT-PCR and sequencing of *FHIT* transcripts

Representative results of nested RT-PCR analysis are shown in Figure 1. Abnormal-sized bands representing aberrant RT-PCR products were detected in 11 (22.9%) of 48 surrounding non-tumorous liver tissues and 27 (56.3%) of the 48 HCC samples. Thus, the number of tumors with aberrant transcripts was greater than that of non-tumor tissues with aberrant transcripts ( $P = 0.002$ ). Such abnormal-sized transcripts were seen at five different positions at 296, 365, 389, 413, and 458 bp (Figure 1). Interestingly, 13 cases displayed two or three aberrant transcripts. Sequence analysis of the aberrant transcripts revealed deletions of exons 3-6 (nt-164 to 249) in 17 cases, exons 4-7 (nt-110 to 279) in 7 cases, exons 4-8 (nt-110 to 348) in 6 cases, exons 5-7 (nt-17 to 279) in 6 cases, and exons 5-8 (nt-17 to 348) in 2 cases (Figure 2). Among 11 surrounding non-tumorous liver tissue samples with aberrant transcripts, 5 were chronic hepatitis, whereas in the remaining 6 cases, the parenchyma surrounding the tumor was cirrhosis.

**Figure 1** Analysis of mRNA expression of *FHIT* gene in matched surrounding non-cancerous and cancerous tissues by RT-PCR. Large arrow: Normal sized *FHIT* cDNA (706 bp); small arrows: Aberrant transcripts (458 bp, 413 bp, 389 bp, 365 bp, and 296 bp); NL: Normal liver tissue; T: Tumor tissue; N: Non-tumor liver tissue.

**Figure 2** Schematic representation of aberrant *FHIT* transcripts in HCC tissues. Sequence analysis of aberrant transcripts reveals deletions of exons 3-6 (nt-164 to 249) in 17 cases, exons 4-7 (nt-110 to 279) in 7 cases, exons 4-8 (nt-110 to 348) in 6 cases, exons 5-7 (nt-17 to 279) in 6 cases, and exons 5-8 (nt-17 to 348) in 2 cases.

In total, 8 patients displayed aberrant transcripts in both tumor and surrounding non-tumor tissues, 5 of whom displayed the same abnormal patterns in the paired tumor and non-tumor samples; however, in the remaining 3 cases, the pattern was different between the paired samples. Whereas 19 cases had aberrant transcripts only in their tumor tissues, we also found 3 cases showing an aberrant transcript in their non-tumor tissues only. However, no point mutations of the *FHIT* gene were found in the region of the open reading frame. All normal-sized transcripts of 706 bp exhibited wild-type sequences. All of 21 tumor tissues without aberrant transcripts were presented normal sized transcripts. Normal-sized transcripts were also observed in 22 of the 27 HCCs with aberrant *FHIT* transcripts, but were barely present or completely absent in the remaining 5 cases. However, normal-sized bands were observed in all surrounding non-tumor tissues samples, regardless of the presence of aberrant transcripts. The presence of *FHIT* aberrations was not associated with clinical parameters, including age, sex, Child-Pugh classification, histological grade of tumor, presence of tumor capsule, AFP, tumor size, microscopic invasion, tumor recurrence, or survival ( $P > 0.05$ ).

**Figure 3** LOH of *FHIT* locus. An example of LOH in tumor (T) and matched non-tumorous (NT) DNA from patients with HCC. LOH is defined as if the signal of one allele is lost or reduced to at least 50% in tumor DNA, compared to the corresponding normal allele.

### Loss of heterozygosity (LOH)

Among the 48 HCCs, 7 displayed LOH of D3S1300, D3S1313, or both markers. Specially, 4 of the 42 informative cases at D3S1300, and 3 out of the 29 cases informative at D3S1313, exhibited LOH. LOH involving both allelic markers was not observed. Examples are shown in Figure 3. In total, 6 of 30 cases with aberrant transcripts, and only 1 of 18 cases without aberrant transcripts showed LOH. Thus, the incidence of LOH appeared higher in cases with aberrant transcripts than cases without aberrant transcripts, although the data were not statistically significant ( $P = 0.23$ ). Moreover, we observed a trend towards *FHIT* aberration in tumors with LOH, although again the difference was not statistically significant ( $P = 0.23$ ). LOH of the *FHIT* gene was not associated with the clinical parameters examined.

### Western blot analysis

Representative results of Western blot analysis are shown in Figure 4. Eight (16.7%) of 48 HCCs exhibited reduced or no Fhit expression, compared with normal liver tissues. Complete loss of Fhit was only identified in one of the above 8 cases. Reduced Fhit expression was observed in 4 among the 30 samples with aberrant transcripts. The remaining 4 cases with reduced Fhit did not show aberrant transcripts. Moreover, Fhit expression was not reduced in the 5 cases where normal transcripts were absent or barely detected. Reduced Fhit expression was observed in only one patient displaying LOH at *FHIT* with no aberrant transcripts. The remaining six cases with reduced Fhit expression did not display LOH at the *FHIT* locus. We observed no association between LOH and abnormal *FHIT* transcripts, abnormal *FHIT* transcripts and abnormal Fhit expression, or, LOH and abnormal Fhit expression. Moreover, the extents of Fhit were not associated with clinical parameters, such as age, sex, Child-Pugh classification, histological grade of tumor, presence of tumor capsule, AFP, tumor size, microscopic invasion, tumor recurrence, or survival ( $P > 0.05$ ).

**Figure 4** Representative results of Fhit expression by Western blot analysis.  $\alpha$ -tubulin is used as the internal control to verify equal loading. The relative values of FHIT protein were normalized internally to  $\alpha$ -tubulin signals. NL: Normal liver tissue; N: Non-cancerous tissue; T: Tumor tissue.

### *p53* mutation analysis

To investigate the association between *p53* mutations and genetic changes in the *FHIT* gene in the pathogenesis of HCC, direct sequencing analysis was performed. *p53* mutations were identified in tumors of 9 of the 48 patients (Table 2), but not in the surrounding liver tissues. However, none of the cases displayed G to T transversion at *p53* codon 249.

## DISCUSSION

Common fragile sites are prone to genomic alterations in cancer, and the majority of cancers exhibit alterations at fragile sites<sup>[26]</sup>. The *FHIT* gene located at one of the most common fragile sites is altered in a variety of tumor cell lines, as well as, in premalignant and malignant lesions of primary tumors, in line with its role as a tumor suppressor gene whose loss or inactivation may contribute to cancer development or malignant progression<sup>[13,15-20]</sup>. Moreover, several studies have been reported results for chromosome 3p rearrangements, decreased or absent *FHIT* mRNA expression, intragenic deletions and absence of protein expression, in HCC cell lines and primary HCC<sup>[13,15-19,21-22]</sup>.

Aberrant *FHIT* transcripts have been identified in 39%-70% of HCC cases<sup>[13,15-18]</sup>. These transcripts are generated by exon skipping, use of alternative 5' and 3' splice sites, and recognition of cryptic splice sites, resulting in insertions of intronic sequences. Consequently, the patterns of aberrant *FHIT* transcripts vary, but the majority of transcript splicing occurs within two large introns 4 and 5<sup>[15-18]</sup>. As the fusion functions coincide exactly with splice sites, aberrant transcripts may represent alternatively spliced products<sup>[9]</sup>. However, point

mutations of the *FHIT* gene are very rare<sup>[13,15-17]</sup>. In our study, all aberrant *FHIT* transcripts displayed deletion of exons 5 and 6. Additionally, no point mutations in the *FHIT* gene were identified in the region of the open reading frame. Aberrant transcripts of the *FHIT* have been identified in both HCC and surrounding non-cancerous tissues<sup>[15-18]</sup>. In our study, abnormal sized bands representing aberrant RT-PCR products were detected in 22.9% of the surrounding non-tumorous liver tissues and 56.3% of HCCs. These results suggested that aberrant *FHIT* transcripts had already accumulated even at the chronic liver diseases, in which persistent viral infection and sequential inflammation have occurred. As alterations of the *FHIT* gene in non-neoplastic tissues of smokers and ex-smokers are observed, *FHIT* alteration may be an early change during the preneoplastic phase of hepatocarcinogenesis<sup>[15-18]</sup>. Gramantieri *et al* reported that HCC cases with aberrant *FHIT* transcripts showed a significantly higher relapse rate and shorter recurrence time<sup>[14]</sup>. However, we observed no correlation between aberrant *FHIT* transcripts and clinicopathological parameters. Ohta *et al* detected full-length RT-PCR products in nearly all cases with aberrant transcripts<sup>[9]</sup>. Most of HCCs also exhibited aberrant and normal-sized transcripts<sup>[15-18]</sup>. Consistent with previous reports, our result showed that almost all cancerous and non-cancerous liver tissues exhibited normal-sized transcripts. In these cases, the normal transcripts have derived from admixed normal cells<sup>[9]</sup>. In our study, mRNA was extracted from tissue homogenates and, it was therefore not possible to assess whether or not the same cells produced normal and abnormal messengers. However, Chen *et al* reported that the normal products were observed in all tumor cell lines<sup>[17]</sup>. It has been suggested that these normal products are derived from neoplastic cells. Moreover, Schlott *et al* reported that aberrant transcripts did not differ between malignant, benign proliferating, and normal hepatocytes<sup>[16]</sup>. That is, formation of aberrant *FHIT* transcripts appears to be a common feature of benign, non-neoplastic hepatocytes. Alternative splicing definitely occurs in normal human tissues<sup>[27]</sup>. It is thus possible that the *FHIT* gene is simply located near to but is not the true target that drives a clonal selection process<sup>[17]</sup>. The *FHIT* gene, containing a common fragile region, FRA3B, is susceptible to the breakage caused by physical or chemical carcinogens. Similar effects may lead to a higher frequency of changes in the *FHIT* gene in chronically damaged liver tissues.

Several mechanisms are associated with dysfunction of the *FHIT* gene, the major being genomic deletion. These chromosomal deletions are frequently identified in HCC cell lines<sup>[13]</sup>. However, LOH at *FHIT* gene in human HCC is only occasionally detected<sup>[13,15,17]</sup>. Our study revealed that LOH of the *FHIT* gene was found in only 15% of HCCs. Although a great number of loci should be analyzed to further define any possible small deletions and rearrangements, these results so far suggest that LOH of *FHIT* gene is an uncommon in hepatocarcinogenesis. Allelic loss at *FHIT* is occasionally observed either in the presence or absence of aberrant

transcripts<sup>[15]</sup>. In our study, LOH of *FHIT* gene was observed in 6 of 30 cases with aberrant transcripts and 1 of 18 cases without aberrant transcripts. However, no significant correlations were evident between the expression of aberrant transcripts and LOH of *FHIT*. These findings imply that LOH alone does not completely suppress *FHIT* expression.

Several studies show that whereas all normal and non-cancerous liver tissues show a strong expression of Fhit, most HCC cell lines and primary HCC express reduced or no Fhit<sup>[13,19,21,22]</sup>. However, our study, reduced Fhit expression was observed in only 8 (17%) of 48 HCCs, and complete loss of Fhit in only one of these cases. Moreover, the extent of Fhit expression was not associated with aberrant transcripts or LOH presence. The data suggests that, in some cases, aberrant splice transcripts are actually transcribed. This hypothesis requires confirmation with a larger, more extended study. Inconsistent with our study, the incidence of Fhit expression was lower in HCC developed in patients chronically infected with HBV and exposed to chemical carcinogens, particularly in Qidong, China<sup>[13,19]</sup>. The exact reasons for the variation in Fhit expression are currently unclear, but may be dependent on different geographic and environmental factors. Hepatitis B virus infection is the most common etiologic factors for the development of HCC in South-East Asian regions, such as China and South Korea. Epidemiological and experimental studies disclose synergistic effects of aflatoxin B1 (AFB1) and HBV on hepatocarcinogenesis<sup>[28]</sup>. Environmental factors, including AFB1, may also contribute to the alteration of the *FHIT* gene. The concentration of AFB1 in the environment is high in China, but, low in South Korea<sup>[29]</sup>. AFB1 is strongly associated with a G to T transversion at codon 249 of the *p53* gene<sup>[28]</sup>. However, in our study, none of the cases displayed this G to T transversion. Loss or reduction of Fhit expression in HCC has been identified in association with altered *FHIT* transcripts, and LOH at the *FHIT* locus<sup>[13]</sup>. In our study, reduced Fhit expression was observed in only 4 of 30 cases with aberrant *FHIT* transcripts, and the remaining 4 cases displayed reduced Fhit expression did not present aberrant *FHIT* transcripts. Only one case with LOH at *FHIT* exhibited reduced Fhit expression. The six other cases with decreased Fhit expression did not show LOH at the *FHIT* locus. In contrast to previous studies, we observed no associations between Fhit expression and altered transcription or LOH. Loss of Fhit expression correlates with poor outcome in various cancers<sup>[14,30]</sup>. Zhao *et al* also reported that the expression of Fhit is inversely related to disease progression in HCC<sup>[19]</sup>. However, we found no correlation between Fhit expression and clinicopathological parameters. Although no interrelationship was evident between Fhit expression and LOH events, it is possible that other mutations, not investigated our study, are responsible for reduced or negative protein expression. Therefore, several genetic or epigenetic factors may potentially contribute to the loss of Fhit expression. One possibility is that inactivation

of the *FHIT* gene results from epigenetic mechanisms, such as hypermethylation of 5'-CpG islands in the promoter region<sup>[19,31]</sup>. In addition, abnormalities in post-transcriptional regulation may also abrogate expression of the *FHIT* gene. However, our results are preliminary and need to be confirmed in a larger study including more cases and an extended follow-up period.

In conclusion, our data indicate that abnormalities in *FHIT* gene transcripts occurred frequently in both cancerous and non-cancerous liver tissues. However, a normal-sized transcript without sequence abnormalities was almost always present. The *Fhit* is under-expressed only in a minor fraction of HCC tissues, while it was strongly expressed in non-cancerous liver tissues. Therefore, our study suggests that *FHIT* plays a role in relatively few HCC in lower AFB1 exposure area such as, South Korea. It is possible that such a finding was attributable to chance due to the relatively small numbers in our study. Thus, additional studies with more subjects are needed to confirm this finding.

## COMMENTS

### Background

The fragile histidine triad (*FHIT*) has been reported that this gene is a bona fide tumor suppressor gene. The *FHIT* gene and its product may be involved in the regulation of cell proliferative and apoptotic process. Down-regulation of *FHIT* inhibits apoptosis and *FHIT* has been shown to interact with a number of key proteins involved in cancer including p53

### Research frontiers

Altered transcripts and allelic loss of the *FHIT* gene are frequently found in premalignant and malignant lesions of various tumors. Moreover, loss or reduction of *FHIT* protein (*Fhit*) expression has been found in most tumors including hepatocellular carcinoma (HCC).

### Innovations and breakthroughs

Abnormalities of the *FHIT* gene transcripts occurred frequently in cancerous and non-cancerous liver tissues. However, a normal-sized transcript without sequence abnormalities was almost always present. Moreover, the *Fhit* was under-expressed only in a minor fraction of HCC tissues in lower AFB1 exposure area such as, South Korea, while it was strongly expressed in non-cancerous liver tissues. Therefore, none of the cases had a G to T transversion at p53 codon 249.

### Applications

*FHIT* behaves as a tumor suppressor gene whose loss or inactivation may contribute to HCC development or malignant progression in patients chronically infected with HBV and exposed to chemical carcinogens, particularly in areas from Qidong, China. In contrast, *FHIT* plays a role in relatively few HCC in lower AFB1 exposure area such as South Korea.

### Peer review

This is an original study that has a large big amount of work. The authors concluded that *FHIT* plays a role in relatively few HCC's in South Korea. This is an interesting study, with sound methodology.

### Abstract

**AIM:** To investigate the cellular defects by analyzing the (Th1/Th2) cytokine levels in vaccine responders and non-responders.

**METHODS:** Peripheral blood mononuclear cell (PBMC) from responders and non-responders were stimulated with or without recombinant HBsAg or PHA. Broad spectrum of cytokines viz (Th1) IFN- $\gamma$ , IL-2, TNF- $\alpha$ , IL-12 and (Th2) IL-10, IL-4 were measured after *in vitro* stimulation with recombinant HBsAg and were compared with respective antibody titers.

**RESULTS:** A significant decrease ( $P = 0.001$ ) in Th1 and Th2 cytokines namely, IL-2, INF- $\gamma$ , TNF- $\alpha$  and IL-10

in non-responders was observed. The level of IL-4 was not significant between the three groups. Furthermore, despite a strong Th1 and Th2 cytokine response, the level of IL-12 was elevated in high-responders compared to other groups ( $P = 0.001$ ) and demonstrated a positive correlation with anti-HBs titers and Th1 cytokine response.

**CONCLUSION:** Our findings suggest that unresponsiveness to recombinant hepatitis B vaccines (rHB) is multifactorial, including specific failure of antigen presentation or the lack of both T helper Th1 and Th2 response.

**Key words:** Hepatitis B vaccine; Cytokines; Humoral response; T cell response; Adult vaccines

**Peer reviewer:** Stephan Menne, Assistant Professor of Virology, Department of Clinical Sciences/GI Unit, College of Veterinary Medicine, Cornell University, C2-005 Veterinary Medical Center, Ithaca, NY 14853, United States

### INTRODUCTION

Hepatitis B is one of the world's major health problems<sup>[1]</sup>. It is estimated that more than 2 billion people are infected with hepatitis B virus (HBV) globally, and more than 400 million are chronic carriers<sup>[2]</sup>. The infection is supposed to be causally related to 1 to 2 million deaths per year worldwide<sup>[2]</sup>. Vaccination with the surface antigen of HBV (HBsAg) is considered the main strategy for effective control of the infection and viral transmission<sup>[3,4]</sup>. Recombinant hepatitis B vaccines (rHB) are recommended for Universal vaccination of neonates, as well as the high-risk healthy adult individuals<sup>[5]</sup>. Even though conventionally it is believed that the available HB vaccines induce only circulating humoral immunity, occasional reports suggest the possibility of induction of cell mediated immune response by HB vaccines.

The HB vaccine induces a protective antibody response (anti-HBs antibody  $\geq 10$  mIU/mL) in the majority of individuals after three dose regimen. However, about 10% of healthy recipients fail to generate protective levels of antibodies to the vaccine after standard immunization<sup>[6,7]</sup>. Furthermore, non-responders remain susceptible to infection with HBV<sup>[8]</sup>.

Inadequate immune response to HBsAg could be attributable to a variety of mechanisms including defect in the generation of primary HBsAg-specific T-cell<sup>[9]</sup> or B-cell repertoires<sup>[10]</sup>, expression of certain human leukocyte antigens (HLA) and haplotypes<sup>[11,12]</sup>, destruction of HBsAg-specific B-cells by antigen-specific cytotoxic T cells<sup>[13]</sup>, immunologic tolerance<sup>[14,15]</sup> and imbalance in T-helper (Th) cell function<sup>[16]</sup>.

HBsAg is a glycoprotein antigen with T-cell dependent characteristics. Induction of specific antibody to this antigen requires coordinated secretion of Th1 and Th2 cytokines leading to maturation and differentiation of the HBsAg-specific B-cell clones. Therefore, defective T-helper (Th) cell function, either Th1 or Th2, could result in failure of immune response to this antigen.

We compared three rHB vaccines; GeneVac-B<sup>®</sup> (Serum Institute of India Ltd, Pune), Engerix-B<sup>®</sup> (SmithKline Beecham Biologicals, Belgium) and Shanvac-B<sup>®</sup> (Shantha Biotechnics, India) in 400 healthy adults<sup>[17]</sup>. All three vaccines induced similar humoral immune (anti-HBs) response in the vaccines. However, a proportion of approximately 2% of the vaccines did not show adequate antibody response ( $> 10$  mIU/mL) to the vaccines. In order to better understand the non-responsiveness to these vaccines, we evaluated, for the first time in south Indian population, the broad spectrum of Th1 and Th2 cytokines levels in healthy adults vaccinated with rHB vaccines.

## MATERIALS AND METHODS

### Subjects

The subjects were healthy volunteers aged between 25 to 40 years. All subjects received intramuscular injections of three doses of 20  $\mu$ g of any of the three rHB vaccines with 0, 1 and 2 month regimen. Four weeks after the three dose of vaccination, serum anti-HBs levels were quantified using commercially available anti-HBs kit. Based on the anti-HBs titers, subjects were identified and recruited in the study as non-responders ( $< 10$  mIU/mL), hypo-responders (10 to 100 mIU/mL) and high-responders  $> 100$  mIU/mL (Figure 1). Four weeks following the third dose, blood samples were obtained and peripheral blood mononuclear cells (PBMCs) were separated from 27 volunteers that comprised of 7 non-responders, 10 hypo-responders and 10 high-responders to rHB vaccines for *in vitro* stimulation of the lymphocytes with HBsAg and PHA.

### Measurement of anti-HBs antibody response

Vaccines were screened for anti-HBs titers 4 wk after vaccination using the commercial Monolisa anti-HBs kit (BioRad, Belgium). Anti-HBs titers were quantified by extrapolation from a standard curve constructed using a serum sample with known concentration of antibody,

**Figure 1** Comparison of anti-HBs levels from vaccine non-responders (NS), hypo-responders (Hypo) and high-responders (High) after booster HBV vaccination. <sup>a</sup> $P < 0.05$ ; <sup>b</sup> $P = 0.001$ .

provided by the manufacturer. All these volunteers were also tested for anti-HCV and anti-HIV antibodies to rule out the possibility of immunosuppression.

### *In vitro* stimulation of PBMC

PBMC were separated from EDTA-anticoagulated venous blood by density gradient centrifugation on Ficoll-Paque (Amersham Biosciences, NJ, USA). After washing in RPMI-1640 medium (Himedia, India), PBMC were suspended in complete culture medium containing RPMI-1640 supplemented with 10% heat-inactivated fetal calf serum (FCS) (Himedia India), 2 mmol/L L-glutamine (Himedia, India), 100  $\mu$ g/mL penicillin and 100  $\mu$ g/mL Gentamicin (Gibco BRL, Scotland). PBMC were seeded at  $1 \times 10^6$  cells/mL in a 24-well sterile tissue culture plate (Nunc, USA) in the presence or absence of 5  $\mu$ g/mL of purified rHBsAg provided by Serum Institute of India, and 5  $\mu$ g/mL of PHA (Gibco BRL, Gaithersburg, MD) were used as positive controls and unstimulated cells act as a negative control. The plates were incubated for 72 h at 37°C in a humidified CO<sub>2</sub> (5%) incubator (Nuair, USA). Culture supernatants were collected and stored at -70°C until use.

### Cytokine assays

Supernatants from the PBMC proliferation assays were harvested after 72 h and cytokine levels (IFN- $\gamma$ , IL-2, TNF- $\alpha$ , IL-12, IL-10 and IL-4) were measured using commercial sandwich ELISA kits (Biosource Europe, SA) as per manufacturer's instructions. Briefly, culture supernatants distributed in 96-well plates coated with corresponding anti-cytokine antibodies were used to detect cytokine anti-cytokine complexes. The reaction was developed with TMB in 0.1 mol/L sodium acetate solutions and H<sub>2</sub>O<sub>2</sub>. Optical density was read at 450 nm. The concentration of cytokines in culture supernatants were calculated from the standard curve for each cytokine plotted on a log-log paper. The sensitivities of the assays for IFN- $\gamma$ , IL-2, TNF- $\alpha$ , IL-12, IL-10 and

IL-10 (pg/mL)	HBsAg	260.8 $\pm$ 128.8	60 $\pm$ 49.7	47 $\pm$ 38.7
	PHA	651.6 $\pm$ 132.07	606 $\pm$ 165.88	519.1 $\pm$ 152.2
	P	0.001	0.001	0.001
IL-4 (pg/mL)	HBsAg	83.2 $\pm$ 72.3	62.8 $\pm$ 44.4	49.2 $\pm$ 39.9
	PHA	610 $\pm$ 135.63	607.9 $\pm$ 163.4	569 $\pm$ 109.34
	P	0.001	0.001	0.001

Test of significance was student independent t test.

IL-4 were 0.1 U/mL, 0.1 U/mL, 3 pg/mL, 1.5 pg/mL, 1 pg/mL, 2 pg/mL, respectively.

### Statistical analysis

The data generated were analyzed using the statistical package for social sciences, (SPSS, version 13.0, Chicago, IL, USA). Anti-HBs response to all volunteers is expressed as geometric mean titers statistical difference was obtained by student t test. Differences in cytokine concentrations between the three groups of subjects were analyzed with the one-way ANOVA F test. Comparison of three groups between two different stimulations were analyzed by using multiple comparisons by Bonferroni "P" test. Correlations were calculated using Pearson's test. P values  $\leq$  0.05 were considered as significant.

## RESULTS

### Booster vaccination to HBV elicited broad spectrum of cytokines in high-responders

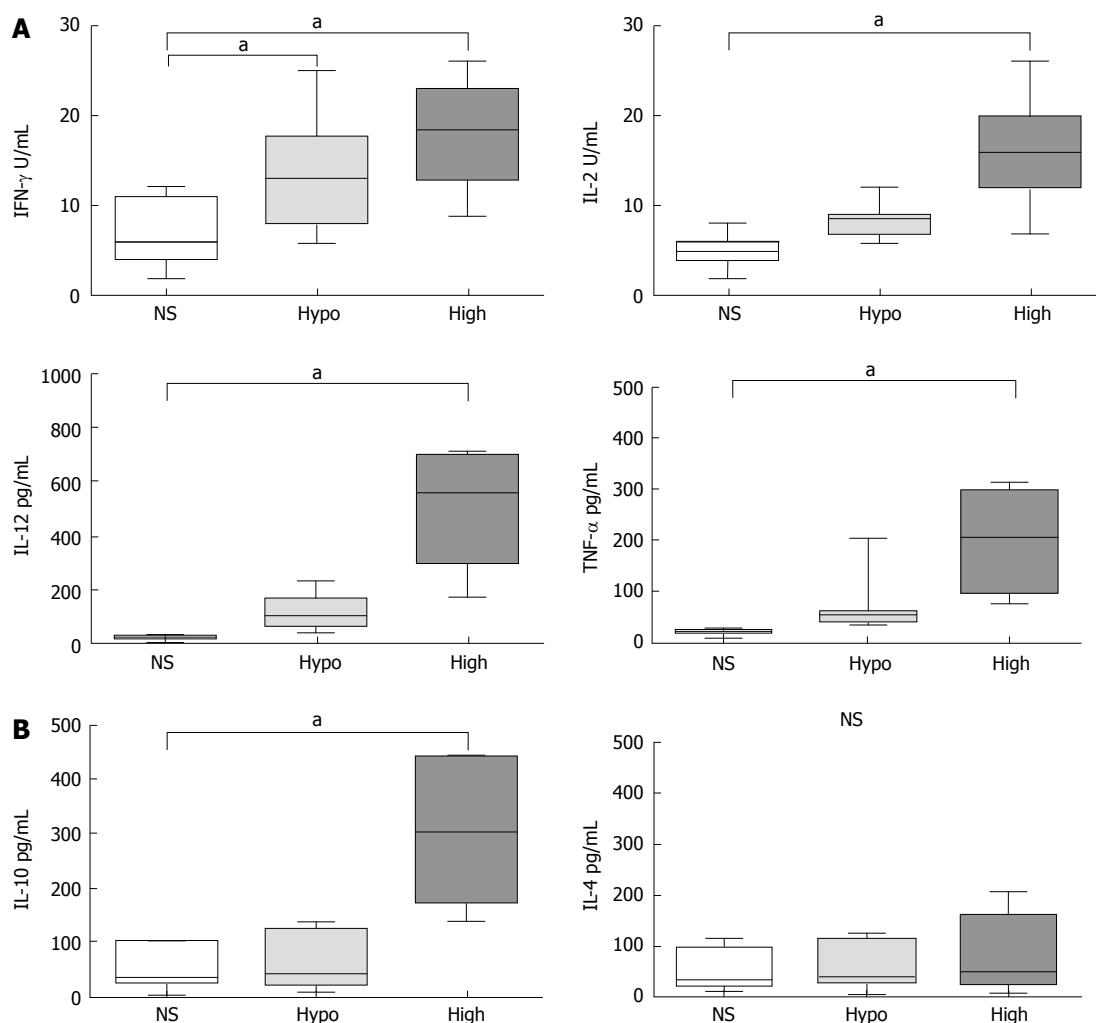

Booster HB vaccination induces a strong humoral response; however, approximately 2% of healthy adults in our study fails to induce Ab response. Based on the production of the antibody levels volunteers were classified in to non responders and responders (Figure 1).

There was a general correlation between serum anti-HBs level and the levels of Th1 and Th2 type cytokine response *in vitro*. A significant increase in the production of Th1 and Th2 cytokines was observed following stimulation of PBMC from high-responders with HBsAg except the Th2 cytokine IL-4. On the other hand, PHA induced two to three fold higher levels of all the cytokines in all the groups compared to HBsAg stimulation (Tables 1 and 2). This difference was significant for TNF- $\alpha$ , IL-10, and IL-4. However, there was no difference in the IFN- $\gamma$ , IL-2 and IL-12 levels. In addition, there was a several fold difference between the production of all cytokines between HBsAg and PHA stimulation in non-responders and hypo-responders (Table 2) which clearly demonstrate that the non-responsiveness is restricted to HBsAg specific response.

### Deficient Th1 cytokine levels in non-responders after booster immunization

The overall Th1 cytokine profile was elevated in high-responders compared with other two groups (Figure 2A). IFN- $\gamma$  production was significantly higher in high and hypo-responders compared to non-responders (P = 0.001). However, high-responders secreted higher levels of IL-2 and TNF- $\alpha$  compared with hypo-

**Figure 2** Cytokine secreted by PBMC's from high-responders, hypo-responders and non-responder adults after *in vitro* stimulation with HBsAg. **A:** Comparison of Th1 cytokines (IFN- $\gamma$ , IL-2, TNF- $\alpha$ , and IL-12) between the three groups of vaccine responders; **B:** Comparison of Th2 cytokines (IL-10 and IL-4) between the three groups of vaccine responders. \* $P < 0.05$ .

responders and non-responders (Table 1 and Figure 2A). IFN- $\gamma$  and IL-2 levels with HBsAg in high-responders were comparable with those of PHA, however, which was not observed in hypo or non-responders. A stronger positive correlation was observed between Th1 cytokine IFN- $\gamma$  ( $r^2 = 0.254$ ) and IL-2 ( $r^2 = 0.424$ ) production when compared with the anti-HBs response between the three groups of volunteers (Figure 3A). On the contrary, a weak correlation was observed with TNF- $\alpha$  ( $r^2 = 0.183$ ) production. Furthermore, the levels of IFN- $\gamma$  and IL-2 strongly correlated with the levels of IL-12 ( $r^2 = 0.52$ ) when compared between the three groups (data not shown).

#### Modulation of IL-12 production in non-responders and high-responders

There was a significant enhancement in production of IL-12 ( $P = 0.001$ ) in high responders compared with hypo-responders and non-responders (Figure 2A). Furthermore, a strong correlation ( $r^2 = 0.436$ ) was observed between the *in vivo* anti-HBs and *in vitro* IL-12 levels (Figure 3A). On the whole, our results suggest the existence of a strong association between the levels of IL-12 and Th1

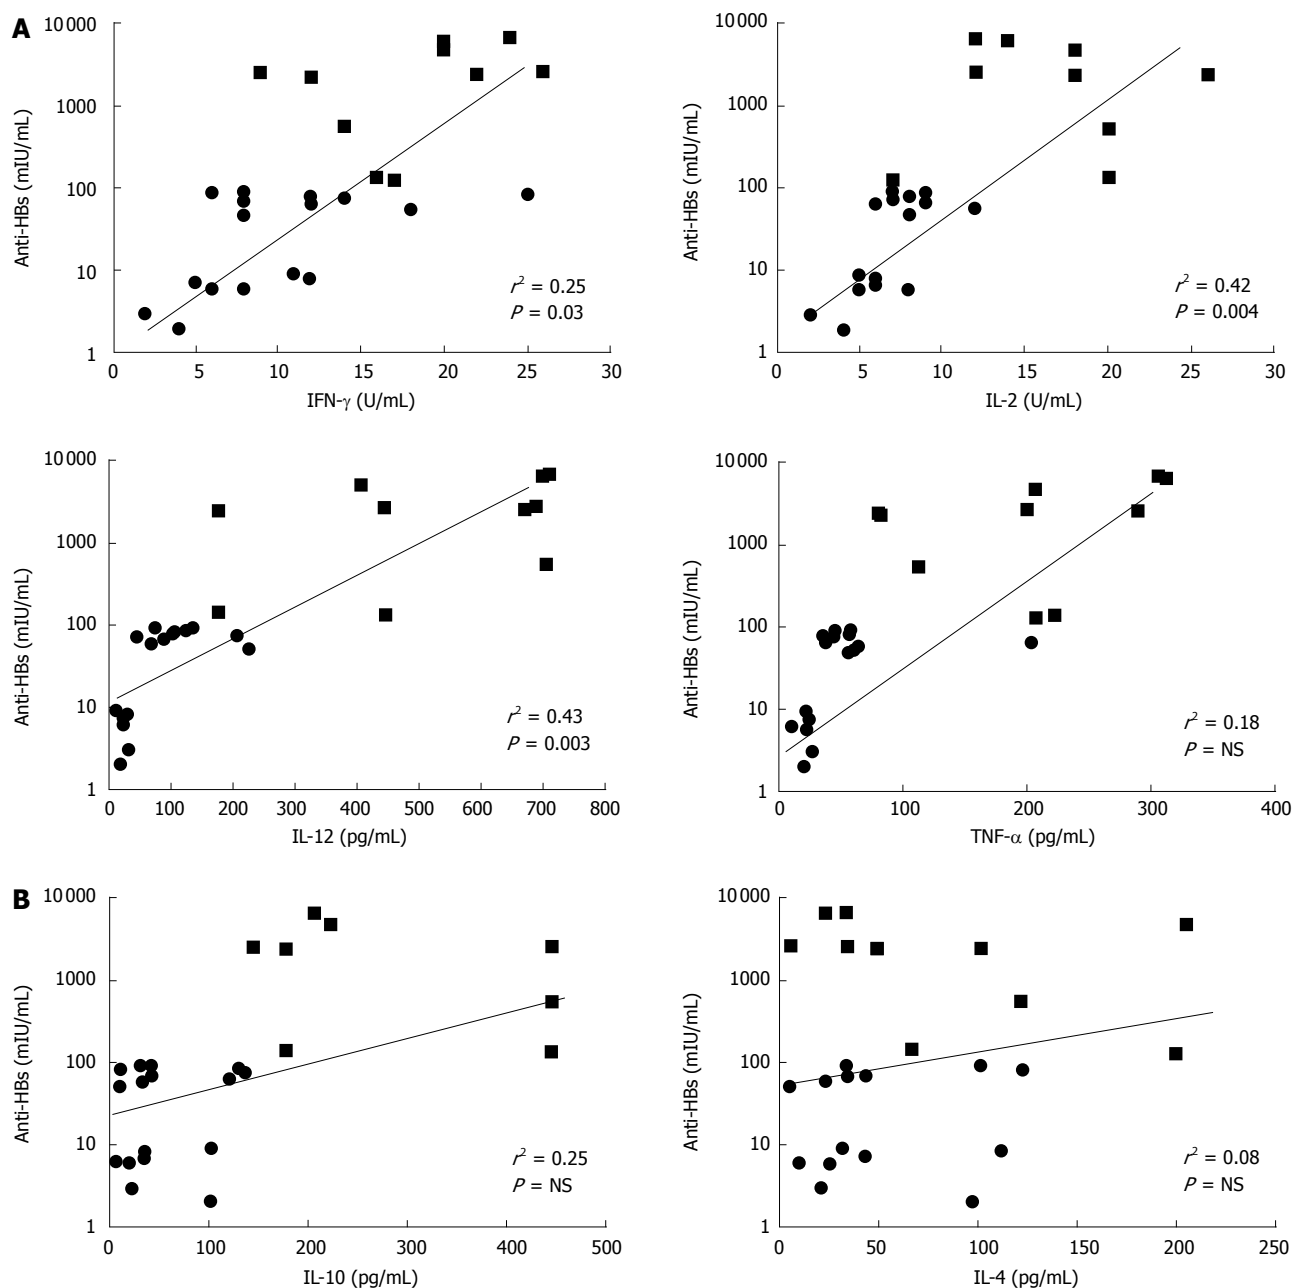

cytokines, which strongly implies that IL-12 may play a major regulatory role in the modulation of Th1 cytokine production in high-responders.

#### Elevated levels of Th2 cytokine response in high-responders after booster immunization

PBMC from high-responders produced significantly more IL-10 levels than those of hypo-responders and non-responders ( $P = 0.001$ ). The levels of IL-4 were very low and were comparable between the three groups of volunteers. However, they were significant when compared with PHA stimulations ( $P = 0.001$ ). No significant correlation was observed between anti-HBs production and IL-4 response ( $r^2 = 0.088$ ) (Figures 2B and 3B). In addition, a strong negative correlation was observed between the Th1 cytokine production and the IL-4 response (data not shown). In contrast, a weakly significant correlation was observed between IL-10 production and anti-HBs response ( $r^2 = 0.25$ ) in the volunteers (Figure 3B).

## DISCUSSION

Correlation between the humoral response *in vivo* and the

**Figure 3** Correlation between anti-HBs titers and cytokine levels secreted after *in vitro* stimulation of PBMC with HBsAg from high-responder, hypo-responder and non-responder adults. **A:** Correlation of anti-HBs antibody response and the Th1 cytokine (IFN- $\gamma$ , IL-2, IL-12 and TNF- $\alpha$ ) response to HBsAg; **B:** Correlation of anti-HBs antibody response and the Th2 cytokine (IL-10 and IL-4) response to HBsAg.

cellular response *in vitro* to HBsAg is dependent on the cytokine secretion profile of activated T lymphocytes<sup>[18]</sup>. Protective immune response to HBsAg is associated with the production of HBsAg specific neutralizing antibody<sup>[19,20]</sup>. The process of antibody production to this HBsAg is T-cell dependent and requires Th cell activation<sup>[20]</sup>. Secretion of Th2-like cytokines, such as IL-4, IL-5, IL-6, IL-10 and IL-13, is thought to be detrimental for B-cell differentiation and production of specific antibodies, whereas secretion of Th1-like cytokines, namely IL-2, IFN- $\gamma$ , TNF- $\alpha$  and transforming growth factor (TGF)- $\beta$  triggers the cell-mediated immune response leading to cure of HBV infected hepatocytes or destruction of HBV-infected cells<sup>[21-23]</sup>.

Several investigators have tried to study the pattern of

cytokine production in a variety of diseases<sup>[20,24]</sup>, including investigations in unresponsiveness to HBsAg in the recent past<sup>[26]</sup>. The results have been contradictory in analysis of *in vitro* HBsAg-induced cytokine production. These included absence of Th1 cytokine production in non-responders<sup>[9,26,27]</sup>, lack of Th2 response in both responders and non-responders<sup>[27]</sup>, absence of Th1 and Th2 cytokines in non-responders<sup>[27,28]</sup> and production of both cytokines in high-responders<sup>[28]</sup>. However, in contrast to the above findings there are also report showing no correlation between the function and cytokine production of HBsAg specific CD4 T cells<sup>[29,30]</sup>. In addition, predominant Th2 and Th1 responses have also been reported in high and low-responders, respectively<sup>[31]</sup>.

Our findings of diminished Th1 and Th2 responses

in non-responders confirmed and extended the results reported by others<sup>[25,28]</sup>. However, those studies assessed only a few cytokines, whereas in our study we looked at a broad spectrum of cytokines which represents Th1/Th2 profiles. Both types of cytokines Th1 cytokines (IL-2, IFN- $\gamma$ , TNF- $\alpha$ , IL-12) and Th2 cytokines (IL-10, IL-4) were secreted at significantly higher levels in high-responders compared with hypo-responders and non-responders. In addition the regulatory cytokine levels IL-12 were highly elevated in the high-responders compared to hypo-responders and non-responders, furthermore it is demonstrated that IL-12 induction of Th1 response is important for viral clearance in subjects suffering with chronic HB infection<sup>[24,27]</sup>.

The limitations in our study would be a small sample size and the variations in responder's cytokine profiles. However, the overall differences between the three groups of vaccines are pronounced (Table 1 and Figures 1 and 2). The significance of our results is more magnified when analyzed in the context of PHA-induced cytokine production. Despite the production of several-folds higher concentration of all cytokines in response to PHA, as compared with HBsAg, in all three groups of responders (Table 2), no significant differences were observed between the stimulations for IFN- $\gamma$ , IL-2, IL-12, IL-10, IL-4 and TNF- $\alpha$  (Table 2). These findings strongly agree and suggest the possibility of involvement of a generalized immune dysfunction in the non-responder subjects with regard to HBsAg stimulation and culture condition.

In summary, we have demonstrated diminished production of broad range of cytokines IFN- $\gamma$ , IL-2, TNF- $\alpha$ , IL-12, IL-10 and IL-4 in PBMC from healthy non-responders to HB vaccine, suggesting insufficient or lack of Th1 and Th2 responses. This could be because of a defect in either the primary HBsAg-specific T-cell repertoire<sup>[9]</sup> or antigen presentation<sup>[32]</sup>. Our study in non-responder adults strongly suggests the contribution of IL-12 cytokine levels which may lead to the dysfunction of antigen-presenting cells in unresponsiveness to the vaccine.

## COMMENTS

### Background

Hepatitis B virus (HBV) infection is one of the leading causes of morbidity and mortality world wide. Since there is no effective treatment for HBV, vaccination plays a vital role in preventing the infection. Hepatitis B vaccine induces a protective immune response in the majority of individuals. However, 4%-10% of healthy recipients fail to generate an effective antibody response against HBV after standard immunization. Inadequate immune response could be attributed to a variety of mechanisms. Here we made an attempt to study the cellular defects attributed to HB vaccine non-responders and responders.

### Research frontiers

This study was undertaken in order to analyze the cellular (cytokines) defects associated with non-responsiveness to hepatitis B (HB) vaccine in healthy individuals. Here we demonstrated that peripheral mononuclear cells (PBMC) isolated from anti-HBs seropositive subjects after booster injection were able to make both Th1/Th2 cytokines *in vitro* by stimulation with the surface antigen of HBV (HBsAg) in responses. In contrast, under the same conditions, non-responder PBMC failed to produce cytokines *in vitro*, furthermore we also demonstrated Th1 cytokine profile dominant compared to the Th2 profile and a strong positive correlation was obtained when comparing the regulatory

cytokine (IL-12) production with the strong anti-HBs response. To the best of our knowledge this is the first study which addressed the lack of Th1/Th2 cytokine profile in the south Indian population.

### Innovations and breakthroughs

Vaccination with HBsAg induces protective immunity through T-helper (Th) cell dependent production of anti-HBs antibody. Several studies have been conducted to investigate the precise role of Th1 and Th2 derived cytokines in the immune response to hepatitis B vaccine and to get further insights into the cellular basis of unresponsiveness to HBsAg. Controversial results, however, have been reported. Analyses of *in vitro* HBsAg-induced cytokine production have revealed defects in: Th1 cytokines in non-responder subjects; Th2 response in both responder and non-responder groups; Th1 and Th2 cytokines in non-responders; Different patterns of cytokine production have been observed in T-cell clones isolated from responder subjects, with either predominant Th0 or Th2 response; or Th1 and Th2 responses in high and low responders, respectively. Insufficient production of both types of cytokines in healthy non-responder individuals has been demonstrated. However, in this study we looked into the broad spectrum of cytokines and correlated them with their antibody production. Furthermore we also observed significant difference in the production of IL-12 by HBsAg in high-responders compared with non-responders. The significance is more magnified when analyzed in the context of the PHA induced IL-12 profile. Despite the production of higher concentration of IL-12 in response to PHA, as compared to HBsAg in both responders and non-responders subjects, no significant difference was observed between the groups, these results emphasize the exclusion of the possibility of involvement of generalized immune dysfunction on non-responders adults. Furthermore increase in IL-12 levels also strongly correlated with the induction of Th1 response. Taken together our data suggest that the non-responsiveness is associated with the defective production of both Th1 and Th2 cytokines.

### Applications

Our findings of significantly increased production of all cytokines in response to HBsAg as compared to control cultures without stimulation in responder vaccines, together with significantly higher secretion of these cytokines induced by PHA compared to HBsAg in non-responder, but not responder adults, may have important implications. These results suggest that in addition to the serum levels of anti-HBs antibody, the profile of cytokine secretion could also be used as an objective criteria and distinctive parameter to identify hepatitis B vaccine responder and non-responder individuals.

### Peer review

The authors compared a broad spectrum of cytokine (Th1/Th2 cytokine) response in hepatitis B vaccine non-responders, hypo-responders and high responders. They also demonstrated that lack of both Th1/Th2 cytokine profiles are associated with the non-responsiveness to hepatitis B vaccine.

### Abstract

**AIM:** To study retrospectively the influence of intra-abdominal hypertension (IAH) and abdominal compartment syndrome (ACS) in patients with early acute pancreatitis (AP) (during the first week after admission) on physiological functions, and the association of the presence of IAH/ACS and outcome.

**METHODS:** Patients ( $n = 74$ ) with AP recruited in this study were divided into two groups according to intra-abdominal pressure (IAP) determined by indirect measurement using the transvesical route *via* Foley bladder catheter during the first week after admission. Patients ( $n = 44$ ) with IAP  $\geq 12$  mmHg were assigned in IAH group, and the remaining patients ( $n = 30$ ) with IAP  $< 12$  mmHg in normal IAP group. For analysis of the influence of IAH/ACS on organ function and outcome, the physiological parameters and the occurrence of organ dysfunction during intensive care unit (ICU) stay were recorded, as were the incidences of pancreatic infection and in-hospital mortality.

**RESULTS:** IAH within the first week after admission was found in 44 patients (59.46%). Although the APACHE II scores on admission and the Ranson scores within 48 h after hospitalization were elevated in IAH patients in early stage, they did not show the statistically significant differences from patients with normal IAP within a week after admission ( $16.18 \pm 3.90$  vs  $15.70 \pm 4.25$ ,  $P = 0.616$ ;  $3.70 \pm 0.93$  vs  $3.47 \pm 0.94$ ,  $P = 0.285$ , respectively). ACS in early AP was recorded in 20 patients (27.03%). During any 24-h period of

the first week after admission, the recorded mean IAP correlated significantly with the Marshall score calculated at the same time interval in IAH group ( $r = 0.635$ ,  $P < 0.001$ ). Although ACS patients had obvious amelioration in physiological variables within 24 h after decompression, the incidences of pancreatic infection, septic shock, multiple organ dysfunction syndrome (MODS) and death in the patients with ACS were significantly higher than that in other patients without ACS (pancreatic infection: 60.0% vs 7.4%,  $P < 0.001$ ; septic shock: 70.0% vs 11.1%,  $P < 0.001$ ; MODS: 90.0% vs 31.5%,  $P < 0.001$ ; mortality: 75.0% vs 3.7%,  $P < 0.001$ ).

**CONCLUSION:** IAH/ACS is a frequent finding in patients admitted to the ICU because of AP. Patients with IAP at approximately 10-12 mmHg and early signs of changes in physiologic variables should be seriously considered for urgent decompression to improve survival.

### INTRODUCTION

Compartment syndrome is a condition in which increased pressure in a confined anatomical space adversely affects circulation and threatens the perfusion of tissues therein. The abdominal cavity can be considered as a single compartment and any change in the volume of any of its contents will elevate intra-abdominal pressure (IAP). Abdominal compartment syndrome (ACS) is the clinical syndrome resulting from a persistent increase in IAP. Intra-abdominal hypertension

(IAH) contributes to organ dysfunction and leads to the development of ACS. The resultant ACS refers to the complications caused by elevated IAP, including diaphragmatic compression with reduced pulmonary compliance, cardiovascular and renal dysfunction, and intestinal and hepatic ischemia<sup>[1]</sup>. Recently, the elevated IAP after onset of acute pancreatitis (AP) has gained growing attentions. ACS is characterized by multiple organ dysfunction syndrome (MODS), and if unrelieved, eventually results in death. This study aims to investigate the incidence and clinical outcome of ACS in patients with AP in early stage (within the first week after admission).

## MATERIALS AND METHODS

### Criteria and definition

AP was diagnosed by the criteria based on the consensus of the international symposium on AP (Atlanta definition)<sup>[2]</sup>. The presence of IAH/ACS was defined by the criteria of the World Society of ACS (WSACS)<sup>[3]</sup>. The association between IAH and organ dysfunction characterized the ACS. IAH was defined as an IAP of 12 mmHg or higher, which often rendered many organs dysfunctional. IAH was a consistently increased IAP value of  $\geq 12$  mmHg recorded by at least three standardized pressure measurements during at least 8 h. ACS was diagnosed when the IAP exceeded 20 mmHg at which IAH caused severe physiologic derangements and associated with new, attributable single organ dysfunction or MODS. Septic shock was defined according to the American-European conference consensus definitions<sup>[4]</sup>.

### Patients

The study population included 74 patients with AP admitted to the surgical intensive care unit (SICU), Xuan Wu Hospital of Capital Medical University, from May 2002 to May 2006. General inclusion criteria for AP were defined as: (1) a time interval between onset of typical abdominal symptoms and study inclusion of 72 h and less; (2) the presence of systemic inflammatory response syndrome (SIRS) manifested by two or more of the following conditions: temperature  $> 38^{\circ}\text{C}$  or  $< 36^{\circ}\text{C}$ ; heart rate (HR)  $> 90$  beats/min; respiratory rate  $> 20$  breaths/min or  $\text{PaCO}_2 < 32$  mmHg; WBC count  $> 12\,000/\text{mm}^3$  or  $< 4000/\text{mm}^3$ , or  $> 10\%$  immature(band) forms; and (3) at least 3-fold elevated serum amylase or lipase levels, or a APACHE II score  $> 8$ , or a C-reactive protein (CRP) of  $\geq 250$  mg/L.

All patients were treated according to our standard management of pancreatitis protocol and the practice guidelines in AP<sup>[5]</sup>. The patients recruited in this study were divided into two groups according to IAP determined during the first week after admission. Patients ( $n = 44$ ) with IAP  $\geq 12$  mmHg were assigned in IAH group, and the remaining patients ( $n = 30$ ) with IAP  $< 12$  mmHg in normal IAP group. Patients with IAH or ACS were treated by lowering IAP with promoting enterokinesia, and/or percutaneous abdominal decompression and drainage and/or

decompressive emergency laparotomy. A silastic covering was placed to achieve a pressure-free abdominal closure when decompressive laparotomy was performed. The definitive closure was performed within 5-7 d. In the setting of gallstone pancreatitis and evidence of common bile duct obstruction, urgent endoscopic retrograde cholangiopancreatography (ERCP) with sphincterotomy was indicated to remove the impacted stone.

### Anthropometric examination and measurement

Patients with AP admitted to SICU underwent intermittent measurement of IAP, recording of the clinical data and calculation of MODS scores by Marshall *et al*<sup>[6]</sup>. Since intravesical pressure (IVP) measurement had been described as a standard and validated technique of indirectly reflecting IAP and rapidly recognizing ACS<sup>[7]</sup>, urinary bladder pressure (UBP) was routinely measured in all AP patients in our study. In brief, the patient was placed in complete supine position with a Foley catheter. One end of a transducer was connected to the Foley catheter through 3-way stopcocks. The monitor was zeroed with the transducer at the level of the symphysis pubis. After clamping the drainage tube of the urinary catheter, the bladder was instilled with 50 mL of sterile normal saline injected through a Foley catheter under aseptic condition, the bladder was then emptied by removing the clamp off the drainage tube. IVP was measured using a pressure transducer, and a series of reading were obtained every 4 h apart and their average calculated as one standardized measurement in mmHg (1 mmHg = 1.36 cmH<sub>2</sub>O). Only end-expiratory values were used in an effort to avoid interference from respiratory excursion of the diaphragm into the intra-abdominal space. A sustained increase in IAP was detected based upon at least three consecutive standardized measurements during at least 8 h.

Hemodynamics and other physiologic parameters, including HR, mean arterial pressure (MAP), central venous pressure (CVP), urine output (UO), peak airway pressure (PAP), arterial carbon dioxide partial pressure ( $\text{PaCO}_2$ ), modified respiratory index (MRI) expressed as the arterial oxygen partial pressure ( $\text{PaO}_2$ ) to fraction of inspired oxygen ( $\text{FiO}_2$ ) ratio ( $\text{PaO}_2/\text{FiO}_2$ ), arterial pH, arterial base deficits (BE) and arterial lactic acid, were registered before and after decompression of ACS. The worst Acute Physiology and Chronic Health Evaluation (APACHE) II score and Ranson scoring system during the first 24 or 48 h of SICU stay were recorded respectively in the identification of the severity of pancreatitis. In this study, we applied a Marshall subscore of 2 or more in any of the 6 organs (respiratory, cardiovascular, coagulation, central nervous system, hepatic, and renal) to indicate organ dysfunction associated with IAH (IAP  $> 20$  mmHg), and defined the presence of ACS. MODS was defined as two or more organs having persistently 2 or more Marshall subscores for more than 24 h despite aggressive resuscitation and organ support. Total Marshall scores were computed daily and for the entire duration of the intensive care stay.

All 74 patients with AP were detected using contrast

Table 1 Etiology of attacks in 74 patients with AP

Etiology of attacks	Number of patients (%)	IAH group No. (%)	Normal IAP group No. (%)
Gallstones	46 (62.16)	26 (59.09)	20 (66.67)

enhanced computed tomography (CT) on admission. The contrast-enhanced CT scan severity index (CT-SI) developed by Balthazar and coworkers was used for evaluating severity of pancreatitis<sup>[8]</sup>. CT-SI was measured for all patients on admission in this study. The incidences of pancreatic infection, septic shock, MODS, and the in-hospital mortality were also recorded. Pancreatic infection included infected necrosis and pancreatic abscess. Necrosis formation of the pancreas was assessed by contrast-enhanced CT. Patients with pancreatic necrosis or large peripancreatic fluid collections who manifested clinical signs of sepsis with a non-improving or deteriorating clinical course despite a reasonable time of medical therapy underwent fine-needle aspiration (FNA) of the necrotic areas or fluid collections under CT or ultrasound guidance to determine the presence of bacterial contamination or pancreatic infection.

### Statistical analysis

Patients' clinical records were retrospectively reviewed. Data were analyzed using the software package SPSS version 11.5. Continuous data are presented as mean  $\pm$  SD. Categorical variables are expressed as numbers and percentages for the group from which they were derived. The comparisons of age, gender, APACHE II score and CT-SI on admission, Ranson score within 48 h after admission, incidences of pancreatic infection and MODS, and the in-hospital mortality between the two groups were analyzed using the independent sample *t* test or  $\chi^2$  test as appropriate. Comparison of clinical parameters between before decompression and after decompression of ACS was performed by paired samples *t* test. Bivariate correlations were analyzed by Pearson test between the mean IAP in any 24-h period within the first week after admission and the Marshall score at the same time interval, or, between the IAP on admission and the

APACHE II score on admission or Ranson score within 48 h after admission. Difference was defined as statistically significant if  $P < 0.05$ .  $P^*$  (corrected  $P$ )  $< 0.017$  indicated statistically significant difference in multiple comparisons of complications and outcome between patients with and without ACS in  $\chi^2$  test.

## RESULTS

### IAH group and normal intra-abdominal pressure group

Seventy-four patients (39 men and 35 women) were included in the study; the mean age was 63.00  $\pm$  9.79 years (range, 42-87 years). The mean time interval between onset of AP and admission was 34.97  $\pm$  30.16 h. IAH developed in 44 (59.46%) of 74 patients with AP. The etiologic causes of their AP are detailed in Table 1. The difference in etiologic causes between the two groups was not statistically significant,  $P = 0.803$  (Fisher two-tail exact probability test). The differences in age, gender, APACHE II score, Ranson score and CT-SI on admission were also not statistically significant between IAH group and group with normal IAP (Table 2). Neither age nor gender was correlated with IAH development. Similarly, APACHE II score and CT-SI on admission, and Ranson score within 48 h after admission, contrary to accepted belief, were not found predictive of early IAH development.

During any 24-h period of the first week after admission, the recorded mean IAP was correlated significantly with the Marshall score calculated at the same time interval in IAH group ( $r = 0.635$ ,  $P < 0.001$ ), but IAP on admission had no significant correlation with APACHE II score on admission and Ranson score within 48 h after admission ( $r = 0.127$ ,  $P = 0.248$ , and  $r = 0.145$ ,  $P = 0.263$ , respectively).

### ACS patients

ACS was recorded during the first week after admission in 20 patients (27.03%) in whom IAH (IAP  $> 20$  mmHg) was associated with organ dysfunction or failure. In 14 of these patients, IAH and organ dysfunction were present on admission, 2 patients had IAH on admission and developed organ dysfunction 24-48 h later, whereas 4 patients had respiratory failure on admission without IAH but went on to develop IAH and ACS 3-5 d after admission. Medicine and physical therapy were applied in all IAH patients to promote enterokinesia for recovery of IAH/ACS. The administration of prokinetic motility agents such as erythromycin, metoclopramide, or neostigmine appeared to hold promise in evacuating the intraluminal contents and decreasing the size of the viscera. Moreover, sedation and muscle relaxant (only for mechanical ventilated patients) were also used properly to lower IAP. Seven ACS patients had restoration of organ function with their UBP lowering less than 12 mmHg *via* non-invasive intervention mentioned above. The remaining 13 ACS patients had progressive deterioration of organ function and increases in IAP despite active persistent non-invasive decompression management for 24 h. Therefore, these

**Table 3** Changes in physiological variables after invasive decompressive procedure in patients with ACS ( $n = 13$ , mean  $\pm$  SD)

Variable	Before decompression	After decompression	$t$ value	$P$ value
MAP (mmHg)	53.77 $\pm$ 8.98	74.15 $\pm$ 6.68	7.23	< 0.001
UBP (mmHg)	36.69 $\pm$ 5.33	18.31 $\pm$ 3.25	-8.77	< 0.001
UO (mL/h)	21.76 $\pm$ 13.42	85.78 $\pm$ 18.46	13.29	< 0.001
CVP (mmHg)	15.01 $\pm$ 5.24	13.02 $\pm$ 5.01	-1.97	0.072
BE	-9.31 $\pm$ 3.09	-1.69 $\pm$ 2.59	6.67	< 0.001
PH	7.28 $\pm$ 0.10	7.36 $\pm$ 0.06	2.35	0.037
PaO <sub>2</sub> /FiO <sub>2</sub> (mmHg)	129.22 $\pm$ 41.30	229.24 $\pm$ 63.47	4.33	0.001
PAP (cmH <sub>2</sub> O)	41.23 $\pm$ 12.90	24.46 $\pm$ 5.41	-4.25	0.001
HR (bpm)	132.38 $\pm$ 13.68	111.62 $\pm$ 12.85	-5.19	< 0.001
PaCO <sub>2</sub> (mmHg)	47.61 $\pm$ 11.24	38.63 $\pm$ 5.78	-2.38	0.034
Lactate (mmol/L)	4.48 $\pm$ 0.95	2.02 $\pm$ 0.80	-8.11	< 0.001

MAP: Mean arterial pressure; UBP: Urinary bladder pressure; UO: Urine output; CVP: Central venous pressure; BE: Arterial base deficits; pH: Arterial Ph; PaO<sub>2</sub>/FiO<sub>2</sub> (MRI): Arterial oxygen partial pressure/fraction of inspired oxygen; PAP: Peak airway pressure; HR: Heart rate; PaCO<sub>2</sub>: Arterial carbon dioxide partial pressure; Lactate: Arterial lactic acid.

patients had abdominal decompression procedure very soon. The mean time interval between diagnosis of ACS and initiation of invasive decompressive procedure was  $28.38 \pm 2.29$  h (range, 26-33 h). Prior to invasive decompression, aggressive attempts should be made to correct coagulation deficits, acidosis and hypovolemia.

The invasive decompressive procedure included two ways: abdominal percutaneous decompression drainage and decompressive laparotomy with temporary closure. IAP was reduced in one of the two ways. The insertion of abdominal drains was performed in 8 patients under CT or ultrasound guidance in the presence of large intra-abdominal collections more than 800 mL. These patients had their abdomens decompressed by percutaneous placement of a large-bore hemodialysis catheter into the intra-abdominal space, with drainage of intra-abdominal fluid. Percutaneous drainage was a continual process with fluid draining for several days. Once the drainage stopped, the catheter was removed. No complication related to the procedure occurred in our study. Decompressive drainage reduced the IAP by less than 20 mmHg and then further resulted in relief of the IAH in 5 patients. Decompressive laparotomy was performed in the remaining 5 patients with ACS and 3 patients of failure in previous percutaneous abdominal decompressive drainage for the reduction in IAP. The typical open abdomen operation was performed with a temporary silastic covering obtained from the sterilized inner surface of an intravenous bag sewn to the fascia to protect the underlying abdominal contents from injury and desiccation, and to prevent excessive amounts of fluid from leaking onto surrounding bandages. Removal of silastic covering and scheduled closure of abdominal wall should be subsequently attempted as soon as possible after the acute episode resolved and the edema and/or inflammatory fluid collections reduced significantly. No complication directly related to decompressive laparotomy itself occurred in our study.

All patients with bladder pressure of more than

20 mmHg immediately benefited from the alternative of invasive decompression methods. Emergency invasive decompressive procedure resulted in statistically significant improvement in physiologic parameters, with the exception of the CVP, within 24 h after decompression (Table 3). Pre-decompression bladder pressure was significantly elevated, with a mean pressure of  $36.69 \pm 5.33$  mmHg. Abdominal compartment release resulted in a dramatic decrease of IAP to  $18.31 \pm 3.25$  mmHg ( $P < 0.001$ ). The high PAP improved significantly from  $41.23 \pm 12.90$  cmH<sub>2</sub>O pre-decompression to  $24.46 \pm 5.41$  cmH<sub>2</sub>O post-decompression ( $P = 0.001$ ). Other general physiologic condition also improved significantly with decompression, as evidenced by a significant improvement in serum pH, BE, PaO<sub>2</sub>/PaCO<sub>2</sub>, arterial lactic acid, MAP and UO. Only one parameter registered in this study, e.g. CVP, was not affected by decompression for ACS ( $P = 0.072$ ).

### Prognosis

Seventeen of 74 patients died with a mortality rate of 22.97%. It appeared that the incidences of pancreatic infection and MODS in patients with ACS in early stage were considerably higher than other patients without ACS. Subsequently, the unacceptably high mortality rate in patients with ACS during their first week after admission was much higher than that in patients without ACS in the course of their attack of AP (75% *vs* 3.33% and 4.17%) (Table 4).

Multiple comparisons of complications and outcome were made between ACS patients (IAP > 20 mmHg), IAH patients without ACS ( $12 \text{ mmHg} \leq \text{IAP} \leq 20 \text{ mmHg}$ ) and normal IAP patients (IAP < 12 mmHg). The incidences of pancreatic infection, septic shock, MODS and in-hospital mortality in patients with ACS were significantly higher than those in IAH patients without ACS and normal IAP patients, respectively (pancreatic infection:  $\chi^2 = 13.42$ ,  $P < 0.001$ ;  $\chi^2 = 16.93$ ,  $P < 0.001$ , septic shock:  $\chi^2 = 12.84$ ,  $P < 0.001$ ;  $\chi^2 = 22.12$ ,  $P < 0.001$ , MODS:  $\chi^2 = 11.01$ ,  $P = 0.001$ ;  $\chi^2 = 21.33$ ,  $P < 0.001$ , in-hospital mortality:  $\chi^2 = 23.65$ ,  $P < 0.001$ ;  $\chi^2 = 28.32$ ,  $P < 0.001$ , respectively). However, the difference in incidences of pancreatic infection, septic shock, MODS and in-hospital mortality was not statistically significant between IAH patients without ACS and normal IAP patients (pancreatic infection:  $P = 1.000$ , Fisher two-tail exact probability test; septic shock:  $\chi^2 = 0.527$ ,  $P = 0.468$ ; MODS:  $\chi^2 = 2.078$ ,  $P = 0.149$ ; in-hospital mortality:  $P = 1.000$ , Fisher two-tail exact probability test).

### DISCUSSION

The ACS is an increasingly recognized complication of both medical and surgical patients. This syndrome has been described in a wide variety of clinical scenarios and results from a persistent elevation in IAP characterized by graded organ system dysfunction. The definitions and diagnosis of IAH or ACS depend greatly on the accuracy and reproducibility of the IAP measurement technique. As a result, IAP must be measured with an

Table 4 Comparison of complications and outcome between patients with and without ACS

Complications and outcome	ACS ( <i>n</i> = 20) (IAP > 20 mmHg)	IAH ( <i>n</i> = 24) (12 mmHg ≤ IAP ≤ 20 mmHg)	Normal IAP ( <i>n</i> = 30) (IAP < 12 mmHg)	$\chi^2$ value	<i>P</i> value
Pancreatic infection (%)	12 (60.00)	2 (8.33)	2 (6.67)	23.84	< 0.001
Septic shock (%)	14 (70.00)	4 (16.67)	2 (6.67)	26.34	< 0.001
MODS (%)	18 (90.00)	10 (41.67)	7 (23.33)	21.85	< 0.001
In-hospital mortality (%)	15 (75.00)	1 (4.17)	1 (3.33)	41.93	< 0.001

MODS: Multiple organ dysfunction syndrome.

accurate, reproducible, and reliable tool. The diagnosis of ACS requires a high level of clinical suspicion combined with an increased IAP, usually obtained *via* UBP measurement. UBP measurement as an estimation of IAP is simple, reliable and widely accepted.

The bladder gold standard measurement techniques reported are not uniform<sup>[9]</sup>. The volume instilled in the bladder is important. This was shown by Fusco *et al*<sup>[7]</sup>, who compared direct laparoscopic insufflation pressure with IVP measured with different bladder volumes. They found that a bladder volume of 50 mL revealed the least bias in measuring elevated IAP. The current standard of IAP measurement in our study *via* the urinary catheter is labor intensive, and its intermittent nature could prevent timely recognition of significant changes in IAP. The continuous IAP measurement proposed by Balogh *et al*<sup>[10]</sup> can be accurately measured via the irrigation port of a three-way catheter and has good agreement with the standard intermittent IAP. Recently, a fully automated IAP measurement technique was described that it can minimize the pitfalls that may alter the accuracy and reproducibility of intermittent IAP measurements (such as volume instilled, zero reference level, air bubbles, over- or underdamping). The IAP catheter is introduced like a nasogastric tube and is equipped with an air pouch at the tip. Automated IAP measurement had good correlation with the standard IVP method<sup>[11]</sup>. Schachtrupp *et al*<sup>[12]</sup> compared different direct and indirect IAP measurement methods in a porcine model and found a very good correlation between the above-mentioned air pouch system and direct insufflator pressure. However, the air pouch system was not available for use in our study.

IAH was defined in our study as a mean IAP ≥ 12 mmHg, whereas ACS was defined as a gradually and consistently increased IAP value of > 20 mmHg associated with at least one organ dysfunction or failure that was not previously present. This study confirms that IAH and ACS are frequent occurrences in patients with AP because these conditions were observed in 59.46% and 27.03% of the studied patients, respectively.

Although ideally the diagnosis of ACS should be made based on the clinical picture and confirmed by measurements of bladder pressure or equivalent, Pickhardt and others<sup>[13]</sup> described the CT findings in four patients with confirmed ACS. They reported that the anteroposterior to transverse abdominal ratio was increased (round belly sign) in patients with ACS. The ACS patients had a ratio of 0.85 compared with 0.70 in controls. Al-Bahrani *et al*<sup>[14]</sup> concluded in their

prospective evaluation of CT features that the presence of round belly sign and bowel wall thickening with enhancement on CT images should alert clinicians to the possibility of presence of IAH and ACS, and to prompt measurement of the IAP and consideration of suitable interventions. The radiological data of CT scans that paralleled with the development of ACS in any course of the disease were deficient in our clinical information, so, we could not analyze the CT findings in ACS patients with SAP in our study.

Patients with AP are at risk for IAH/ACS because of the large volume of intra-abdominal and peripancreatic inflammatory fluid collection, capillary leakage caused by increased permeability, bowel and splanchnic edema, resuscitation fluid, and other factors. Gastrointestinal ileus or distension is a common risk factor for IAH among patients with AP. Both air and fluid within the hollow viscera can raise IAP and lead to IAH. IAH also leads to intestinal edema and visceral swelling triggering a vicious cycle. IAH impairs organ perfusion and leads to organ dysfunction. Manifestations of ACS include cardiovascular, pulmonary, renal, splanchnic and neurologic impairment. Hypoperfusion of the gastrointestinal tract was reported at IAP of 12 mmHg<sup>[15]</sup>. Oliguria and marked reduction in cardiac output have been shown to develop at an IAP greater than 20 mmHg<sup>[16,17]</sup>. The relationship among rise in IAP, greater organ dysfunction and, subsequently, higher disease mortality was well illustrated in our study. A positive significant correlation was observed between IAP and Marshall organ dysfunction score. We also observed significant improvement in Marshall score and MODS of patients with resolution of IAH. The overall mortality rate in our study of approximately 23% is comparable to the 10%-50% reported in AP patients by others<sup>[18-21]</sup>. The mortality in ACS patients in our study (75%), however, was much higher than that in patients without ACS which is not acceptable for us, although post-injury ACS has been consistently reported to have a high mortality ranging from 25%-75%. We then compared the early onset of organ dysfunction (within 7 d of admission with AP) and risk of the disease.

While non-operative medical management strategies are now recognized as playing a vital role in both the prevention and treatment of physiologic compromise and organ dysfunction due to elevated IAP, surgical decompression is commonly considered the only treatment for aggravated ACS. All patients with IAH/ACS in our study were initially managed with

noninvasive measures. In an attempt to decrease the elevated IAP, nasogastric decompression, prokinetic motility agents, bowel care, sedation, analgesia and pharmacologic paralysis were administered. Those patients who failed to improve rapidly after institution of these conservative measures underwent percutaneous abdominal decompressive drainage or operative abdominal compartment release. Although the obvious amelioration in physiological variables within 24 h after decompression have been observed in ACS patients, the clinical relevance of ACS in patients with AP in our study was illustrated, in part, by the greater probability of pancreatic infection, MODS and mortality. For this reason, a high index of suspicion and low threshold for decompressive procedure appear appropriate in patients with AP. Patients at risk for ACS warrant close monitoring and we recommend prompt abdominal decompression following documentation of increased IAP in the setting of physiologic compromise, despite in the absence of organ dysfunction/failure.

However, there is no clear consensus on the critical level of IAP at which decompression is necessary. The critical level of IAP requiring decompression thus has not been established for AP patients. Evidence of significant organ dysfunction has been demonstrated at an IAP of 10 mmHg<sup>[22]</sup>. It partially explains why the outcome of ACS patients in our study is poor even though invasive decompression appeared to be effective in reducing IAP and potentially ameliorating IAH-induced physiologic compromise. One of the most important determinants of mortality is the time interval between occurrence of IAH and sustained reduction in IAP of < 12 mmHg by decompression. As shown above, hypoperfusion and acidosis start occurring at pressures from 10 to 12 mmHg, an IAP near 10 mmHg is thus gaining acceptance as a cut-off value in our institution.

Some papers have demonstrated that a persistent splanchnic hypoperfusion may induce irreversible damage in organ function and death<sup>[23-25]</sup>. We speculate that a global mechanism of ischemia and reperfusion may explain these findings. Increased IAP resulted in a decrease of mucosal blood flow to 63% of baseline despite maintaining normal mean arterial blood pressure<sup>[17]</sup>. In addition, elevated IAP could significantly reduce bowel tissue oxygenation due to bowel ischemia<sup>[26]</sup>. In the 1990s, several authors observed a positive correlation between bacterial translocation and IAP in animal models, even when IAP was raised for less than 1 h. This result was caused by increased gut permeability induced by splanchnic ischemia with and without reperfusion<sup>[27,28]</sup>. The mechanism by which the necrotic pancreas becomes infected is unclear, but experimental and clinical data suggest that the gastrointestinal tract is the likely source of organisms, since intestinal colonization by pathogens often precedes pancreatic infection<sup>[29-33]</sup>. The gut clearly plays a major role in the development of MODS. IAH has been shown to be associated with increased bacterial translocation to pancreas and probability of pancreatic infection followed by MODS and death. This increase may be more pronounced when the rise in IAP is followed

by splanchnic ischemia/reperfusion after decompression because of ACS. Moreover, ACS decompression showed to provoke and amplify proinflammatory cytokine release that served as a second insult for the induction of severe organ dysfunction in the two-hit model of MODS<sup>[34]</sup>. Time interval effect of decompression is consistent with the "vulnerable window" of inflammatory mediators cascade priming. As a result, abdominal decompression of established ACS probably causes a fulminant reperfusion syndrome. The mean time interval between diagnosis of ACS and initiation of invasive decompressive procedure in our study was  $28.38 \pm 2.29$  h. The relatively long time for persistence of ACS before invasive decompression might be enough to induce the higher pre-decompression IAP ( $36.69 \pm 5.33$  mmHg) and occurrence of splanchnic ischemia/reperfusion, and soon thereafter, to trigger the bacteria residing within the gastrointestinal lumen to cross the intact intestine into pancreas<sup>[35]</sup>. The sequential effects might mainly contribute to pancreatic infection, MODS and the higher mortality of ACS patients in our study. We therefore advocate performing invasive decompression for an acute IAP of 20-25 mmHg rather than 30-40 mmHg. We also should keep firmly in mind that the earlier treatment is instituted, the more likely a progression to irreversible damage is prevented. The key to managing IAH and ACS is the early recognition of the harmful effects. It is better to prevent ACS than to allow it to occur, and manage the sequelae. However, the timing, indications and threshold value for surgical decompression are controversial with very few large trials available to give firm guidance. Decompression must be strongly considered if the IAP continues to rise or if clinical deterioration occurs. We agree with the concept that IAH is a part of a continuum leading to ACS; therefore, early detection and treatment are preferable to treating the overt clinical manifestations of ACS.

The widely disparate patient populations who may develop IAH/ACS make a standardized therapeutic approach to this syndrome difficult. Thus a single threshold value of IAP cannot be globally applied to the decision making of all patients. No one management strategy can be uniformly applied to every patient with IAH/ACS. Several fundamental management concepts, however, remain appropriate among all patients with AP. While initial conservative measures are implemented and the patient nonetheless proceeds to develop IAPs by greater than 20 mmHg, invasive abdominal decompression should be performed immediately, particularly in the presence of general trend of signs towards overt ACS, including a tendency towards high airway pressures or oliguria refractory to aggressive resuscitation. In AP patients, decompression can be accomplished either by percutaneous decompression with a large-bore catheter inserted or by formal laparotomy. Failure of catheter decompression invariably leads to formal laparotomy. With an increased awareness of the signs of ACS, early conservative treatment of IAH and rapid abdominal decompression when the trend towards the syndrome manifests, clinicians can expect a lower mortality in severe AP patients. In our experience with 74 patients with AP,

the following clinical features may predispose ACS in early stage of the disease: gastrointestinal ileus or distension, a large volume of intra-abdominal and peripancreatic inflammatory fluid collection, massive fluid resuscitation and oliguria.

Indeed, the data presented from our retrospective study raise more questions than answers. Further prospective multi-center studies involving a large number of AP patients are necessary to identify subgroups that might benefit from a therapeutic intervention. The outcome of ACS remains very poor in present study. This result suggests that efforts at prevention may be as fruitful as the efforts directed at early recognition and decompression. Further efforts should focus on prevention of the syndrome. For better prevention of ACS, further studies are essential to identify the independent risk factors for ACS in AP patients and build prediction models for the syndrome to identify high-risk patients with early signs and symptoms of ACS, so as to permit prevention or timely modified treatment before organ failure occurs.

In summary, we conclude that ACS is one of the most important causes of significant morbidity and mortality in AP patients. Early detection and rapid treatment of IAH via abdominal decompression should be essential to preventing the subsequent development of pressure induced organ dysfunction in AP patients.

## ACKNOWLEDGMENTS

We are indebted to resident surgeons, and critical care fellows who participated in the data collection for this study. We thank all the nurses from the intensive care unit in our hospital for IAP measurement.

## COMMENTS

### Background

Intra-abdominal hypertension (IAH) contributes to organ failure in patients with abdominal trauma and sepsis and leads to the development of abdominal compartment syndrome (ACS). ACS has also been described in patients with severe acute pancreatitis (SAP). Significant visceral edema associated with massive fluid resuscitation, paralytic ileus and formation of pancreatic ascites in patients with SAP can lead to ACS which may cause the early development of multiple organ dysfunction syndrome (MODS), especially in the early stages of the disease. Despite recent advances in the management of patients, SAP remains a disease with an unpredictable clinical course and significant morbidity and mortality. Pancreatic infection and the presence of organ dysfunction still remain the most fearing complications and are increasingly recognized as important risk factors for mortality in patients with SAP. The development of ACS in patients with SAP seems to be associated with increased mortality. The clinical impact of IAH/ACS on pancreatic infection and organ failure in SAP patients is needed to investigate.

### Research frontiers

Only recently has the important role of ACS been recognized as a contributing factor for the multiple organ failure commonly seen in SAP. Percutaneous drainage of ascites and surgical decompression are the preferred methods of treatment for ACS. However, some studies, including this study, show that although decompression has a significant effect in lowering IAP, mortality still remains high in SAP patients with ACS. The poor response might be due to an intervention performed too late. Although the 2004 international ACS conference consensus definitions committee has proposed the evidence-based treatment guidelines to assist clinicians in the management of IAH and ACS, there is no clear consensus on the critical level of IAP at which decompression

is necessary. The critical level of IAP requiring decompression thus has not been established for AP patients. Because of the close correlation between ACS and death in SAP patients as suggested by this study, there is a great need for well-designed, prospective clinical trials to clarify the questions and issues that remain unanswered with respect to IAH and ACS.

### Innovations and breakthroughs

The notion that patients with SAP may develop ACS, which necessitates emergency abdominal decompression, has been ignored by some current literatures. The currently prevailing paradigm calls for non-operative management of SAP as long as there is no evidence of infection. The authors of this study proposed that there is a subset of patients who may necessitate an emergency abdominal decompression or laparotomy in the absence of infection in order to decompress a clinically significant ACS, which is associated with the acute pancreatitis (AP).

### Applications

The present study implicated that the timing of surgical decompression may play a crucial role in improving poor survival rates of SAP patients with ACS. Increased awareness of the syndrome of IAH/ACS in AP and transvesical measurement of intra-abdominal pressure (IAP) will reveal its prevalence and significance. This experience with the 74 patients may reinforce the enthusiasm for prevention of ACS and decompression in SAP patients with IAH. This study also gave proof of necessity for establishing a critical IAP level at which abdominal decompression or laparotomy should be performed for SAP patients.

### Terminology

IAP is the steady-state pressure concealed within the abdominal cavity. IAH is a sustained or repeated pathological elevation in IAP  $\geq 12$  mmHg. ACS is a sustained IAP  $> 20$  mmHg associated with new organ dysfunction/failure.

### Peer review

Although the IAP was described by Etienne-Jules Marey in 1863 and ACS described in details by Korn *et al* in 1984 and more information is appearing recently in the literature, it is still important to gather more knowledge about ACS complicating severe pancreatitis. This article constitutes a fairly good number of patients with ACS.

### Abstract

**AIM:** To analyze the clinical features and risk factors of adverse reactions associated with telbivudine.

**METHODS:** Clinical data were collected from cases that presented with serious adverse reactions to telbivudine. We analyzed general information and medicine status, clinical features, results of examination, and misdiagnosis.

**RESULTS:** Out of 105 patients who were treated with telbivudine for hepatitis B in an outpatient department from January, 2007 to January, 2008, five presented with serious adverse drug reactions. Most of these five patients had used other nucleoside analogues in the past. Four were treated with a combination of telbivudine and interferon or another nucleoside analogue, while the other received an increased dose of telbivudine. The main adverse reactions were myalgia and general weakness. This was accompanied by cardiac arrhythmia in one patient, and nervous symptoms in three. Serum creatine kinase was elevated. The rate of misdiagnosis was high.

**CONCLUSION:** The adverse reactions were related to telbivudine, but the biological mechanism of the reactions is not yet clear. Combination therapy with interferon or another nucleoside analogue and a high dose may increase the risk of adverse reactions.

### INTRODUCTION

Telbivudine is a new synthetic nucleoside analogue<sup>[1]</sup>. Since it came on the market in October, 2006, it has been a new option for clinicians in treating chronic hepatitis B, because it significantly suppresses hepatitis B virus (HBV) replication. In our recent clinical practice, however, adverse reactions associated with telbivudine have been increasing. To understand this better, we retrospectively analyzed the clinical records of patients taking telbivudine. We hope that the result will provide clinic references for the future safe use of telbivudine.

### MATERIALS AND METHODS

#### Subjects

Of 105 patients who were treated with telbivudine for hepatitis B at an outpatient department from January, 2007 to January, 2008, five presented with serious adverse reactions.

#### Methods

A retrospective method was employed to analyze the medical records of the five patients, including: general information, medicine history, telbivudine treatment, dosage, combined medication, time of occurrence and clinical features of adverse reactions, possible misdiagnosis, as well as results of laboratory tests, such as routine blood analysis, myozyme, liver function, and kidney function.

### RESULTS

#### General information and medication status

All patients were male with an age range of 25-45 years, and a mean of 34 years. Four patients were infected with

HBV after birth and one acquired the infection directly during pregnancy. One patient had been diagnosed with liver cirrhosis, and the other four with chronic hepatitis B. Four were given other nucleoside analogues before telbivudine. The duration of treatment with telbivudine varied from 1 to 9 mo. In case 1, whose dosage was changed from telbivudine 600 mg twice daily alone in the first 2 mo, to 600 mg once daily in combination with adefovir for 5 mo because of the incidence of myopathy. Cases 2, 4 and 5 were treated with a combination of telbivudine and interferon (Table 1).

### Clinical features of adverse reactions

Occurrence of adverse reactions varied from 0.5 to 5 mo after treatment. Myalgia was most commonly observed, mainly of the limb skeletal muscles, companied by general weakness. There were four cases with nervous damage which included symptoms of numbness, while one case had neuralgia. One case presented with cardiac arrhythmia. After telbivudine treatment was discontinued, myalgia was reduced to a varying extent, but cardiac and nervous system symptoms persisted for a long time (Table 2).

### Laboratory tests

Serum creatine kinase (CK) was elevated. There was

no direct correlation between CK level and severity of fatigue. Liver function was not impaired. All blood cell counts were normal except that platelets were decreased in case 1 due to hypersplenism. Neither bone marrow inhibition nor kidney toxicity was observed (Table 3).

### Initial diagnosis, misdiagnosis and confirmed diagnosis

Misdiagnosis commonly took place because clinicians failed to recognize the adverse reactions. As a result, the patients had to endure further examinations and incurred the associated extra medical expenses (Table 4).

## DISCUSSION

To date, there have been no special reports about telbivudine-related adverse reactions in the literature. In this investigation, the following suggested that the adverse events reported were related to treatment with telbivudine: (1) patients did not present with obvious adverse reactions to interferon or other nucleoside analogues in the past; (2) adverse reactions occurred after taking telbivudine and were reduced or resolved after discontinuing treatment; and (3) the ratio for the occurrence of adverse reactions was approximately 1:20 (5:105), which was high.

Table 4 Diagnosis process

Case	Confirmed time	Misdiagnosis	Examinations	Medication
1	1 d	Arthritis	No	Paste for arthritis
	2 d	Myocarditis	Cardiac enzymes	-
2	3 mo	Neuritis, arthritis	Lumber spinal MRI, laboratory examination	Vitamin B
3	0.5 mo	Neuritis, myocarditis	Myozyme, holter, ECG, ultrasoundcardiography	Mecobalamin, propafenone
4	1 d	-	-	-
5	2 mo	Neuritis	-	Vitamin B

### Possible mechanisms of telbivudine-associated adverse reactions

Telbivudine, as a new synthetic analogue of thymidine, is phosphorylated by host cellular kinases to telbivudine-5'-triphosphate, which has a half-life of 14 h *in vivo*. Telbivudine-5'-triphosphate is then incorporated into HBV DNA by HBV polymerase, through competition with thymidine-5'-triphosphate, the natural substrate. Once inserted, telbivudine-5'-triphosphate causes DNA chain termination, thereby inhibiting HBV replication<sup>[2-4]</sup>.

Some studies<sup>[5-8]</sup> have indicated that telbivudine treatment has considerable clinical efficacy, was and is well tolerated at all doses (25, 50, 100, 200, 400 and 800 mg/d), with no dose-related or treatment-related clinical or laboratory adverse events. However, other research has shown<sup>[9]</sup> that 3/680 patients treated with telbivudine presented with myopathy. However, our study is different.

At present, the biological mechanism of telbivudine-related adverse reactions is not yet clear. Given that the adverse reactions involve multiple organs, including muscle, nerves and the heart, we suggest that the mechanism is associated with cell energy metabolism. Mitochondria are involved in the production of energy. They contain many important proteins, enzymes and carriers that participate in energy transduction. Deficiency in any of these leads to a poor substrate supply for oxidative phosphorylation, and eventually to inadequate manufacture of the energy molecule ATP<sup>[10]</sup>, and this causes mitochondrial disease. Organs that are highly dependent on ATP, such as the nervous system, skeletal muscle, myocardium, retina and pancreas are the most vulnerable to mitochondrial dysfunction. Symptoms of pathological conditions often take place in related areas. Clinically, skeletal muscle is a frequent target and symptoms include fatigability, weakness, as well as myalgia in 50% of cases, and CK level is not elevated significantly<sup>[11]</sup>. ATP deficiency in the heart may result in cardiac arrhythmia, dilated cardiomyopathy, or unexplainable cardiomyopathy; while deficiency in the nervous system can lead to peripheral neuropathy. It has been suggested that muscle biopsy and chromosome examination are beneficial for the diagnosis of mitochondria disease<sup>[12-14]</sup>. There is no mature experience as to the treatment at present<sup>[15-18]</sup>.

The possible links between telbivudine and mitochondrial disease are as follows. (1) Mitochondrial toxicity<sup>[19-22]</sup> is a serious adverse reaction associated with nucleoside analogues, which can inhibit mtDNA polymerase- $\gamma$ , then interfere with energy transduction

in mitochondria. Some nucleoside analogues such as adenine arabinoside and acyclovir can cause mitochondrial toxicity<sup>[23]</sup>. (2) As a competitive substrate of natural thymidine, telbivudine is phosphorylated by host mitochondrial thymidine kinases to telbivudine-5'-triphosphate, and thymidine kinases are extensively exhausted. As a result, the normal energy transduction process is disturbed. (3) In the process of phosphorylation, high levels of phosphates are captured, which leads directly to exhaustion of ATP, which results in poor energy supply.

Although the telbivudine-related adverse reactions could not be definitely diagnosed as mitochondrial disease without a muscle biopsy and DNA study, the symptoms were identical to those of mitochondrial disease. This reminds us to pay close attention to it along with telbivudine treatment in future practice.

### Risk factors related to telbivudine treatment

In case 1, symptoms of myalgia intensified following treatment with 600 mg telbivudine twice daily, while the symptoms became milder at lower doses. This suggests that myalgia is dose-dependent. Other studies<sup>[24-27]</sup> have shown that telbivudine plasma concentration is correlated with dosage when in the range 200-600 mg/d. As a result of the long half-life of this drug, a dose of 600 mg twice daily may lead to drug accumulation. Therefore, the risk may increase with higher doses.

### Synergistic effect of drug combinations

Among the patients with adverse events mentioned above, three were given combination treatment with telbivudine and interferon. Although the therapeutic mechanisms of the two drugs are different<sup>[28-30]</sup>, they share a common feature in causing myalgia as an adverse reaction<sup>[31]</sup>. Synergistic effects can happen when two drugs are used at the same time. It is known that most nucleoside analogues are metabolized in the kidney. According to the literature<sup>[1]</sup>, plasma concentration of drugs may be elevated, if it is combined with other drugs secreted through kidney proximal tubular or altered of kidney proximal tubular function. Overall, combination therapy consisting of two or more nucleoside analogues may increase their plasma concentration, lead to a higher risk of adverse events.

Although there was no direct proof of telbivudine inducing mitochondrial disease in our study, we demonstrated that the adverse reactions were associated with telbivudine. This emphasizes that we ought to exercise caution when using telbivudine to treat hepatitis

B. First of all, practitioners need to be aware of possible adverse reactions, and inform the patient before prescription. Secondly, if telbivudine is prescribed, practitioners need to pay close attention to relevant symptoms and physical signs. Lastly, once the symptoms have been observed, an immediate medical response should be initiated. Diagnosis should be made as soon as possible, and drug therapy discontinued if necessary. Only in this way can telbivudine be used safely and effectively in clinical practice.

## COMMENTS

### Background

Telbivudine is a new synthetic nucleoside analogue. Since it came on the market in October, 2006, it has been a new option for clinicians to treat chronic hepatitis B, because it significantly suppresses replication of hepatitis B virus (HBV). There has been no special report about telbivudine-related adverse reactions to date, except in clinical trials.

### Research frontiers

According to the results of clinical trials, myopathy, one of the telbivudine-associated adverse reactions, was found in 3/680 patients.

### Innovations and breakthroughs

In the present study, the occurrence ratio of telbivudine-related myopathy was approximately 1:20 (5:105), which is different significantly different from the above result.

### Applications

The study reminds us of the importance of adverse reactions when using telbivudine to treat hepatitis B. Once the symptoms are observed, doctors can diagnose the condition and initiate an immediate medical response as soon as possible, so as to relieve pain.

### Terminology

Nucleoside analogues are synthetic nucleosides, which are phosphorylated in host cells, then incorporated into virus DNA instead of the natural nucleoside. Once inserted, they cause virus DNA chain termination, and therefore, inhibit virus replication. Nucleoside analogues can inhibit mtDNA polymerase- $\gamma$ , and then interfere with energy transduction in mitochondria.

### Peer review

The interest of the study is in the description of telbivudine-related adverse reactions during clinical practice, which may be different from those reported during clinical trials characterized by strict patient selection.

formation and increase of total bilirubin, and alanine aminotransferase in the 5-Fu group, but no change in those of the other three groups. There was no change in white blood cell count and creatinine among the four groups. Pathological section of liver and nephridial tissues showed that the damage in the 5-Fu group was more severe than that in the CTS-Pasp-5Fu group. 5-Fu and CTS-Pasp-5Fu groups could both down-regulate the Bcl-2 expression and up-regulate the Bax expression to different extent, and the accommodate effect of CTS-Pasp-5Fu was more obvious than 5-Fu.

**CONCLUSION:** The tumor inhibition rate of CTS-Pasp-5Fu nanoparticles is much higher than that of 5-Fu alone.

### Abstract

**AIM:** To prepare chitosan-polyaspartic acid-5-fluorouracil (CTS-Pasp-5Fu) nanoparticles and investigate its anti-carcinoma effect and toxicity.

**METHODS:** CTS-Pasp-5Fu nanoparticles were synthesized by ionic gelatification. Male BABL/c nude mice were injected with SGC-7901 gastric carcinoma cell line mass to establish a human gastric carcinoma model. They were randomly allocated into 4 groups: CTS-Pasp-5Fu (containing 5-Fu 1.25 mg/kg), 5-Fu (1.25 mg/kg), CTS-Pasp and normal saline groups. Tumor weight was measured and assay of colony forming unit-granulocyte and macrophage (CFU-GM) was performed. The structural change of cells and tissues was observed and the Bax and Bcl-2 genes were detected.

**RESULTS:** Compared with normal saline, the inhibition rates of tumor growth for the CTS-Pasp, 5-Fu and CTS-Pasp-5Fu groups were 5.58%, 58.69% and 70.82%, respectively. The tumor inhibition rates for the CTS-Pasp, 5-Fu and CTS-Pasp-5Fu groups were 5.09%, 65.3% and 72.79%, respectively. There was a significant decrease in the number of CFU-GM

### INTRODUCTION

As is well known, gastric carcinoma is one of the most familiar gastrointestinal malignant tumors. 5-fluorouracil (5-Fu) is universally used as an antineoplastic agent in gastrointestinal cancer<sup>[1]</sup>; however, it has a short plasma half-life period *in vivo* (only 5-10 min). This requires us to make continuous infusion (CI) schedules of 5-Fu in order to maintain an effective concentration *in vivo*<sup>[2-3]</sup>. The novel oral fluoropyrimidine appears to offer comparable efficacy while providing a more convenient schedule<sup>[4]</sup>. Chitosan (CTS) is the second most abundant polysaccharide and a cationic polyelectrolyte present in nature. CTS has shown a favorable biocompatibility<sup>[5-6]</sup>

as well as the ability to increase membrane permeability both *in vitro*<sup>[7,8]</sup> and *in vivo*<sup>[9]</sup>, which are degraded by lysozyme in serum. CTS has received more attention in the pharmaceutical field for a wide range of drug-delivery applications<sup>[10-14]</sup>. Polyaspartic acid is a kind of newly biodegradable, innocuous and friendly environmental bio-organic polymer, recognized as a green material, and widely applied in the areas such as agriculture, medicine, commodity, water treatment, *etc.* The synthesis and application of polyaspartic acid have been studied in many companies. However, little work focused on the complex of chitosan and polyaspartic acid. Our previous study showed that chitosan can encapsulate appreciable quantities of polyaspartic acid (Pasp) into stable nanoparticles, and the method of ion gelatification for preparing chitosan-polyaspartic acid-5-fluorouracil (CTS-Pasp-5Fu) nanoparticles is stable, simple and well biocompatible. Compared with 5-Fu, the Cmax of its nanoparticles is decreased, the AUC was increased and the T1/2 is prolonged obviously. The CTS-Pasp-5Fu nanoparticles are released controllably and could overcome some disadvantages of 5-Fu<sup>[15]</sup>. The major goal of the present work was to prepare CTS-Pasp-5Fu nanoparticles and investigate its anti-carcinogenic effect and toxicity.

## MATERIALS AND METHODS

### Materials

Chitosan with a deacetylation degree (DD) of 95.3% and the molecular weight (Mw) of 6-270 kDa was purchased from Kabo Biochemical Company (Shanghai, China). Polyaspartic acid was prepared by the Department of Macromolecular Science, Key Laboratory of Molecular Engineering of Polymers of Chinese Ministry of Education, Fudan University (Shanghai) as previously described<sup>[16]</sup>. The average molecular weight of PAsp was 5.0 kDa. 5-fluorouracil was purchased from Donghai Pharmaceutical Company (Shanghai, China). The human gastric cancer cell line, SGC-7901, was serially subcultivated by the Department of Laboratory of Gastroenterology, Zhongshan Hospital. Nude male BALB/c mice (aged 35-42 d and weighing 20-23 g) and Kunming male mice (weight 5-20 g) were obtained from the Department of Laboratory Animals, Fudan University. Methyl cellulose M450 was purchased from China Medicine (group) Shanghai Chemical Reagent Corporation. Iscove's modified Dulbecco's medium was purchased from GIBCO Company (UK). Fetal bovine serum was purchased from Hangzhou Sijiqing Biological Engineering Materials Co, Ltd (Hangzhou, China). Antisubstance R-0023 was purchased from Changdao Biotechnology Ltd (Shanghai). All other chemicals were of analytical grade and used without further purification.

### Preparation of CTS-Pasp-5Fu nanoparticles

Chitosan nanoparticles were prepared as reported by Calvo *et al.*<sup>[17]</sup> (1997) based on the ionic gelation of CS with TPP anions. Briefly, chitosan was dissolved in dilute acetic acid solution (10 g/L). The concentration

of acetic acid in aqueous solution was the same as that of chitosan. Quantum satis 5-Fu was dissolved in this solution at room temperature. Afterwards, under magnetic stirring, the mixture solution of 5-Fu and CS was dropped into the Pasp solution at a rate of one drop/sec. Then, opalescent suspension was formed. The obtained suspension was filtered with a paper filter for use. Glutaraldehyde crosslinking nanoparticles were dropped in to drug-loaded CTS-Pasp suspension under magnetic stirring. This mixture was further stirred for three hours at room temperature. CTS-Pasp-5-Fu nanoparticles were separated from the aqueous suspension medium by ultra-centrifugation at 35000 r/min for 30 min at 25°C, washed by dilute acetic acid (pH 5.0) solution and separated by three times ultracentrifugation. The sample was re-dispersed.

Dynamic light scattering (DLS) (Malvern, Autoszer 4700) was used to measure the hydrodynamic diameter and size distribution<sup>[18]</sup>. DLS measurement was done with a wave length of 532 nm at 25°C with an angle detection of 90°.

The morphology and dried TEM-assessed size measurement of the CTS-Pasp-5Fu nanoparticles were examined under transmission electron microscope (TEM; Hitachi, H-600). The sample was dried at room temperature and examined using a TEM without staining.

The encapsulation efficiency and loading capacity of nanoparticles were determined by separation of nanoparticles from the aqueous medium containing non-associated 5-Fu by ultracentrifugation at 35000 r/min for 30 min at 14°C. The amount of free 5-Fu in the supernatant was measured by HPLC. HPLC was performed using a LC-4A HPLC system equipped with a LC-4A pump, and a SPD-10A UV detector (Shimadzu, Kyoto, Japan). The detective wavelength was set at 270 nm. HPLC analysis of samples was performed using a Science C18 column (4.6 × 250 nm, 5 µm, Japan) preceded by a C18 guard column (GL Science, Japan). The column temperature was maintained at 30°C. The mobile phase was a mixture of methanol/3.6% acetic acid. The flow rate was 1.0 mL/min. The 5-Fu encapsulation efficiency (EE) and the 5-Fu loading capacity (LC) of the nanoparticles were calculated as follows:

$$EE = \frac{\text{The amount of 5-Fu in the nanoparticles}}{\text{Total amount of 5-Fu}} \times 100\%$$

$$LC = \frac{\text{The amount of 5-Fu in the nanoparticles}}{\text{Total amount of nanoparticles weight}} \times 100\%$$

All measurements were performed in triplicate.

### In vitro drug release from nanoparticles

*In vitro* 5-Fu release profiles of chitosan-Pasp-5-Fu nanoparticles were determined as follows. The CTS-Pasp-5-Fu nanoparticles were separated from the aqueous suspension medium through ultra-centrifugation. CTS-Pasp-5-Fu nanoparticles and 5-Fu were re-dispersed in 4.0 mL of phosphate buffer saline (PBS), respectively, and placed into a dialysis membrane bag with a molecular weight cut-off of 10 kDa, tied and placed into 40.0 mL

PBS medium. The entire system was kept at 37°C with continuous magnetic stirring. At 15 min, 1, 4, 8, 24, 48, 96, 144 or 192 h, 3 mL release medium was removed at each time point and 3 mL fresh medium PBS solution was added into the system. The amount of 5-Fu in the release medium was evaluated by HPLC. All measurements were performed in triplicate.

#### ***In vivo release from nanoparticles***

Kunming male mice (weight 20-25 g) were randomly divided into two groups. Each group was administrated with 5-Fu and CTS-Pasp nanoparticles. The plasma concentrations of 5-Fu were evaluated by HPLC after 15 min, 1, 2, 4, 6, 8, 12, 16, 24 and 48 h to compare their concentration curves<sup>[9]</sup>.

#### ***Establishment of human gastric carcinoma model and tumor inhibition experiment***

Nude BALB/c male mice (aged 35-42 d and weighing 20-23 g) were inoculated subcutaneously near the nape with the transplanted human SGC-7901 gastric carcinoma cell line ( $1 \times 10^7$  cells per mouse). Two weeks later, the exuberantly proliferating tumor tissues were cut into 1.5 mm thick pieces and inoculated subcutaneously near nape of the 32 nude male BALB/c mice (aged 33-42 d and weighing 20-23 g) under aseptic conditions. The diameter of the tumor tissue transplanted into each nude mouse was measured with a slide caliper rule.

When the tumors grew to 100-300 mm<sup>3</sup>, the animals were randomly allocated into 4 groups with 8 mice in each group: CTS-Pasp-5Fu (containing 5-Fu 1.25 g/L), 5-Fu (1.25 g/L), chitosan-polyaspartic acid, and normal saline groups. Tumor weight was measured and the diameter measurement method was used to observe the dynamic changes in the antitumor response. Twenty-five mg/kg CTS-Pasp-5Fu and 0.025 g/kg 5-Fu were given<sup>[19]</sup> each time whereas the control group was given an equal amount of normal saline or CTS-Pasp by gastric perfusion. The formula for calculating the tumor volume (TV) is:  $TV = 1/2 \times a \times b^2$ , where a and b represent the length and width<sup>[20]</sup>.

The inhibition rate of tumor growth (IR)<sup>[20]</sup> was calculated based on the results of the measurements. IR was calculated using the following formula:  $IR = (Tc - Tt)/Tc \times 100\%$ , where Tc represents control group and Tt represents treatment group.

The tumor was weighed when the experiment was over and the tumor inhibition rates (TIR) were calculated according to the following formula:  $TIR = (1 - \text{tumor weight of treatment group} / \text{tumor weight of control group}) \times 100\%$ .

The white blood cell (WBC) count, total bilirubin (TB), alanine aminotransferase (ALT) and creatinine in the four groups were detected after 2 wk.

#### ***Assay of colony forming unit-granulocyte and macrophage (CFU-GM)***

The nude mice were killed under aseptic conditions. The mice were sterilized thoroughly with 70% alcohol and the pelt was peeled off to fully expose the hip joint. Sterile

sharp dissecting scissors were used to cut the knee joint and the femur near hip joint. The tissues were removed and bones were placed in DMEM culture solution. The ends of the bones were trimmed, a 1 mL sterile syringe needle was inserted into marrow shaft at the end of the femur and the marrow was flushed with Iscove's MDM with 2% FBS in a sterile tube. Flushing was repeated and the number of nucleated cells were counted. The bone marrow cell suspension was done at a concentration of  $2 \times 10^5$ /mL and 0.3 mL of those cells was added into 3 mL MethoCult<sup>TM</sup> medium (prepared by Department of Gastroenterology, Zhongshan Hospital, Fudan University). The tubes were thoroughly mixed and let stand for 2-3 min to allow bubbles to rise to the top. MethoCult<sup>TM</sup> of 1.1 mL was dispensed into each 35 mm dish. Cultures were placed in a water-jacket at 37°C, 5% CO<sub>2</sub>,  $\geq 95\%$  humidity for 7 d. The growth of bone marrow cell colonies ( $\geq 30$  nucleated cells constituted one colony) was observed<sup>[21]</sup>.

#### ***Pathophysiology***

The tumors, liver and nephridial tissues of the four groups were collected, fixed with 10% formalin, stained with hematoxylin and eosin, paraffin embedded and sectioned. The structural change of cells and tissues was observed. Four-grade histological denominator was used: +++, total necrosis; ++, necrosis areas exceed half of total areas; +, necrosis areas less than half of the total areas; -, no necrosis<sup>[22]</sup>.

#### ***Immunohistochemical analysis***

Tumor tissues from the four groups were paraffin embedded and shaken. The sections were deparaffinized and doused with PBS 5 minutes after quenching the endogenous peroxidase with 3% hydrogen dioxide. They were repaired twice with citric acid fluid for 15 min, added with the first antistain (Bcl-2, 1:100; Bax, 1:100) and stayed overnight at 4°C. The second antistain with HRP was incubated for 30 min at 37°C and stained with a diaminobenzidine (DAB) developer. The sections were bleached with alcohol, cleared with methyl benzene, mounted with neutral balsam and photographed (ZEISS microscope, Germany). The ratio of positive expression area to the total image area was calculated.

#### ***Statistical analysis***

The SPSS software package (SAS Institute Inc, North Carolina, USA) was used for analysis of variances.  $P < 0.05$  was considered statistically different.

## **RESULTS**

#### ***Morphology, encapsulation efficiency and loading capacity***

The mean hydrated size of particles and distribution of CTS-Pasp-5Fu nanoparticles were determined by DLS. The results indicated that the mean size and distribution of the samples were 206 nm and 0.14, respectively. The encapsulation efficiency (EE) of CTS-Pasp-5Fu was 40.2%, and the loading capacity was 34.9%. Figure 1

**Figure 1** TEM photography of CTS-Pasp-5Fu nanoparticles showing. It shows the morphological characteristics of CTS-Pasp-5Fu nanoparticles synthesized by ion gelatinification. **A:** The nanoparticles are in regular spherical shape and well distributed; **B:** The diameter of the particles is between 150-250 nm.

**Figure 2** Typical *in vitro* release profile of pure 5-Fu (■) and CTS-Pasp-5Fu (▲) in PBS. All pure 5-Fu escaped rapidly from the dialysis bag within the first 1 h. CTS-Pasp-5Fu nanoparticles released 5-Fu gradually up to 100% in 100 h.

shows the morphological characteristics of CTS-Pasp-5Fu nanoparticles which were synthesized by ion gelatinization. The nanoparticles were spherical in shape and well distributed. The diameter of the particles ranged from 150 to 250 nm. 5-Fu was dispersed in nanoparticles by electrostatic interaction with particulate form.

**In vitro release**

Figure 2 shows the release profile of 5-Fu and CTS-Pasp-5Fu. All the pure 5-Fu released rapidly from the dialysis bag within the first 1 h. CTS-Pasp-5Fu nanoparticles released 5-Fu gradually up to 100% in 100 h. Compared with the drug release of pure 5-Fu with 5-Fu loading CTS-

**Figure 3** The concentration-time curves of 5-Fu group and CTS-Pasp-5Fu nanoparticles group (48 h). The maximal concentration (C<sub>max</sub>) of 5-Fu group occurred within 15 min and decreased rapidly, and that of CTS-Pasp-5Fu nanoparticles group occurred 6 h after the administration and the effective concentration lasted about 14 h.

**Table 1** The mean weight in four groups (g)

Groups	Before treatment	After treatment (d)			
		3	7	10	14
NS	20.96 ± 0.82	22.35 ± 1.17	23.41 ± 1.53	24.28 ± 1.72	24.11 ± 1.73
5-Fu	22.16 ± 2.83	22.20 ± 2.86	22.58 ± 2.80	20.86 ± 3.16	18.34 ± 3.69
CTS-Pasp	20.80 ± 1.19	22.96 ± 1.34	24.45 ± 1.26	24.14 ± 1.07	24.52 ± 1.75
CTS-Pasp-5Fu	22.01 ± 2.78	23.31 ± 2.39	25.15 ± 2.15	25.46 ± 2.08	25.53 ± 1.80

Pasp nanoparticles, CTS-Pasp-5Fu nanoparticles might be used to provide a continuous release. We considered that 5-Fu embedded into the nanoparticles might be bound to PAsp by ionic reaction resulting in slow 5-Fu diffusion. 5-Fu released slowly and incompletely.

**In vivo release**

Figure 3 shows the concentration-time curves for the 5-Fu and CTS-Pasp-5Fu groups. The maximal concentration (C<sub>max</sub>) in the 5-Fu group occurred within 15 min and decreased rapidly, while that in the CTS-Pasp-5Fu group occurred 6 h after the administration and the effective concentration lasted about 14 h. The plasma C<sub>max</sub> in the CTS-Pasp-5Fu group was lower than the 5-Fu group.

**Anti-carcinoma effect of CTS-Pasp-5Fu nanoparticles on tumor growth in nude mice**

Before the treatment, the weight and tumor volume in four groups were not significantly different ( $P > 0.05$ ). After the treatment, the mice in the 5-Fu group lost weight gradually (Table 1) and became hypokinetic and were in a poor general state. The other three groups were in a good general state. At the end of the experiment, 6 of 8 nude mice survived in the 5-Fu group and no mouse died in the other three groups. The inhibition rate of tumor growth (IR) for the 5-Fu and CTS-Pasp-5Fu groups was significantly higher than that for the NS group (58.69%,  $P = 0.004$ ; 70.82%,  $P = 0.00015$ ; Table 2). The IR for the CTS-Pasp-5Fu group was also enhanced but was not significantly different from that for the 5-Fu group ( $P > 0.05$ ,  $P = 0.206$ ; Table 2). There was no difference in the IR between CTS-Pasp and NS groups

CTS-Pasp	8	2	6	0	0
5-Fu	6	1	4	1	0
CTS-Pasp-5Fu	8	0	4	3	1

( $P > 0.05$ ,  $P = 0.607$ ). The tumor size in the NS group was bigger than that in the 5-Fu and CTS-Pasp-5Fu groups (all  $P < 0.001$ , Table 3), and the tumor weight of CTS-Pasp and NS groups was not different ( $P > 0.05$ ). Tumor inhibition rate (TIR) for the CTS-Pasp-5Fu and 5Fu groups was significantly higher than that for the NS group (72.79% and 65.3%; Table 3). TIR for the CTS-Pasp-5Fu group was higher than that for the 5-Fu group, but the difference was not significant (Table 3, Figure 4).

Figure 4 shows all the tumors of the four groups at the end of the experiment. There were only 6 tumors left in the 5-Fu group. The tumors of those of NS and CTS-Pasp groups were obviously bigger than the other two groups. The size of tumors in the 5-Fu and CTS-Pasp-5Fu groups was not significantly different, but TIR for the CTS-Pasp-5Fu group was higher than that for the 5-Fu group (72.79% *vs* 65.3%, Table 3).

### Side effects

The white blood cell count, total bilirubin and alanine aminotransferase (ALT) in the NS, CTS-Pasp and CTS-

Figure 4 Tumors in four groups.

Pasp-5Fu groups were not significantly different ( $P > 0.05$ ). Those in the 5-Fu group were higher than those in the other three groups (Table 4). There was no difference in creatinine among the four groups ( $P > 0.05$ ).

The bone marrow inhibition effect in the 5-Fu group was significantly different from that in the other three groups ( $P < 0.001$ , Table 4, Figure 5).

Nucleated cells  $\geq 30$  constituted one bone marrow cell colony<sup>[16]</sup> in the four groups (Figure 5). The growth of bone marrow cell colonies in the NS, CTS-Pasp and CTS-Pasp-5Fu groups was vigorous, while that in the 5-Fu group was sparse. CTS-Pasp-5Fu did not suppress the growth of bone marrow cells.

### Histological change after treatment

Table 5 shows the histological change in the four groups after treatment. The tumor cells in the NS and CTS-Pasp groups aligned regularly with slight inflammatory cell infiltration. The tumor cells in the CTS-Pasp-5Fu group were swollen with degeneration, necrosis and inflammatory cell infiltration which was less severe than in 5Fu group. The damage liver in the 5-Fu group was more severe than that in the CTS-Pasp-5Fu group.

### Immunohistochemistry

5-Fu and CTS-Pasp-5Fu down-regulate the Bcl-2 expression and up-regulation of the Bax expression were observed in the 5-Fu and CTS-Pasp-5Fu groups, but not in the CTS-Pasp group and NS group. The accommodate effect of CTS-Pasp-5Fu was more obvious than that of 5-Fu (Table 6, Figures 5 and 6).

Figure 6 shows the expression of the apoptotic proteins Bcl-2 and Bax in the four groups. The masculine expression of Bax in the CTS-Pasp-5Fu was more obvious than that in the 5-Fu group. CTS-Pasp-5Fu and 5Fu could up-regulate Bax expression. The

**Figure 5** Bone marrow cell colonies ( $\geq 30$  nucleated cells constituted one colony) in four groups ( $\times 100$ ). The growth of bone marrow cell colonies in the normal saline group (A), CTS-Pasp group (D) and CTS-Pasp-5Fu group (C) was vigorous, while the cell colonies in the 5-Fu (B) group was sparse. It demonstrated the inhibition effects of 5-Fu used alone. The marrow cell count indicated that CTS-Pasp-5Fu could not suppress the growth of bone marrow cells.

**Table 6** Expression of Bcl-2, Bax in four groups ( $n = 8$ )

Groups	Bcl-2	Bax
NS groups	$39.14 \pm 5.84$	$18.94 \pm 9.92$
CTS-Pasp	$38.62 \pm 6.53$	$18.26 \pm 7.65$
5-Fu	$31.74 \pm 5.49^a$	$33.24 \pm 4.89^a$
CTS-Pasp-5Fu	$22.74 \pm 4.55^{b,c}$	$37.22 \pm 9.21^d$

<sup>a</sup> $P < 0.05$  vs NS; <sup>c</sup> $P < 0.05$  vs 5-Fu; <sup>b</sup> $P < 0.001$  vs NS; <sup>d</sup> $P < 0.001$  vs NS group.

masculine expression of Bcl-2 in the CTS-Pasp-5Fu group was obviously lower than that in the other three groups. The difference in the expression of Bax and Bcl-2 between NS group and CTS-Pasp group was not significant (Figure 6).

## DISCUSSION

5-Fu is a thymidylate synthetase (TS) inhibitor that undermines the stability of DNA molecular structure<sup>[23]</sup>, thus it is among the top priority of consideration in chemotherapy for gastrointestinal tumors. 5-Fu is also disadvantageous in terms of irregular absorption, treatment dose, toxicity and severe side effects with high doses which result in complications by long-term intravenous administration. Consequently, the research and development of highly effective oral fluorouracil preparation or fluorouracil analogs with mild side effects has been a major topic for many medical scientists.

Biologically degradable drug-loaded nanoparticles are a novel carrier for targeted drug delivery. Its advantages include greater magnitude of drug load, controlled release, longer biological half-life, less administration time, and fewer side effects. Nanoparticles have all the

advantages of liposomes including the size property. Some investigators have also observed that the number of nanoparticles which cross the intestinal epithelium is greater than that of the microspheres ( $> 1 \mu\text{m}$ )<sup>[24]</sup>. Recently, polymer nanoparticles have been widely studied as a carrier for drug delivery. They are expected to be adsorbed in an intact form in the gastrointestinal tract after oral administration<sup>[25]</sup>. Chitosan (CTS), a poly [(1 $\rightarrow$ 4)- $\beta$ -linked 2-amino-2-deoxy-D-glucose], is prepared from chitin by N-deacetylation. It is a biologically compatible and degradable material with almost no side effects, and is receiving worldwide interest for its industrial uses as antimicrobials, biomedical materials, cosmetics, food additives, separators, sewage disposal, agricultural materials, *etc.* Nanoparticles prepared with CTS are characterized by delayed release, controlled release and targeted delivery with a higher bioavailability and fewer side effects. We have developed nanocarriers made of CS which have shown a great capacity in drug controlled release<sup>[26,27]</sup>.

Polyaspartic acid is another favorable drug carrier<sup>[28]</sup>. Polyaspartic acid or its salts are a kind of newly innocuous, biodegradable bio-organic polymer. It has been widely applied in many areas such as agriculture, medicine, commodity, water treatment, petroleum, *etc.*<sup>[29,30]</sup>. The synthesis and application of polyaspartic acid have been studied in many companies over the past years. The medical realm of polyaspartic acid has gradually caught more attention of people. Our previous studies showed that CTS-Pasp-5Fu nanoparticles prepared by ionic gelation *in vitro* and *in vivo* can delay release of 5-Fu with longer effective concentration time, and that it may render solution to the 5-Fu problems of a short half-life and more side effects brought by a higher serum concentration soon after administration.

**Figure 6** Immunohistochemical atlas of Bcl-2 and Bax expression in four groups ( $\times 200$ ). Bax expression is shown in normal saline group (A), CTS-Pasp group (B), 5-Fu group (C) and CTS-Pasp-5Fu group (D). Bcl-2 expression is shown in normal saline group (E), CTS-Pasp group (F), 5-Fu group (G) and CTS-Pasp-5Fu group (H). The masculine express of Bax in was CTS-Pasp-5Fu group was more obvious than that in the 5-Fu group. CTS-Pasp-5Fu and 5-Fu could up-regulate Bax expression compared with NS. The masculine expression of Bcl-2 in the CTS-Pasp-5Fu group was obviously lower than that in the other three groups. Both CTS-Pasp-5Fu and 5-Fu could both down-regulate the Bcl-2 expression.

We observed in our experiment that chitosan-polyaspartic acid-5fluorouracil (CTS-Pasp-5Fu) nanoparticles could slowly release 5-Fu compared to 5-Fu. The  $C_{max}$  of CTS-Pasp-5Fu nanoparticles was decreased, and the AUC was increased. The CTS-Pasp-5Fu nanoparticles were controllably released.

It is observed in the transplant nude mouse model of human gastric cancer that the inhibition rate of tumor growth (IR) and tumor inhibition rate (TIR) for the CTS-Pasp-5Fu group were significantly higher than

those for the 5-Fu group (70.82%, 58.69%, 72.79%, 65.3%), and oncopathology documented prominent degeneration and necrosis of tumor cells in the CTS-Pasp-5Fu group compare with the other three groups. These results demonstrated that the anti-tumor effects of CTS-Pasp-5Fu were better than those of 5-Fu at the same dose, and this preparation method enhanced the pharmacodynamics of the drugs.

Nude mice in the 5-Fu group seemed to be obviously emaciated, in which 2 died at the end of the study. The

total serum bilirubin and ALT in the 5-Fu group were higher than those in the other three groups, and CFU-GM values were much lower. However, biochemical examination and CFU-GM values were not significantly different between CTS-Pasp-5Fu, CTS-Pasp and NS groups, indicating that single use of 5-Fu brings about liver toxicity and bone marrow suppression. Nevertheless, there was no significant difference in liver or kidney functions and CSF-GM values of the bone marrow between CTS-Pasp-5Fu and NS groups, suggesting that chitosan-Pasp nanoparticles coated with 5-Fu bring about less bone marrow suppressing effect, and can be used as a safe and effective drug carrier.

The Bcl-2 gene family is an important regulatory factor group for apoptosis, including Bcl-2, Bcl-xl, *etc.* The ratio of Bcl-2/Bax is an important index affecting apoptosis<sup>[31]</sup>. Bcl-2 inhibits cell apoptosis by inhibiting the release of cytochrome c while Bax promotes cell apoptosis by promoting the release of cytochrome c and activates the key enzyme caspase in the process of apoptosis. Activated caspase causes tumor apoptosis by its effect on substrate<sup>[32]</sup>. The previous investigation *in vitro* showed that 5-Fu can up-regulate Bax protein expression in some tumor cells<sup>[33]</sup>. Our immunohistochemical detection of the apoptosis-related genes among four tumor groups showed that 5-Fu and CTS-Pasp-5Fu could down-regulate the Bcl-2 expression, and up-regulate Bax expression. Since the regulation effect of CTS-Pasp-5Fu nanoparticles is more powerful, it can enhance the inhibitory effect compared with 5-Fu alone, and induce the apoptosis of the gastric carcinoma.

In conclusion, in this study we successfully synthesized CTS-PASP nanoparticles coated with 5-Fu, which demonstrated significant anti-tumor effects in the transplanted nude mouse model of human gastric cancer, with less bone marrow suppression. Therefore, it may be used as a safe and effective novel anti-tumor preparation with profound prospects in clinical application.

## COMMENTS

### Background

5-Fluorouracil (5-Fu) is often used as an anti-tumor agent in the treatment of gastrointestinal cancer. However, it often causes inconvenience of patients because of its short plasma half-life and requires continuous infusion (CI) schedules. So it is important to investigate and develop new drugs which can reduce the side effects of 5-Fu.

### Research frontiers

Chitosan (CTS) has received more attention recently in the pharmaceutical field for a wide range of drug-delivery applications. Polyaspartic acid is a kind of a new biodegradable, innocuous and friendly environmental bio-organic polymer, recognized as a green material, and widely used in the areas such as agriculture, medicine, commodity, water treatment, *etc.*

### Innovations and breakthroughs

In this study, the authors successfully synthesized chitosan-polyaspartic acid-5-fluorouracil (CTS-Pasp-5Fu) nanoparticles and investigated their anti-carcinoma effect and toxicity to overcome the disadvantage of 5-Fu in gastric carcinoma mouse model. The results show that the tumor inhibition rate of CTS-Pasp-5Fu nanoparticles was much higher than that of 5-Fu alone, and the inhibition on bone marrow was alleviated efficiently. Thus, it may be used as a safe and effective novel anti-tumor preparation with profound prospects in clinical application.

### Applications

Based on the results of this study, it is supposed that CTS-Pasp-5Fu nano-

particles may substitute 5-Fu in the future treatment of gastrointestinal cancer.

## Peer review

This study focused on the preparation of CTS-Pasp-5Fu nanoparticles and investigation of its anti-carcinoma effect and toxicity to overcome the disadvantage of 5-Fu in gastric carcinoma mouse model. The data demonstrate that CTS-Pasp-5Fu appears to offer comparable efficacy while providing a more convenient schedule and showed insight into the novel oral fluoropyrimidine.

### Abstract

**AIM:** To analyze the imaging findings of hepatic malignancy with right atrial (RA) embolus.

**METHODS:** Forty-six patients with an embolus in the RA were diagnosed, including 44 patients with hepatocellular carcinoma (HCC), 1 patient with cholangiocellular carcinoma and 1 patient with hepatic carcinoma metastasis. The diagnosis was confirmed by clinical examination, serum  $\alpha$ -fetoprotein and imaging. Seventeen patients underwent transcatheter arterial chemoembolization (TACE).

**RESULTS:** On enhancement computer tomography (CT) or magnetic resonance (MR) imaging, a nodular filling defect in the RA could be easily found, with a slight enhancement in the arterial phase. The coronal images of CT or MR showed the extent of lesion. Lipiodol entered the embolus after TACE, hence reducing the speed of embolus growth. There was a survival benefit for patients receiving anticancer treatment.

**CONCLUSION:** Patients with HCC, showing a filling defect of the inferior vena cava (IVC), hepatic vein (HV) and RA on images, can be diagnosed with RA embolus. Encroachment of the RA is very rare in patients with hepatic malignancies. Furthermore, a prolongation of survival time is found in those patients who underwent TACE.

### INTRODUCTION

Malignant tumors of various organs and tissues, originating from all over the body, may disseminate to the right atrium (RA) and form a nodular embolus. Current literature reports that malignant tumors, such as hepatocellular carcinoma (HCC), pancreatic carcinoma, adrenal carcinoma, testicular cancer, lymphoma, leiomyosarcoma, hysterocarcinoma, nasopharyngeal cancer, esophageal cancer, Ewing's sarcoma and Wilm's tumor can encroach on the RA<sup>[1-3]</sup>.

HCC is the most prevalent of the liver tumors, and the portal vein (PV), hepatic vein (HV), and the inferior vena cava (IVC) are often affected. Although it is rare, tumors may also intrude on the RA. This study describes the imaging findings in 46 patients with malignant hepatic tumors that formed a tumor embolus in the RA.

### MATERIALS AND METHODS

#### Patients

From August, 2001 to May, 2007, 46 patients with hepatic malignancy and RA embolus were enrolled (41 men and 5 women, aged 23-75 years; average 52.5 years). The patients were diagnosed by computed tomography (CT) and magnetic resonance (MR), laboratory values (i.e.,  $\alpha$ -fetoprotein) and clinical examination. The malignant hepatic tumors were designated as HCC ( $n = 44$ ), intrahepatic cholangiocellular carcinoma ( $n = 1$ ) and lung and liver metastasis from post-operation retroperitoneal

sarcoma ( $n = 1$ ). All these patients had encroachment of the IVC and the RA.

Two of the 46 patients underwent surgery while 17 patients had transcatheter arterial chemoembolization (TACE). TACE was performed 4 times in 4 patients, twice in 10 patients and once in 3 patients. The remaining 27 patients had serious liver function damage. These patients were not treated with anti-tumor drugs, but were given liver protective medication until discharged.

### **Imaging protocols**

CT was performed using multi-slice spiral CT (Lightspeed QX/i, GE) scanning with high-quality scanning mode, thickness 5 mm, 120 kV, 270-300 mA. The contrast medium was 100 mL Ioversol Injection 350 (Mallinckrodt, Canada), and the velocity was 3 mL/s.

The MR image (Signa Excite Twin Speed 1.5T, GE) was preformed with a T2-weighted image using RFSE+FS, TR: 5000-10000 ms, TE: 80-130 ms, ETL: 16-23; the T1-weighted image using FSPGR, TR: 175 ms, TE: 4.2 ms; and the 2D Fiesta coronal image using TR: 4.2 ms, TE: 1.5 ms. The contrast medium was 30 mL gadopentetic acid dimeglumine salt injection (Schering, Germany), and the velocity was 4 mL/s. Dynamic CT and MR images were produced with an arterial phase of 25 s, a portal phase of 60 s, and a delayed phase of 3 min.

Plate digital subtraction angiography (DSA, INNOVA 4100, GE) with 40 mL of contrast medium, and a velocity of 6 mL/s were used in TACE treatment. Angiography was initially performed on the abdominal cavity and superior mesenteric artery to determine the variant hepatic arterial supply, the blood supply type, and size, number and position of tumors in all patients. Then, the celiac axis was selected. A 5 Fr Yashiro angiographic catheter (Terumo) was advanced over a 0.035 inch guide wire (Terumo) into the desired hepatic artery branch, depending on the tumor location. Because the optimal agents or doses for TACE have not been determined,<sup>[4]</sup> the dose of anticancer drug and lipiodol (Lipiodol Ultra Fluide, Guerbet, France) was determined based on the size, number, and blood supply of the tumor, and also on the basis of practical infusion procedures during the operation<sup>[5]</sup>. Anticancer drugs used were epirubicin hydrochloride (20-40 mg), hydroxycamptothecin (OPT, 10 mg) and ultra-liquefied lipiodol (10-30 mL). Before infusion, epirubicin hydrochloride and lipiodol were fully mixed together to form an emulsion. At the end, some gel foam sponge powder was infused to decrease blood flow. Lidocaine (5 mL) was also given intra-arterially after chemoembolization for pain control.

The relationship between RA embolus and hepatic cancer was observed to determine the development pathway.

### **Follow-up of life span and growth velocity of the embolus**

Patients were monitored from the moment of discovery of the RA embolus to an occurrence of hard end-point (i.e. patients' death) or to the end of the study period

(May 30, 2007). The growth velocity of the embolus was monitored in 10 cases. In these cases the RA embolus was discovered during follow-up and the patients had no RA embolus at first examination. The relationship between the type of intrahepatic tumor and RA embolus was observed.

## **RESULTS**

### ***Intra-hepatic malignancy and external hepatic metastasis***

The types of intra-hepatic malignancy found were: huge-mass type in 37 cases (80.4%), multinodular type in 8 cases (17.4%) and single nodular type in 1 case. The location of the tumor was the right hepatic lobe in 39 cases, the left hepatic lobe in 5 cases, and between the right and left lobe in 2 cases. There were 4 cases of lung metastasis and 5 cases of abdominal lymph node metastasis.

### ***Imaging findings of RA embolus***

On imaging, the RA embolus was commonly a regular, slight irregular round, orbicular-ovate, or lobulated type. The maximum size was 6.1 cm × 12 cm, almost filling the entire RA. The minimum size was 1.5 cm × 2.1 cm.

A plain CT scan showed low-density or iso-density, which corresponded to a normal cordis density. The CT value was 27-52 HU, without an obvious density difference and sometimes hardly differentiated. There was a low density line around the embolus edge. On the arterial phase scan, the contrast medium filled the cordis intracavity and the embolus showed a well-defined filling defect. On this arterial phase scan, the embolus had a slight inhomogenous "stick"-like enhancement (Figure 1A), while the tumor encroaching the IVC could be seen as a "stick"-like enhancement arterial vessel inside the IVC (Figure 2). The CT value of the embolus increased by about 30 HU following enhancement. On the portal phase scan, the contrast medium in the cordis intracavity was partially discharged, and the density of the embolus was slightly increased or decreased. The edge of the embolus was comparatively blurred. On the delay phase scan, the density of the embolus decreased, but the edge was clear; hence there was a small increase in embolus size when compared to the arterial phase scan.

The embolus showed a nodular high or iso-signal in the T1-weighted image (Figure 3A). A higher signal was found in the T2-weighted image (Figure 3B) because in this image, larger vessels, the atrium and the ventricles, have a flowing void effect. There was a low signal in the lumina and cavity of the greater vessels and cordis, while the thrombus signal was an indicator of intrahepatic HCC with a higher signal. In the arterial phase image, the thrombus was shown as a low signal filling defect with a slightly "stick"-like enhancement (Figure 3C). The portal and delay phase images showed low nodular signals. In the coronal image, the relationship between the intrahepatic tumor, IVC, and RA embolus could be seen very clearly (Figure 3D and Figure 4B).

**Figure 1** A 52-year-old man with a big massive HCC located in the right lobe, the tumor encroaches the PV and IVC and intrudes into the RA. The embolus increased 5 cm within 3 mo. **A:** Arterial phase of CT scan shows a well-defined lobulated filling defect (6.7 cm x 7.5 cm) in the RA (arrow) and an irregular "stick"-like enhancement; **B:** Angiographic image in the second time TACE shows that the tumor is a hypervascular lesion and the artery enters the RA by passing the IVC, and is a "grating"-like type (arrow).

**Figure 2** A 42-year-old man with a massive HCC located in the right lobe, the tumor encroaches the HV and IVC and intrudes into the RA. Arterial phase of CT scan shows a "stick"-like enhanced arterial vessel entering the entrance of the RA.

**Figure 3** A 69-year-old man with a multinodular HCC located in the right lobe, 7 mo after the 6th TACE, embolus in the RA increased to 4 cm (**A-C** are the same patient). **A:** T1-weighted image shows a higher signal nodular (TR: 195 ms/TE: 4.2 ms, ST: 8.0 mm) in RA (arrow); **B:** T2-weighted image shows a higher signal nodular of HCC in the right diaphragmatic dome, the same well-defined higher signal nodular in the RA and a low signal around the core-cavity (TR: 7058.8 ms/TE: 89.2 ms, ST: 8.0 mm); **C:** The arterial phase image shows an embolus with low signal filling defect and a "stick"-like enhancement (TR: 190 ms/TE: 1.9 ms, ST: 8.0 mm); **D:** The coronal image shows the tumor entering into the RA via the widened IVC, the IVC lumen was almost completely filled (arrow) (TR: 3.7 ms/TE: 1.6 ms, ST: 7.0 mm).

Angiography images showed that the tumor vessel entered the RA and was a grating-like type (Figure 1B). After TACE with lipiodol perfusion, the lipiodol was retained in the HCC and the embolus and there were higher density group masses in the intra-liver area and the RA (Figure 4C). This suggested that TACE could be used successfully to treat an embolus of the HCC.

Invasion of the PV, HV, and IVC was seen in 38 cases, 11 cases, and all cases, respectively. The range of invasion of IVC varied in size in different patients and the longest invasion size was 8.3 cm. The coronal images from CT and MR showed the relationship between the intra-liver tumor, IVC and the RA embolus best (Figures 3D, 4A and B). Vein invasion was discovered by the presence of a filling defect in the vena cava. In a portal phase cross section

image there was no contrast medium in the center of the IVC cava with embolus and there was clear enhancement around the embolus, which showed up as a "ring" sign (Figure 5).

There were two routes of HCC invasion into the RA. One directly invaded into the IVC, then upward into the RA and downward into IVC. The second one was invasion into the HV, and then into the IVC and RA. The first route was more common.

#### Growth velocity of RA embolus

Thirty-six of the 46 patients had an RA embolus when imaging examination was performed, and the embolus was discovered during follow-up in 10 cases. The growth velocity of the embolus in these 10 cases was slow

**Figure 4** A 49-year-old man with multinodular recurrence after HCC operation, with the embolus of RA discovered at the same time. The patient underwent TACE twice. **A:** The portal phase T1-weighted image shows a low signal embolus entering the IVC from middle HV (arrow) (TR: 220 ms/TE: 18ms, ST: 8.0 mm); **B:** The coronal image shows a well-defined "bottle-gourd" -shape filling defect in RA (arrow) (TR: 3.3 ms/TE: 1.5 ms/TI: 7.0 ms, ST: 3.0 mm); **C:** The image after perfused Lipiodol shows a nodular and lump tumor of the right and left lobe filled with Lipiodol, which was also retained in the embolus of RA (arrow).

**Figure 5** A 46-year-old man with a large mass of HCC in the right lobe. The intra-liver tumor entered the RA by IVC. Cross sectional CT scan in portal phase shows a well-defined filling defect in IVC and a "ring"-like sign (arrow).

growth of 3 cm in 6 mo, and quick growth of 4 cm in 1 mo. The embolus may remain in steady state for a long time after TACE treatment.

### Survival time

Twenty-seven patients without anticancer treatment died after 6 mo. The shortest time to death was 1 mo, and longest time to death was 8 mo (average 3.5 mo). In 17 patients who received TACE treatment the longest survival time was 19 mo, and the shortest survival time was 4 mo (average 8.4 mo). The survival time of 2 patients who underwent surgery were 5 and 7 mo, respectively.

## DISCUSSION

About 70% patients with HCC have HV and PV invasion, but encroachment into the RA is very rare. According to the literature<sup>[3,6-10]</sup>, less than 50 cases have been reported. A combination of literature and our hospital clinical data indicates HCC encroachment into the RA may not be an overt symptom. However, when the embolus obstructs the tricuspid orifice and coronary sinus opening, it may result in a severe hemodynamic disorder. This can include venous engorgement of both

upper extremities and the chest, hydropneumothorax, pleural effusion, and flustered or even dyspneic respiration. An electrocardiogram will show right bundle branch block. When the IVC is obstructed, engorgement of the veins of the lower extremities will appear, leading quickly to Budd-Chiari syndrome<sup>[10,11]</sup>, and in this situation the prognosis of patients is very bad. Even when the HCC and embolus are surgically resected the patient may quickly die due to the severity of the pathogenetic condition or cardiac failure<sup>[12-15]</sup>.

The formation of the RA embolus had a growth process. Firstly, the tumor perforated, involving the wall of the HV and/or IVC, then the tumor extended into the lumen of the vein and grew there. The tumor within the lumen can grow upward and/or downward, and if it grows upward it may get into the RA and continue slow growth there. On the basis of overview data from 10 patients, the quickest velocity of embolus growth was 4 cm in 1 mo, and the slowest velocity of growth was 3 cm in 6 mo (average growth of 3.7 cm in 3.2 mo). Slow growth of the embolus was due to receiving TACE. TACE treatment was effective and controlled hepatic malignancy and tumor embolus.

Using the plain CT scan, the density difference between the embolus and cardiac tissue was not obvious, but sometimes there was a low density single band appearance between them. When this appearance is found, we should distinguish between normal interventricular septum, interatrial septum and tumor in the cordis as the location of each was not the same.

In the arterial phase scan, the malignant embolus was mildly enhanced. The heart chambers were filled with a high concentration of contrast medium whereas the embolus showed a filling defect so that there was a very significant contrast and a clear density difference. The arterial phase scan produced an image showing the embolus. In the portal phase scan, the embolus continued to display slight enhancement. In the delay phase, most of the contrast medium in the heart chambers was discharged, but the density of the embolus was still lower than that of cardiac tissue. In this phase, the size of the embolus was increased

compared with the arterial phase. This was because the high density contrast medium submerged part of the edge of the embolus in the arterial phase.

CT and MR images can display and distinguish between a tumor, thrombi, and a malignant embolus<sup>[16]</sup>. The malignant embolus was round, orbicular-ovate or cauliflower in shape. The embolus was part of the arterial blood supply. On angiography, a lot of blood vessels and signs of “stria” are seen with a hypervascular tumor, but there is no enhancement or staining for hypovascular tumors. The thrombus was not enhanced when it has lower density and there was no intrahepatic malignant tumor. Cardiac tumors can be divided into 2 types: primary tumor and metastasis. The most common is the primary myxoma; 93.5% of them are located in the left atrium and 6% are located in the RA. A myxoma can activate and the stem can cohere on the atrial septum. But when the malignant embolus was solid and was not transfigured, the stem cohered on the IVC.

MR images showed the embolus better than CT as MR showed it from different direction of view.

The PV, IVC and HV may be encroached by HCC, and show a filling defect of the venous lumen. Most patients with HCC had PV encroachment. IVC encroachment was relatively rare. The tumor encroached from the IVC to the RA and formed an embolus. When the tumor grew in the IVC the image showed a prismatic filling defect. The vessel wall was not destroyed unless the tumor encroached directly upon the wall. There was a gap between the embolus and vessel wall and the contrast medium flowed through the gap. This gap was shown as a high density ring-shape with low density in the center on the arterial phase scan, like a “ring”. Tumors in the right hepatic lobe usual encroach upon the hepatic vein and directly affect the IVC, and tumors in the left lobe firstly encroach upon the left hepatic vein and middle hepatic vein, get into IVC, then re-enter the RA.

Patients who could not take TACE generally had PV embolus, pulmonary metastasis, retroperitoneal lymph node metastasis, medium dose or high dose ascites, and a grade C Child-Pugh hepatic function classification. Patients could take TACE treatment if they had class A or B hepatic function and if they could tolerate TACE treatment. The tumor could be controlled for a certain time and to a certain degree after TACE treatment, and the survival time of patients could be prolonged<sup>[7,17-19]</sup>.

CT and MR images can exhibit and distinguish between tumor, thrombi and malignant embolus<sup>[16]</sup>. The malignant embolus was round, orbicular-ovate or cauliflower shape. The embolus was arterial blood supply, on the angiography, it may show a lot of blood vessel and “stria” sign for hypervascular tumor, but for hypovascular tumor it showed no enhancement and stain. The thrombus was no enhancement with more low density and no intrahepatic malignant tumor.

and form a nodular embolus. Hepatocellular carcinoma (HCC) is the most prevalent of the liver tumors, and the portal vein (PV), hepatic vein (HV) and the inferior vena cava (IVC) are often affected. Although rare, the RA may show signs of tumor intrusion.

### Research frontiers

Nodular filling defects in the RA could be easily found on enhancement computer tomography (CT) or magnetic resonance (MR) imaging. The coronal images of CT or MR show the extent of the lesion. Lipiodol can enter the embolus after transcatheter arterial chemoembolization (TACE) and reduce the speed of embolus growth.

### Innovations and breakthroughs

Lipiodol can enter the embolus after TACE and reduce the speed of embolus growth. There was a survival benefit associated with anticancer treatment.

### Applications

CT and MR images can exhibit and distinguish between the tumor, thrombi and a malignant embolus. MR images showed the embolus better than CT because MR can show it from a different direction of view.

### Terminology

TACE: One of most commonly used technologies for liver cancer therapy. The chemotherapeutic agents and embolic agents (and/or particles) were delivered via selective catheter placement to the tumor(s) feeding vessels in an attempt to achieve cytoreduction by enabling more focused drug delivery or deposition of a higher concentration of drug within the liver cancer.

### Peer review

This study reported imaging characteristics of an RA tumor embolus in patients with advanced HCC. It arouses interest for readers and provides an important clue for diagnosing and treating patients with tumor emboli.

### Abstract

**AIM:** To study the preventive effects of *Qianggan-Rongxian* Decoction on liver fibrosis induced by dimethylnitrosamine (DMN) in rats.

**METHODS:** Male Wistar rats were randomly divided into hepatic fibrosis model group, control group and 3 treatment groups (12 rats in each group). Except for the normal control group, all the rats received 1% DMN (10  $\mu$ L/kg body weight, i.p), 3 times a week for 4 wk. The rats in the 3 treatment groups including a high-dose DMN group (10 mL/kg), a medium-dose DMN group (7 mL/kg), and a low-dose DMN group (4 mL/kg) were daily gavaged with *Qianggan-Rongxian* Decoction, and the rats in the model and normal control groups were given saline vehicle. Enzyme-linked immunosorbent assay (ELISA) was used to determine the changes in serum hyaluronic acid (HA), laminin (LN), and type IV collagen levels. Serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels were measured using routine laboratory methods. Pathologic changes, particularly fibrosis, were examined by hematoxylin and eosin (HE) and Sirius red staining. Hepatic stellate cells (HSC) were examined by transmission electron microscopy.

**RESULTS:** Compared with the model control group, the serum levels of HA, LN, type IV collagen, ALT and AST were decreased markedly in the other groups after treatment with *Qianggan-Rongxian* Decoction, especially in the medium-dose DMN group ( $P < 0.05$ ).

Moreover, the area-density percentage of collagen fibrosis was lower in the *Qianggan-Rongxian* Decoction treatment groups than in the model group, and a more significant drop was observed in the medium-dose DMN group ( $P < 0.05$ ).

**CONCLUSION:** *Qianggan-Rongxian* Decoction can inhibit hepatic fibrosis due to chronic liver injury, delay the development of cirrhosis, and notably ameliorate liver function. It may be used as a safe and effective therapeutic drug for patients with fibrosis.

### INTRODUCTION

In China, the incidence of liver cirrhosis is still high<sup>[1]</sup>. Hepatic cirrhosis results from fibrosis<sup>[2-4]</sup>. Many factors can lead to chronic liver disease and hepatic fibrosis<sup>[5-9]</sup>. Hepatic fibrosis is associated with a number of morphological and biochemical changes leading to structural and metabolic abnormalities in the liver. Hepatic stellate cells (HSC) play a major role in various types of liver fibrosis through initial myofibroblast transformation. Although new therapeutic approaches have recently been proposed, there is no established therapy for liver fibrosis<sup>[10,11]</sup>. *Qianggan-Rongxian* Decoction is a traditional Chinese medicine. The aim of the present study was to investigate its protective effects on rat liver fibrosis induced by dimethylnitrosamine (DMN).

### MATERIALS AND METHODS

#### Composition of *Qianggan-Rongxian* Decoction

The compositions of *Qianggan-Rongxian* Decoction

mainly include 13 Chinese herbs, including 15 g *Pig Bile powder*, 10 g *Bupleuri*, 10 g *Baical Skullcap Root*, 10 g *Pinellia Tuber*, 10 g *Chinese Angelica*, 10 g *Barbary Wolfberry Fruit*, 10 g *Nutgrass Galingale*, 10 g *Oriental Waterplantain Rhizome*, 3 g *Pangolin Scale*, 153 g *Danshen Root*, 10 g *White Peony Alba*, 10 g *Radix Glycyrrhizae*, 15 g *Tangshen*.

### Animals and experiment protocol

Male Wistar rats weighing 175-200 g were obtained from the Experimental Animal Center of Chengde Medical College. The rats were randomly divided into control group, model group, and 3 treatment groups (12 rats in each group). Except for the normal control group, all the rats were abdominally injected with 1% DMN (10  $\mu$ L/kg body weight, i.p.), 3 times a week for 4 wk, while the rats in the control group were abdominally injected with an equivalent amount of saline. The rats in the 3 treatment groups, including a high-dose DMN group (10 mL/kg), a medium-dose DMN group (7 mL/kg), and a low-dose DMN group (4 mL/kg), were given *Qianggan-Rongxian* Decoction daily via a gastric tube, once a day for 4 wk. After 4 wk, except for the dead, all the rats were anesthetized with 200 g/L urethane (5 mL/kg, abdominal injection). Blood was taken from the abdominal aorta, centrifuged at 4°C, and plasma was kept at -20°C for assay.

### Measurement of serum levels of hyaluronic acid, type IV collagen and laminin

Quantitative enzyme-linked immunoabsorbent assay (ELISA) was used to determine serum levels of hyaluronic acid (HA), type IV collagen, and laminin (LN).

### Measurement of plasma levels of alanine aminotransferase and aspartate aminotransferase

Plasma levels of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were measured using routine laboratory methods.

### Sirius-red and HE staining

Formalin-fixed and paraffin-embedded liver tissues were cut into 4- $\mu$ m thick sections which were stained with hematoxylin and eosin (HE) and Siriusred. HE staining was used to observe liver pathologic structures, Siriusred staining and CMIAS image analysis system (Beihang, China) were used to determine the area-density percentage of collagen fibrosis in hepatic tissue. At least five high-power ( $\times 400$ ) fields were chosen and positive collagen fibrosis (red staining) was determined. The area-density percentage of collagen fibrosis was calculated by dividing the number of positive collagen fibres (positive optical density) over the total number of collagen fibres (integrated optical density).

### Electron microscopy

Fresh liver tissue sections (1 mm  $\times$  1 mm  $\times$  1 mm) were fixed in 10% paraform fixative, dehydrated and embedded in Epon-812 resin, and then stained with uranyl acetate and lead citrate for 15 min, respectively.

Table 1 Serum levels of HA, LN, and type IV collagen (mean  $\pm$  SD)

Groups	n	HA (ng/mL)	LN (ng/mL)	Type IV collagen (ng/mL)
Control	12	19.81 $\pm$ 2.86	11.02 $\pm$ 1.70	13.49 $\pm$ 2.49
Model	10	44.64 $\pm$ 3.09 <sup>c</sup>	33.27 $\pm$ 5.81 <sup>c</sup>	62.71 $\pm$ 19.16 <sup>c</sup>
High-dose DMN group	10	23.14 $\pm$ 4.58 <sup>a,c</sup>	14.02 $\pm$ 2.63 <sup>a,c</sup>	22.10 $\pm$ 2.44 <sup>a,c</sup>
Medium-dose DMN group	12	22.58 $\pm$ 3.60 <sup>a</sup>	13.87 $\pm$ 1.45 <sup>a</sup>	25.64 $\pm$ 4.68 <sup>a,c</sup>
Low-dose DMN group	10	26.08 $\pm$ 5.62 <sup>a,c</sup>	19.12 $\pm$ 5.02 <sup>a,c</sup>	27.64 $\pm$ 4.68 <sup>a,c</sup>

<sup>a</sup>P < 0.05 vs model group; <sup>c</sup>P < 0.05 vs control group.

Liver "transitional" HSC were observed under JEM-1200EX, 80 kV electron microscope (JEOL, Japan).

### Statistical analysis

Results were expressed as mean  $\pm$  SD. Quantitative data were analyzed using ANOVA with statistical software SPSS 11.0. P < 0.05 was considered statistically significant. Ridit test was used for statistical analysis of the qualitative data.

## RESULTS

### Changes in serum HA, LN levels and type IV collagen levels

The serum levels of HA, LN, and type IV collagen were markedly increased in the model group compared with the control group (P < 0.05). Compared with the model group, the serum levels of HA, LN, and type IV collagen were significantly decreased in the 3 treatment groups (P < 0.05) (Table 1).

### Siriusred and HE staining

At the end of the study, the liver of control rats had no appreciable alterations in the model group (Figure 1A), more fibrous tissues formed and extended into the hepatic lobules to separate them incompletely and thick intralobular septa were evident (Figure 1B). While in the 3 treatment groups, especially in the medium-dose DMN group, the pathological changes in liver were rather milder, showing less fibrous tissue proliferation (Figure 1C). The rat liver was stained with Siriusred. The area occupied by the fibrotic septa was markedly increased in the model group compared with the control group (P < 0.05). Compared with the model group, the area occupied by the fibrotic septa was significantly decreased in the 3 treatment groups (P < 0.05) (Table 2).

### Plasma levels of ALT and AST

Plasma levels of ALT and AST were higher in the model group than in the control group (P < 0.05), while ALT and AST levels were significantly lower in the *Qianggan-Rongxian* Decoction treatment groups than in the model group. No difference was found in the serum levels of ALT and AST between the medium-dose DMN group and normal group (Table 3).

**Figure 1** Light microscopy showing normal liver tissue in the control group (HE staining,  $\times 100$ ) (A), liver fibrosis tissue and formation of more fibrous tissue as well as a large amount of inflammatory cells soaked in intralobules and interlobules in model group (van Gieson staining,  $\times 100$ ) (B), and liver fibrosis tissue in *Qianggan-Rongxian* Decoction treatment group (C). The pathological change in liver was rather milder compared with the model group (van Gieson staining,  $\times 100$ ).

### Ultrastructure observation under electron microscope

HSC were normal in the control group and typical myofibroblasts were observed in the fibrous septum of the model group (Figure 2A). The elongated cell body contained indented nuclei and numerous microfilaments outlined by a lamina-like structure. Collagen fibers of variable size were seen all around the myofibroblasts (Figure 2B). “Transitional” HSC could be observed under the electron microscope (Figure 2C).

## DISCUSSION

Hepatic fibrosis at the intermediate and crucial stage is characterized by reversibility. If treated properly at this stage, cirrhosis could be successfully prevented. However, it remains a problem to prevent cirrhosis or

<sup>a</sup>*P* < 0.05 vs model group; <sup>c</sup>*P* < 0.05 vs control group.

to control its progression. Great efforts have been made to find safe and effective drugs. Recent clinical and experimental observations demonstrated that Chinese medicines have some preventive and therapeutic values against fibrosis<sup>[12-14]</sup>. *Astragalus*, one of the compositions of *Qianggan-Rongxian* Decoction, can relieve stasis by activating blood circulation, and eliminate fullness by strengthening the “spleen”, supplementing and smoothing “Qi”, reinforcing the body’s immunological function. It also could preserve the integrity of hepatocytes, eliminate toxic free radicals, inhibit lipid peroxidation of cytomembrane, relieve necrosis of hepatocytes, and reduce fibrosis<sup>[15-19]</sup>. Thoroughfare is mainly used to activate blood circulation, remove stasis, and dredge the liver<sup>[20]</sup>. *Qianggan-Rongxian* Decoction has been used for 20 years to prevent liver fibrosis in clinical practice. However, its effect and associated mechanisms need further study. DMN-induced experimental model may be helpful in understanding the relationship between liver injury and development of hepatic fibrosis<sup>[21]</sup>. As estimated by histological analysis of liver tissue stained with Sirius red<sup>[22]</sup>, it can be used to detect different degrees of hepatic fibrosis, and examination of the liver can reveal a progressive increase in fibrosis scores and expansion of fibrous septa<sup>[23]</sup>. Serum HA, LN and collagen type IV levels were significantly increased in the rats as detected by ELISA, showing that simultaneous determination of HA, LN and collagen type IV levels is an optimal choice<sup>[24]</sup>. We treated the rat liver fibrosis induced by injection of DMN with *Qianggan-Rongxian* Decoction. After 4 wk, no appreciable alterations were found in the control

**Figure 2** Electron microscopy showing normal HSC in the model group (A), typical myofibroblasts in the control group (B) ( $\times 5000$ , bar = 1  $\mu\text{m}$ ), and "transitional" HSC ( $\times 6000$ , bar = 1  $\mu\text{m}$ ) in *Qianggan-Rongxian* Decoction treatment group (C).

group. However, the rats in the model group had an almost integrity fibrosis septum, and pseudolobules could be seen in nearly all sections. While the rats that received *Qianggan-Rongxian* Decoction had less fibrosis, reticular fibrosis in the interlobular septum was limited and no pseudo-lobules could be seen. HSC play a central role in the pathogenesis of liver fibrosis and are able to regulate matrix degradation in the liver. Following liver injury, HSC become activated and express extracellular matrix. *Qianggan-Rongxian* Decoction can inhibit transition from HSC to myofibroblasts and fibroblasts. In addition, *Qianggan-Rongxian* Decoction could decrease the area-density percentage of collagen fibrosis. HA, LN, and type IV collagen are good serum markers of hepatic fibrosis. In this study, the serum levels of these 3 markers in the model group were much higher than those in the control group ( $P < 0.05$ ). The serum levels of HA, LN and type IV collagen were significantly lower

in the *Qianggan-Rongxian* Decoction treatment groups than in the control group. ALT and AST are the indexes of liver functions. Since ALT in cytoplasm of liver cells is discharged into blood when degeneration, hyper permeability and necrosis of liver cells occur, increased serum ALT levels reflect the degree of liver cell injury. Our study showed that *Qianggan-Rongxian* Decoction could decrease the serum levels of ALT and AST in rats with hepatic injury induced by DMN, indicating that *Qianggan-Rongxian* Decoction may work by protecting liver against fibrosis. The mechanism underlying rat liver fibrosis induced by DMN is associated with immune function, which is similar to the mechanism underlying human liver fibrosis<sup>[25]</sup>. Thus, DMN-induced rat liver fibrosis may be a useful model for determination of liver fibrosis during drug screening. The mechanism of *Qianggan-Rongxian* Decoction may need further study.

In summary, *Qianggan-Rongxian* Decoction may play a role in anti-fibrotic therapy by protecting liver cells and inhibiting the deposition of collagen fibers in liver, thus providing a safe and effective strategy for inhibition of cirrhosis in clinic practice.

## COMMENTS

### Background

In China, the incidence of liver cirrhosis is still high, liver fibrosis and cirrhosis are due to chronic liver injury. Although new therapeutic approaches have recently been proposed, there is no established therapy for liver fibrosis. The authors investigated the preventive effect of *Qianggan-Rongxian* Decoction on rat liver fibrosis induced by dimethylnitrosamine (DMN).

### Research frontiers

*Qianggan-Rongxian* Decoction can protect the liver against fibrosis induced by DMN in rats.

### Innovations and breakthroughs

Enzyme-linked immunosorbent assay (ELISA) and hematoxylin and eosin as well as Sirius red staining and transmission electron microscopy demonstrated that *Qianggan-Rongxian* Decoction could prevent liver against fibrosis.

### Applications

ELISA can determine the changes in serum levels of hyaluronic acid (HA), laminin (LA), and type IV collagen. Pathologic changes, particularly fibrosis can be examined by light microscopy. Hepatic stellate cells (HSC) can be examined by transmission electron microscopy.

### Terminology

*Qianggan-Rongxian* Decoction is a kind of Chinese medicine, which may protect the liver against fibrosis.

### Peer review

This is an interesting article. *Qianggan-Rongxian* Decoction can protect the liver against fibrosis and inhibit the deposition of collagen fibers in liver, thus providing a safe and effective strategy for inhibition of cirrhosis in clinical practice. The paper is well organized and the results are clearly described and commented.

( $P < 0.05$ ). On days 3-5 of treatment, acute physiology and chronic health evaluation II (APACHE II) scores for the study and control groups were significantly different ( $P < 0.05$ ). Both the effectiveness and outcome of the treatment with *Da Cheng Qi* Decoction on abdominalgia, burbulence relief time, ascites quantity, cyst formation rate and hospitalization time were quite different between the two groups ( $P < 0.05$ ). The mortality rate for the two groups had no significant difference.

**CONCLUSION:** *Da Cheng Qi* Decoction enema and external use of Glauber's salt combined with routine non-operative conservative treatment can decrease the intra-abdominal pressure (IAP) of SAP patients and have preventive and therapeutic effects on abdominal compartment syndrome of SAP.

### Abstract

**AIM:** To investigate the therapeutic effect of traditional Chinese traditional medicines *Da Cheng Qi* Decoction (Timely-Purging and Yin-Preserving Decoction) and Glauber's salt combined with conservative measures on abdominal compartment syndrome (ACS) in severe acute pancreatitis (SAP) patients.

**METHODS:** Eighty consecutive SAP patients, admitted for routine non-operative conservative treatment, were randomly divided into study group and control group (40 patients in each group). Patients in the study group received *Da Cheng Qi* Decoction enema for 2 h and external use of Glauber's salt, once a day for 7 d. Patients in the control group received normal saline (NS) enema. Routine non-operative conservative treatments included non-per os nutrition (NPON), gastrointestinal decompression, life support, total parenteral nutrition (TPN), continuous peripancreatic vascular pharmaceutical infusion and drug therapy. Intra-cystic pressure (ICP) of the two groups was measured during treatment. The effectiveness and outcomes of treatment were observed and APACHE II scores were applied in analysis.

**RESULTS:** On days 4 and 5 of treatment, the ICP was lower in the study group than in the control group

### INTRODUCTION

Severe acute pancreatitis (SAP) is a serious surgical disease with a mortality of 25%-40%<sup>[1,2]</sup>. Patients with SAP tend to have elevated intra-abdominal pressure (IAP), which eventually leads to intra-abdominal hypertension (IAH). IAH causes organ dysfunctions such as respiratory, circulatory and renal failure, known as abdominal compartment syndrome (ACS)<sup>[3,4]</sup>. About 11% of SAP patients suffer from complications of ACS. SAP patients complicated by ACS, a special type of pancreatitis, tend to have a mortality of 66.7%<sup>[5]</sup>. There are certain guidelines for treatment of SAP, but no standard treatment for ACS

in SAP patients is available at present<sup>[2]</sup>. In our previous study, *Da Cheng Qi* Decoction showed beneficial effects on acute pancreatitis (AP) with no adverse effects<sup>[6]</sup>. In the present study, we used *Da Cheng Qi* Decoction and Glauber's salt combined with routine non-operative conservative treatments, including non-per os nutrition (NPON), gastrointestinal decompression, life support, total parenteral nutrition (TPN), continuous peripancreatic vascular pharmaceutical infusion and drug therapy in the treatment of ACS in SAP patients. Through comparison with the control group, we demonstrated whether the TCM-wm therapy is effective for treatment of ACS in SAP patients.

## MATERIALS AND METHODS

### Patients

A total of 80 consecutive SAP patients were treated in the Surgery Department of Affiliated Central Hospital of Huzhou Normal College. The age of the patients ranged 27-76 years (mean 54.4 years, median 47 years). There were 38 males (47.5%) and 42 females (52.5%), the male to female ratio was 0.905:1. When they were hospitalized, the severity of SAP was evaluated according to the serum level of amylase, CT serious index (CTSI)<sup>[7]</sup>, acute physiology and chronic health evaluation II (APACHE II) score<sup>[8]</sup>, and the diagnostic criteria and severity grade for AP proposed by the Japanese Ministry of Health, Labor, and Welfare (JMHLW)<sup>[9]</sup>. The diagnosis of ACS was made as previously described<sup>[10]</sup>. Demographic data, serum level of amylase, CTSI, APACHE II scores, ACS rate and severity grade ratio were not statistically different between the study and control groups (Table 1).

### Methods

Eighty patients of SAP admitted for routine non-operative conservative treatment were randomly divided into study group and control group (40 patients in each group). Patients in the study group received *Da Cheng Qi* Decoction enema (one dosage, 100 mL) for 2 h and external use of Glauber's salt (100 g) once a day for 7 d. Patients in the control group received 100 mL normal saline (NS) enema. One dosage of *Da Cheng Qi* Decoction consists of 10 g *Rheum officinale* Baill, 10 g *Sodium sulfate*, 10 g *Magnolia obavata*, 10 g *Fructus aurantii*, 10 g *Radix paeoniae rubra*, and 10 g *Raphanus sativus*. Routine non-operative conservative treatment modalities included NPON, gastrointestinal decompression, life support, TPN, continuous peripancreatic vascular pharmaceutical infusion<sup>[11,12]</sup> and drug therapy. Intracystic pressure (ICP) in the two groups could reflect the IAP conditions at admission and on days 1-7 of treatment. ICP data were defined as previously described<sup>[13]</sup>. Effectiveness of the treatment on abdominalgia, burbulence relief time, ascites quantity, cyst formation, mortality rate and hospitalization time were observed. The ascites quantity in patients was defined by B-ultrasound test on day 7 of treatment. APACHE II scores, defined using Microsoft APACHE

**Table 1** Demographic data, serum level of amylase, CTSI score, APACHE II score, ICP data and severity grade ratio of the two groups when hospitalized (mean  $\pm$  SD)

	Study group (n = 40)	Control group (n = 40)
Age (yr)	54.2 $\pm$ 7.4	54.6 $\pm$ 8.1
Sex (male/female)	20/20	18/22
serum levels of amylase (U/L)	328.23 $\pm$ 13.89	354.51 $\pm$ 14.22
ICP (cmH <sub>2</sub> O)	19.5 $\pm$ 3.4	18.7 $\pm$ 3.6
CTSI score	7.85 $\pm$ 1.1	7.90 $\pm$ 1.4

II graded compute program version 5.1, were applied for analysis.

### Statistical analysis

All data were prepared and compiled using the SPSS computer program (version 11.0 for windows). The data were expressed as mean  $\pm$  SD. Kolmogorov-smirnov test was used for the pattern of data distribution. Student's unpaired *t*-test was used to compare data between the two groups when they were normally distributed. The Mann-Whitney *U* test was used when the data were not normally distributed. Chi square test and Fisher's exact test were used for quantitative data analysis. Step-wise regression analysis was used for multivariate analysis to determine any confounding factors. *P* < 0.05 was considered statistically significant.

## RESULTS

### ICP and APACHE II scores

On days 4 and 5 of treatment, the ICP data obtained from the study group were lower than those obtained from the control group (*P* < 0.05). On days 3-5 of treatment, the APACHE II scores of the study group and control group were significantly different (*P* < 0.05, Table 2). As shown in Table 2, the ICP data were significantly decreased from the 4th treatment day in the study group (*P* < 0.05), while significantly decreased from the 6th treatment day in the control group (*P* < 0.05). The cumulative scores of APACHE II were significantly decreased from the 3rd treatment day in the study group (*P* < 0.05), while significantly decreased from the 6th treatment day in the control group (*P* < 0.05).

### Effectiveness of treatment

As shown in Table 3, the relief time of abdominalgia and burbulence was shorter in the study group than in the control group (*P* < 0.05). The amount of ascites on day 7 of treatment was less in the study group than in the control group (*P* < 0.05).

### Outcome of treatment

As shown in Table 4, the mortality rate was lower for the study group than for the control group, and there was no significant difference between the two groups. The cyst formation rate was significantly lower for the

study group than for the control group (*P* < 0.05). The hospitalization time of the study group was significantly shorter than that of the control group (*P* < 0.05).

## DISCUSSION

SAP is a serious pathological condition and SAP patients tend to suffer from ACS<sup>[14,15]</sup>. It was reported that SAP can result in systemic inflammatory response syndrome (SIRS) triggered by local inflammation in the pancreas<sup>[16]</sup>. The fundamental pathophysiology of SIRS is hypercytokinemia, a pathological condition in which inflammatory cytokines are excessively released from immunocompetent cells<sup>[17]</sup>. During SIRS, activated inflammatory mediators result in the development of systemic capillary leakage syndrome (SCLS)<sup>[18]</sup>. In SCLS, vascular permeability is increased by the pathologic effects of humoral mediators, leading to interstitial edema and reduction of circulating blood volume<sup>[19]</sup>. Progressive edema of peritoneum and gut contents could rapidly increase IAP. Moreover, massive pancreatic liquid collection in the abdominal and retroperitoneal cavity and a large amount of pancreatic necrotic tissue combined with infection would lead to the formation of abscess, causing intestinal obstruction and erosion of the surrounding organs, which further result in perforation and massive bleeding and recurrence of SIRS and SCLS. Edema caused by the septic retroperitoneal necrosis pushes the peritoneum, thus rapidly increasing IAP<sup>[20]</sup>. Furthermore, for the treatment of SAP, early resuscitation with a large volume of fluid is essential to maintain organ perfusion. However, aggressive fluid

**Table 4** Mortality rate, cyst formation rate and hospitalization time of the two groups (mean  $\pm$  SD)

	Study group ( <i>n</i> = 40)	Control group ( <i>n</i> = 40)	<i>P</i> -value
Mortality rate (%)	7.5 (3/40)	20.0 (8/40)	0.194
Cyst formation rate (%)	10.0 (4/40) <sup>a</sup>	32.5 (13/40)	0.029
Hospitalization time (d)	16.59 $\pm$ 3.89 <sup>a</sup>	29.58 $\pm$ 4.52	0.037

<sup>a</sup>*P* < 0.05 vs control group.

resuscitation may aggravate intestinal edema, further increasing IAP<sup>[21]</sup>, indicating that SAP can induce retroperitoneal edema or abscess, fluid collection in the abdominal and retroperitoneal cavity, intestinal edema, and that aggressive fluid resuscitation could increase IAP and abrupt elevation of IAP eventually causes IAH. IAH causes organ dysfunctions such as respiratory, circulatory and renal failure, known as ACS<sup>[22]</sup>. Since SAP patients with complication of ACS have a very high mortality, it is very important to find a right way to prevent and treat ACS in SAP patients.

*Da Cheng Qi* Decoction is a traditional Chinese medicine documented in Shang Han Lun (Treatise on Febrile Diseases). Its major components include Rheum officinale Baill, sodium sulfate, Magnolia obovata, Fructus aurantii, Radix paeoniae rubra, and *Raphanus sativus*. Modern clinical and experimental researches have focused on the effect of such components<sup>[23-25]</sup>. Glauber's salt, a sodium sulfate dehydrate (Na<sub>2</sub>SO<sub>4</sub>), is widely used as an anti-tissue edema agent in modern medical treatment<sup>[26,27]</sup>. Non-operative conservative treatment has been widely accepted for AP<sup>[28,29]</sup>. Especially, in our previous studies<sup>[11,12,30]</sup>, continuous peripancreatic vascular pharmaceutical infusion could efficiently remove various humoral mediators and inflammatory cytokines from circulating blood, and decrease the mortality of SAP patients. In the present study, we used *Da Cheng Qi* Decoction and Glauber's salt combined with routine non-operative conservative treatments including continuous peripancreatic vascular pharmaceutical infusion for treatment of ACS in SAP patients.

In this study, the ICP data were lower in the study group than in the control group on days 4 and 5 of treatment (*P* < 0.05). The APACHE II scores in study group were significantly less in the study group than in the control group on days 3-5 of treatment (*P* < 0.05). The ICP data were significantly decreased from the 4th treatment day in the study group (*P* < 0.05) while significantly decreased from the 6th treatment day in the control group (*P* < 0.05). The cumulative scores of APACHE II were significantly decreased from the 3rd treatment day in the study group (*P* < 0.05) while significantly decreased from the 6 treatment day in the control group (*P* < 0.05). The relief time of abdominalgia and burbulence was shorter in the study group than in the control group (*P* < 0.05). The amount of ascites on day 7 of treatment was less in the study group than in the control group (*P* < 0.05). The cyst formation rate was significantly lower for the study group than for the

control group ( $P < 0.05$ ). The hospitalization time was significantly shorter in the study group than in the control group ( $P < 0.05$ ). These results suggest that *Da Cheng Qi* Decoction and Glauber's salt combined with non-operative conservative treatments including continuous peripancreatic vascular pharmaceutical infusion can treat IAH by decreasing IAP, relaxing symptoms of ACS, slowing down the pathological condition exacerbation, and accelerating the recovery of illness.

In summary, *Da Cheng Qi* Decoction and Glauber's salt combined with non-operative conservative treatments including continuous peripancreatic vascular pharmaceutical infusion (TCM-wm therapy) can prevent and treat ACS in SAP patients.

## COMMENTS

### Background

Severe acute pancreatitis (SAP) is a familiar surgical disease and about 11% of SAP patients suffer from abdominal compartment syndrome (ACS). SAP patients complicated by ACS tend to have a mortality of 66.7%. There are certain guidelines for treatment of SAP. However, no standard treatment for ACS in SAP patients is available at present.

### Research frontiers

*Da Cheng Qi* Decoction is a traditional Chinese medicine documented in Shang Han Lun (Treatise on Febrile Diseases). Modern clinical and experimental research results have proved its effect. Glauber's salt is widely used as an anti-tissue edema agent in modern medical treatment. *Da Cheng Qi* Decoction or Glauber's salt has beneficial effects on SAP with no adverse effects. Non-operative conservative treatment, especially continuous peripancreatic vascular pharmaceutical infusion for SAP could efficiently remove various humoral mediators and inflammatory cytokines from circulating blood, and decrease the mortality of SAP patients.

### Innovations and breakthroughs

In this study, *Da Cheng Qi* Decoction and Glauber's salt combined with routine non-operative conservative treatments, including continuous peripancreatic vascular pharmaceutical infusion were used in the treatment of ACS in SAP patients. Whether the TCM-wm therapy is effective for ACS in SAP patients was also studied. The results suggest that *Da Cheng Qi* Decoction and Glauber's salt can treat IAH by decreasing IAP, relaxing symptoms of ACS, slowing down the pathological condition exacerbation and accelerating the recovery of illness.

### Applications

The study results provide an important new clue to the treatment of ACS in SAP patients.

### Terminology

SAP is a serious type of acute pancreatitis (AP) complicated by pancreas necrosis and toxic shock. ACS is a syndrome due to factors that cause abrupt elevation of intra-abdominal pressure (IAP), leading to organ dysfunctions such as respiratory, circulatory and renal failure. *Da Cheng Qi* Decoction is a traditional Chinese medicine. Its major components include *Rheum officinale* Baill, sodium sulfate, *Magnolia obovata*, *Fructus aurantii*, *Radix paeoniae rubra*, and *Raphanus sativus*. Glauber's salt is a sodium sulfate dehydrate ( $\text{Na}_2\text{SO}_4$ ). Acute physiology and chronic health evaluation II (APACHE II) is a disease classification system, which is used to evaluate the severity of disease. Intra-cystic pressure (ICP) is the pressure of an empty cyst.

### Peer review

This paper describes the beneficial effect of *Da Cheng Qi* Decoction and Glauber's salt on ACS in SAP patients. Although the medication could not significantly improve the prognosis of SAP patients complicated by ACS, the data are encouraging and provide an important new clue to the treatment of ACS in SAP patients.

### Abstract

**AIM:** To investigate the clinical value of ultrasonographic diagnosis of biliary atresia (BA), a retrospective analysis of the sonogram of 20 children with BA was undertaken.

**METHODS:** Ultrasonography (US) was performed in 20 neonates and infants with BA, which was confirmed with cholangiography by operation or abdominoscopy. The presence of triangular cord, the size and echo of liver, the changes in empty stomach gallbladder and postprandial gallbladder were observed and recorded.

**RESULTS:** The triangular cord could be observed at the porta hepatis (thickness: 0.3-0.6 cm) in 10 cases. Smaller triangular cord (0.2-0.26 cm) can be observed in 3 cases. The gallbladder was not observed in 2 cases, and 1 case showed a streak gallbladder without capsular space. The gallbladders of 15 cases were flat and small. The gallbladders of 2 cases were of normal size and appearance, however, there was no postprandial contraction. The livers of all cases showed hepatomegaly and heterogeneous echogenicity. Statistical analysis was performed to compare the hepatomegaly and heterogeneous echogenicity and the stage of hepatic fibrosis.

**CONCLUSION:** The presence of the triangular cord at

### INTRODUCTION

Biliary atresia (BA)<sup>[1]</sup> is a common progressive and obstructive pathological change in the intrahepatic and extrahepatic ducts, often causing immediate cirrhosis and leading to death. Prompt and accurate early diagnosis determines its optimal operation opportunity and therapeutic efficacy. With the updating of ultrasonic apparatus, especially the application of high resolution detecting head, the sonogram becomes increasingly clear, and more doctors have accumulated experience with the ultrasonic diagnosis of BA. However, no general and unitive diagnostic criteria for BA are available at present. The present study was to summarize the manifestations of sonogram for BA, and the clinical diagnostic value of ultrasonography (US) for biliary atresia, in order to provide evidence for its early diagnosis.

### MATERIALS AND METHODS

Twenty children with BA admitted to our hospital from January, 2004 to March, 2007 were included in this study. The diagnosis of BA was confirmed at operation in 17

**Figure 1** Ultrasonography. **A:** Fibrous plaque of inverted triangular shape at the confluent site of right and left hepatic ducts; **B:** Longitudinal section of streak-shaped fibrous plaque at the confluent site of right and left hepatic ducts; **C:** Cross section of streak-shaped fibrous plaque at hepatic portal vein (arrow indicates fibrous plaque surrounding the right anterior area of the right branch of portal vein); **D:** Flat and small gallbladder with low tension. The thickness of capsule wall was uneven.

children and at abdominoscopy in 3 children. There were 6 males and 14 females at the age of 37-146 d. According to Kasai classification, BA was classified as type I in 1, type II in 3 and type III in 16 children, respectively.

Voluson 730D (Kretz Company) was used. The frequency of transducer for convex and linear array was 3.5-5.5 MHz and 7.5-10 MHz, respectively. The patients were fasted for 3-4 h before examination. Examination was performed with suckling. Sedative was administered to those who kept crying. The patients were examined at a supine position. Oblique section scan under the right rib and multiple cross section scan between ribs were performed to examine liver, gallbladder, and porta hepatis. The transducer was inclined to the right branch of portal vein. Presence of triangular cord, roughness and internal echo of the liver and gallbladder was recorded. Gallbladder at empty stomach and 1, 2 and 3 h postprandial was determined. Changes in size of gallbladder before and after meal were observed dynamically to understand the contractile function of gallbladder. All the sonograms were maintained in the picture archiving and communication system (PACS).

### Statistical analysis

Pearson correlation coefficient was used to determine the correlation of liver size and heterogeneous echogenicity to the liver fibrosis stage.

## RESULTS

### Triangular cord sign at porta hepatis

Fourteen out of the 20 BA cases were accurately

diagnosed by ultrasound. A triangular cord sign was found at the porta hepatic in 13 cases and an obvious triangular cord was observed in 10 cases. The diameter was about 1.2-2.5 cm and the thickness was about 0.3-0.8 cm. An inverted triangular cord was observed (Figure 1A) and a long streak of the triangular cord was found in 7 cases (Figure 1B). The triangular cord found in 3 cases too small to be identified in 3 cases. The diameter was about 0.9-1.6 cm, and the thickness was about 0.2-0.26 cm. Cross section scan of the right branch of portal vein showed that the triangular cord sign at the porta hepatis surrounded the right anterior part of the right branch of portal vein, rather than the whole part. In addition, cross section scan of the right branch of portal vein was easier than longitudinal section scan of the triangular cord sign. As shown in Figure 1C, one case of BA had no triangular cord sign at the porta hepatis. Six cases were misdiagnosed due to the absence of triangular cord sign at the porta hepatis.

### Changes in size, appearance and contractile function of gallbladder

The manifestations of gallbladder in 20 cases of BA were as follows: (1) absence of gallbladder in 2 cases, (2) vacant and flat gallbladder in 1 case with a streak high echoic area; (3) flat and small gallbladder in 14 cases (Figure 1D), (4) gallbladder with almost a normal size and appearance.

### Size of liver and manifestations of parenchyma echo

The liver in the 20 BA cases was generally enlarged, and its length under the ribs was 1.8-4.5 cm. Rough

parenchyma echo was observed in 7 cases. General echo enhancement and roughness were observed in 13 cases. The degree of hepatomegaly and heterogeneous echogenicity was not related with age, but with the degree of liver fibrosis, suggesting that the size of liver and changes in parenchyma echo could indicate the course and prognosis of BA.

## DISCUSSION

Different diagnostic methods of BA, such as radionuclide-imaging and magnetic resonance cholangio-pancreatography (MRCP), have been reported in the literature<sup>[2-5]</sup>. However, they have different limitations. It was reported that radionuclide-imaging of liver and gallbladder can give false positive results, since there is a fully obstructive stage due to cholangitis or cholestasis in neonatal hepatitis syndrome and infantile hepatitis syndrome<sup>[6-8]</sup>. When there is deficient choleresis or the diameter of biliary tract is too small, they would be easily misdiagnosed as BA<sup>[9-11]</sup>. With the improvement and updating of ultrasonic apparatus, and the enhancement of resolution, clear image can be obtained with a high frequency detecting head. Since the abdominal wall of children is thin, ultrasonic inspection is repeatable, convenient and non-invasive, making it more predominant than other diagnostic methods<sup>[12,13]</sup> for BA.

Some studies demonstrated that the triangular cord at the porta hepatis in BA patients is a direct and specific diadynamic criterion for US, which emphasizes its importance in the diagnosis of BA and significantly increases the accurate rate of BA diagnosis<sup>[14-16]</sup>. In the present study, 13 cases were diagnosed as BA according to the triangular cord at the porta hepatis. Among them, the triangular cord in 3 cases was relatively small and difficult to identify. The diameter was only 0.2-0.26 cm. However, accurate diagnosis was made based on flat and small gallbladder, irregular shape, poor contraction, enlarged liver and parenchyma echo. Six cases were misdiagnosed due to the absence of the triangular cord. The reasons why the triangular cord is absent are as follows: (1) there is no triangular cord sign at the porta hepatic, (2) the triangular cord is too small to be identified, and (3) the doctor cannot show the triangular cord due to his or her inexperience with US<sup>[17-19]</sup>. These problems suggest that the triangular cord is not the only diagnostic criterion for BA. We should not ignore some important indirect changes in liver and gallbladder when diagnosing BA<sup>[20,21]</sup>. When the triangular cord at the porta hepatis is relatively small or does not exist, the size and appearance of gallbladder and liver<sup>[22]</sup>, changes in their contractile function<sup>[23]</sup> and parenchyma echo will help to diagnose BA<sup>[24,25]</sup>.

In this study, the triangular cord at the porta hepatis did not surround the whole right branch of portal vein. Cross section scan of the right branch of portal vein showed that the triangular cord adhered tightly to its right anterior area and was easier to show the triangular cord than longitudinal section scan.

In conclusion, the manifestations of sonograms on

BA can be summarized as follows. (1) The triangular cord sign at the porta hepatis is one of the direct and specific objective criteria for BA, but not the only one. (2) The manifestations of gallbladder can be classified into four types: absence of gall bladder, vacant and flat gallbladder, flat and small gallbladder, and gallbladder with almost normal size and appearance. (3) The degree of hepatomegaly and heterogeneous echogenicity of liver parenchyma echo are positively correlated to liver fibrosis, which is able to indicate duration and prognosis of BA and provide reliable clinical evidence for choosing operation opportunity.

## COMMENTS

### Background

The present research was to summarize the manifestations of sonogram on biliary atresia (BA), and the clinical diagnostic value of ultrasonography (US) for BA. The presence of triangular cord in the right and left hepatic ducts can become an objective index of the ultrasonic diagnosis of BA. However, it is not the only diagnostic criterion. Flat and small gallbladder and poor contraction are also important for diagnosis and differential diagnosis of BA.

### Research frontiers

Studies demonstrated that the triangular cord at the porta hepatis in BA patients is a direct and specific criterion for US, which emphasizes its importance in the diagnosis of BA and significantly increases the accurate BA diagnosis rate. It has become an indispensable evidence for the diagnosis of BA.

### Innovations and breakthroughs

The triangular cord at the porta hepatis did not surround the whole right branch of portal vein. Cross section scan of the right branch of portal vein revealed that the triangular cord adhered tightly to its right anterior area and was easier to show the triangular cord than longitudinal section scan.

### Applications

The manifestations of sonogram on BA and the clinical diagnostic value of US for BA can provide strong evidence for its early diagnosis. The presence of triangular cord in the right and left hepatic ducts was specific, and can become an objective index for the ultrasonic diagnosis of BA. However, it was not the only diagnostic criterion. Flat and small gallbladder and poor contraction were also important in the diagnosis and differential diagnosis of BA.

### Peer review

The authors investigated the clinical value of ultrasonographic diagnosis of BA and a retrospective analysis of the sonogram of 20 children with BA was undertaken. The manuscript is very interesting and the study was well designed.

of even vague abdominal symptoms, adjustment of immunosuppression, broad-spectrum antibiotics, and immediate surgical treatment are critical. Moreover, strategies to reduce the risk of this complication should be implemented. Pretransplantation colon screening, prophylactic pretransplantation sigmoid resection in patients with diverticulosis, and elective surgical intervention in patients with nonoperatively treated acute diverticulitis after transplantation deserve consideration and further studies.

### Abstract

Acute complicated diverticulitis, particularly with colon perforation, is a rare but serious condition in transplant recipients with high morbidity and mortality. Neither acute diverticulitis nor colon perforation has been reported in young heart-lung grafted patients. A case of subclinical peritonitis due to perforated acute sigmoid diverticulitis 14 years after heart-lung transplantation is reported. A 26-year-old woman, who received heart-lung transplantation 14 years ago, presented with vague abdominal pain. Physical examination was normal. Blood tests revealed leukocytosis. Abdominal X-ray showed air-fluid levels while CT demonstrated peritonitis due to perforated sigmoid diverticulitis. Sigmoidectomy and end-colostomy (Hartmann's procedure) were performed. Histopathology confirmed perforated acute sigmoid diverticulitis. The patient was discharged on the 8th postoperative day after an uneventful postoperative course. This is the first report of acute diverticulitis resulting in colon perforation in a young heart-lung transplanted patient. Clinical presentation, even in peritonitis, may be atypical due to the masking effects of immunosuppression. A high index of suspicion, urgent aggressive diagnostic investigation

### INTRODUCTION

Abdominal complications are common in solid organ transplant recipients. They include esophagitis, gastritis, duodenitis, hernia, cholelithiasis or diverticulosis with minor morbidity and peptic ulcer disease, choledocholithiasis, acute cholecystitis, acute cholangitis, acute pancreatitis, hepatitis, hepatic or pancreatic abscess, bowel obstruction, megacolon, colitis, perirectal abscess, acute appendicitis, acute diverticulitis, gastrointestinal tract hemorrhage and viscus perforation with significant morbidity and mortality<sup>[1-12]</sup>. They may occur early after transplantation or even years later<sup>[4,5,7,8,10,12]</sup>. Successful management requires a high index of suspicion, early diagnosis and prompt treatment; wherever doubt exists, laparotomy is the appropriate way to establish a definite diagnosis<sup>[1,2-4,7,9,10,12]</sup>.

**Figure 1** Abdominal X-ray showed air-fluid levels.

**Figure 2** Abdominal CT scan revealed a markedly dilated sigmoid colon, extrasceral free air, and peritonitis.

Colon perforations may also occur in the early to late post-transplantation period<sup>[4,5,9,12]</sup>. Early-onset perforations are secondary to perioperative hypoperfusion, increased intraluminal pressure from narcotics, use of bowel stimulants, and high-dose immunosuppression while late perforations are often related to acute diverticulitis and invasive fungal or viral colonic disease<sup>[4,5,9,12]</sup>.

Acute complicated diverticulitis, particularly with colon perforation, is a rare but very serious condition in transplant recipients and remains a challenging surgical problem. Furthermore, neither acute diverticulitis nor colon perforation has been reported until now in heart-lung transplanted young patients. We herein report a case of subclinical peritonitis due to perforated acute sigmoid diverticulitis 14 years after heart-lung transplantation in a 26-year-old woman.

## CASE REPORT

A 26-year-old female patient presented with vague abdominal pain of 24 h duration. The patient received combined heart-lung transplantation because of Eisenmenger's syndrome 14 years ago. During the post-transplantation period, her medical history was uneventful. She was treated with azathioprine and cyclosporine. On admission, vital signs and physical examination were normal while blood tests

revealed leukocytosis (WBC:  $19 \times 10^9/L$ ). Upright chest radiography was normal and abdominal X-ray showed air-fluid levels but no free air (Figure 1). Tests were negative for acute cytomegalovirus (CMV) disease. Abdominal computed tomography (CT) scan demonstrated sigmoid colon perforation resulting in peritonitis (Figure 2).

Operative intervention was carried out immediately under broad spectrum antibiotic coverage. Laparotomy revealed diffuse fecal contamination of the abdomen due to perforated sigmoid diverticulitis. Meticulous lavage of the peritoneal cavity, sigmoidectomy and an end-colostomy (Hartmann's procedure) were performed. Histopathologic examination of the resected specimen confirmed sigmoid colon diverticula, acute diverticulitis, and perforation of one diverticulum. No signs of bacterial, fungal, or viral infection were detected.

The postoperative course was uneventful and the patient was discharged on the 8th postoperative day. The colostomy was closed 6 months later. At a follow-up of 6 months, she is alive with no recurrence of colonic disease.

## DISCUSSION

Abdominal and, particularly, gastrointestinal complications are common in transplanted patients representing an important source of morbidity and mortality<sup>[2-4]</sup>. They are reported in 6.3%-51% of solid organ transplanted patients with a mortality rate, particularly of major complications, of 7.7%-63%<sup>[1-6,8,9,13-16]</sup>. Clinical presentation, even in peritonitis, may be atypical in the immunosuppressed transplant recipient due to the masking effects of the immunosuppression, particularly steroid medication on symptoms and signs<sup>[5,8,16]</sup>. This may result in delayed presentation and diagnosis or even misdiagnosis<sup>[15]</sup>. This patient, although not receiving corticosteroids, but azathioprine and cyclosporine, presented with vague abdominal pain and normal abdominal clinical examination despite suffering from peritonitis due to colonic perforation.

The high mortality of gastrointestinal complications appears to be related to the effects of the immunosuppression and the associated response to sepsis. Reduction of these complications and associated morbidity and mortality can be achieved by improved preventive measures, prompt diagnosis, immediate surgical management, and reduced or steroid-sparing immunosuppressive protocols<sup>[1,2,9,10,12,16]</sup>. Increased dosages of maintenance steroid regimens may correlate with the occurrence of gastrointestinal complications<sup>[16]</sup> while the time interval between onset of symptoms and operative intervention and mean corticosteroid dose are associated with mortality<sup>[10]</sup>.

Asymptomatic diverticulosis has been reported in 39.8% of heart transplanted patients<sup>[7]</sup>. In a study of renal transplant recipients, the incidence of diverticulosis was 12.7%; major colonic complications eventually developed in 57.1% of these patients resulting in a mortality of 75%<sup>[17]</sup>. In patients with diverticulosis and

a previous history of diverticulitis, consideration for elective segmental colectomy prior to transplantation was, thus, advocated<sup>[17]</sup>. It is worth mentioning, however, that the presence of colonic diverticula is deemed unlikely in young patients such as this case, and this may lead to late diagnosis. Although uncommon, the presented complication should, therefore be included in the differential diagnosis of young transplanted patients presenting with vague abdominal complaints.

Acute diverticulitis is a relatively rare, but serious problem in transplanted patients<sup>[6,11,12,15]</sup>. It is reported in 0.4%-8% of solid organ transplanted patients with a 0%-83.3% mortality rate<sup>[4,8,11,16,18-20]</sup>. However, no case of acute diverticulitis in patients with heart-lung transplantation has been reported before, particularly in young patients. Compared to the general population, heart and lung transplant recipients are at substantially increased risk of experiencing acute diverticulitis<sup>[18,20]</sup>. In the study of Qasabian *et al.*, all patients with severe diverticulitis survived and death occurred only in a conservatively treated patient in whom a definite diagnosis was not reached until post-mortem examination was made<sup>[18]</sup>.

Diagnosis of diverticulitis poses a significant challenge in the immunosuppressed patients<sup>[11,18,19]</sup>. Symptoms and physical examination usually do not reflect the severity of the disease while signs of infection, such as fever and tachycardia, may be absent. Laboratory testing is often unreliable and misleading in estimating the severity of the disease. Abdominal radiographs may be non-specific such as in our patient. Abdominal CT scan is the most reliable modality in determining the location and degree of pathology. A high index of suspicion, prompt diagnosis, reduction of immunosuppression, and early administration of broad spectrum antibiotics are essential for management and prognosis of these patients<sup>[11,18-20]</sup>. If bowel perforation is suspected, immediate operative intervention with bowel resection and colostomy is indicated. In the setting of uncomplicated diverticulitis, it is prudent to proceed with colectomy following resolution of the acute episode, provided the patient is a reasonable operative candidate<sup>[11,18-20]</sup>.

Colon perforation has been observed in 0.5%-5.3% of solid organ recipients with a mortality of 0%-100%<sup>[1,3-6,13-15]</sup>. Moreover, colon perforation due to acute diverticulitis is a rare complication with a high mortality<sup>[2,4,9,10,12]</sup>. It has been described in kidney, heart, and lung transplant recipients<sup>[2,4,9,10,12,14]</sup>. Regarding colon perforation due to acute diverticulitis in renal graft recipients, 0.5%-3% have been reported to sustain perforation with a mortality of 12.5%-83.3%<sup>[2,9,10]</sup>. In heart and lung grafted patients, this incidence is 3.4% and 4.8%-6.7%, respectively, with a mortality of 0%-50%<sup>[12,16]</sup>. However, up to now, there has been no report of colon perforation due to acute diverticulitis in heart-lung transplanted patients.

History of diverticula<sup>[2]</sup> or acute diverticulitis<sup>[10]</sup> and steroid therapy<sup>[16]</sup> have been found to be risk factors for colon perforation. The time between onset of symptoms and operation, intensity of immunosuppression (mean corticosteroid dose), and nutritional status (levels of serum

albumin) are associated with the mortality of patients with colon perforation<sup>[9,12]</sup>. Immediate diagnosis and early, aggressive care consisting of surgical intervention, broad spectrum antibiotics, and reduced or steroid-sparing immunosuppression are crucial to outcome<sup>[8,10,12]</sup>. Furthermore, although not uniformly supported in the literature, pretransplantation colon screening and prophylactic sigmoidectomy in patients with diverticulosis, and elective surgical intervention in patients with a nonoperatively treated episode of acute diverticulitis after transplantation have been suggested<sup>[11,12,18,20]</sup>.

Even though in the presence of an acute abdomen laparotomy is the appropriate approach to establish a definitive diagnosis and to treat these patients, abdominal operations for urgent surgical conditions are associated with increased morbidity and mortality<sup>[4,12]</sup>. Significant reduction of morbidity and mortality can be achieved by prompt diagnosis and early surgical management<sup>[1,2,9,10]</sup>.

In conclusion, acute complicated diverticulitis, particularly with colon perforation, is a rare but serious condition in transplanted patients with high morbidity and mortality. Our patient is the first case of acute diverticulitis resulting in colon perforation in a young heart-lung graft recipient in the literature. Clinical presentation may be atypical. A high index of suspicion, urgent aggressive diagnostic investigation of even vague abdominal symptoms, adjustment of immunosuppression, adequate selection of antimicrobial agents, and prompt surgical treatment are critical. Strategies to reduce the risk of this complication should also be implemented in transplantation centres; thus, pretransplantation colon screening, prophylactic pretransplantation sigmoidectomy in patients with diverticulosis and elective surgical intervention in patients with a prior episode of acute diverticulitis after transplantation deserve further consideration and studies.

### Abstract

We herein report a case of a hilar tumor with extensive invasion to the proper hepatic artery, which was successfully treated with a radical resection in a 57-year-old female patient after a stepwise hepatic arterial embolization. She underwent right colectomy and partial hepatectomy for advanced colon cancer two years ago and radiofrequency ablation therapy for a liver metastasis one year ago, respectively. A recurrent tumor was noted around the proper hepatic artery with invasion to the left hepatic duct and right hepatic artery 7 mo previously. We planned a radical resection for the patient 5 mo after the absence of tumor progression was confirmed while he was undergoing chemotherapy. To avoid surgery-related liver failure, we tried to promote the formation of collateral hepatic arteries after stepwise arterial embolization

### INTRODUCTION

Locally advanced hilar tumor often involves the hepatic artery (HA) within the hepatoduodenal ligament, and a concomitant resection may be required for its cure. However, hepatic arterial resection is uncommon, because the reconstruction requires microvascular techniques<sup>[1-3]</sup> and major complications may occur<sup>[4,5]</sup>. Arterioportal shunting has reported as an alternative to microvascular reconstruction<sup>[6,7]</sup>. However, this approach also requires vascular reconstruction and could cause an occlusion. We herein report the use of stepwise arterial embolization as another alternative to microvascular reconstruction and arterioportal shunting after performing a hepatic arterial resection.

### CASE REPORT

A 57-year-old female patient underwent a right

**Figure 1** A CT during hepatic angiography showing a recurrent tumor with extensive invasion to the proper HA.

**Figure 2** An angiogram of the celiac artery showing the proper and right arterial encasements (arrows) (A) and PRHA embolized with coils (B).

colectomy for ascending colon cancer in March, 2001. In January, 2003, liver metastasis was noted in the left medial segment (Couinaud's Segment 4; S4). She underwent a partial hepatectomy and ligation of the gastroduodenal and right gastric arteries for hepatic arterial infusion. In September, 2004, a recurrence in S4 was identified and a partial hepatectomy was carried out again. In September, 2005, a metastatic tumor appeared in S4 again and radiofrequency ablation therapy was performed.

In April, 2006, a recurrent tumor was noted around the proper HA with invasion to the left hepatic duct and the proper and right HAs (Figure 1). After 5 mo of continuing chemotherapy, we decided to perform a radical resection since no tumor progression or other metastatic lesions were observed. For the radical resection, left hepatectomy and proper hepatic arterial resection were needed. To avoid surgery-related liver failure, we tried to form collateral hepatic arteries after stepwise arterial embolization of the HA. At first, the posterior right hepatic artery (PRHA) was embolized with interlocking detachable coils (IDC) and fibered platinum coils (FPC; Boston Scientific, USA) (Figure 2). We placed seven IDC with their diameter ranging from 2 mm to 4 mm and length ranging from 4 cm to 8 cm, and 3 FPC (straight) measuring 5 mm in length. Two weeks later, the branches of the PRHA were enhanced from the branches of the anterior right hepatic artery (ARHA) (Figure 3). After the development of collateral arteries was confirmed in the right liver, the ARHA was embolized with IDC and FPC. We placed nine IDC, with their diameter ranging from 2 mm to 5 mm and length ranging from 4 cm to 6 cm, and 4 FPC (straight) measuring 5 mm in length. Finally, the proper HA was occluded with IDC after confirming the formation of collateral flow from the inferior phrenic artery (IPA) and the superior mesenteric artery (SMA)

**Figure 3** An embolized angiogram of the celiac artery 2 wk after enlargement of PRHA with its branches supplied from branches of the ARHA (arrow).

**Figure 4** An angiogram of the celiac artery after the proper HA embolized with coils showing the collateral pathways from IPA to the branches of PRHA (arrow) (A), and an angiogram of the SMA after the proper hepatic artery embolized with coils showing the collateral pathways from SMA to the branches of ARHA (arrow) (B).

was confirmed (Figure 4). We placed two IDC, 2 mm and 4 mm in diameter, 4 cm and 8 cm in length, respectively. After such embolization, the patient had no complications including hepatic dysfunction or liver abscess.

One month later, a left hepatectomy was performed with hepatic arterial resection. The tumor was located around the common, proper, anterior right and posterior right HA. Fortunately, the portal vein and bile duct were not resected because the tumor did not invade them. The operating time was 325 min. The operative blood loss was 1380 mL and no red blood cell transfusion was required. The serum concentration of aspartate aminotransferase and alanine aminotransferase one day after the operation was 381 U/L and 259 U/L, respectively, which returned to normal within 5 d. The maximum postoperative concentration of total serum bilirubin was 1.5  $\mu\text{mol/L}$ . Fourteen days after the operation, a biloma from the cut margin of the liver was noticed and treated with percutaneous drainage. Thereafter, it improved and the patient was discharged 30 d after the operation without major complications.

The tumor measured 3.0 cm  $\times$  2.5 cm  $\times$  4.0 cm (Figure 5A). Histological examination of the resected specimen revealed tumor invasion of the HA (Figure 5B). Neural invasion also was observed. The radial margin was free of tumor. The histological diagnosis was mucinous adenocarcinoma compatible with metastasis of colon cancer.

**Figure 5** Tumor around the proper HA showing the anterior and posterior right hepatic arterial stump (arrows) (A) and histology revealing direct invasion of the tumor into the vascular wall of proper HA (\*) (HE staining, x 200) with traces of the coils in vascular lumen (arrow) (B).

## DISCUSSION

Because hilar tumor approximates the HA, it easily spreads to it. It is necessary to excise the tumor with negative margins to cure it. A concomitant vascular resection could be employed whenever the tumor invades the HA supplying the remnant liver. It is necessary to preserve the hepatic arterial flow, as an interruption of the arterial flow can cause major complications, such as liver failure and liver abscess<sup>[8,9]</sup>. It was reported that arterial reconstruction using a microvascular anastomosis is useful<sup>[1-3]</sup>. However, the approach is difficult in cases in which the arterial diameter is small due to with multiple arterial stumps or the deep operative field is deep<sup>[4]</sup>. As an alternative, an arteriportal shunt has been reported with favorable results<sup>[6,7]</sup>. This procedure also requires vascular reconstruction with the possibility of fatal complications, including occlusion, aneurysm, or dissection<sup>[4-7]</sup>.

Stepwise hepatic arterial embolization does not require a vascular surgical procedure, can eliminate the possibility of the above complications and decrease the complexity of the surgical procedure and the operating time. In addition, it makes possible to perform an en bloc resection of the tumor and lymph nodes around the proper and common HA. If an extra-hepatic bile duct resection with removal of the HA can sufficiently eradicate the tumor, an extensive hepatectomy would be unnecessary. Therefore, in regard to safety and potential cure, this approach is acceptable for a hilar tumor with hepatic arterial invasion.

Wachsberg *et al.*<sup>[10]</sup> reported a case in which liver necrosis occurred after the right HA was occluded. It was reported that in most patients who undergo angiography within 1 or 2 wk after hepatic arterial ligation, collateral arteries are present and subsequent angiograms show progressive enlargement<sup>[11]</sup>. We scheduled embolization of the PRHA, ARHA, and proper HA at 2 week intervals. As a result, collateral pathways from ARHA to PRHA, IPA to PRHA, and SMA to ARHA were formed without complication.

This procedure also has some limitations. For example, whether collateral arteries form as expected. Takeuchi *et al.*<sup>[12]</sup> reported that almost all patients have an extra-hepatic arterial supply from the IPA and SMA. Since intersegmental hepatic collateral arteries are formed after hepatic arterial embolization<sup>[13]</sup>, collateral vessels should form as expected. However, if no collateral vessels are formed, an arteriportal shunt may be required.

Though this case involved a metastatic tumor, almost all cases of hilar tumor are associated with biliary cancer. Usually, the bile duct is excised and a bilioenteric anastomosis is performed. In the case of stepwise hepatic arterial embolization, the bile duct stump lacks of arterial blood flow *via* the hepatoduodenal ligament and is only supplied from collateral arteries through the liver. An impairment of the blood supply to the bile duct stump could cause disruption of the bilioenteric anastomosis. However, Plengvanit *et al.*<sup>[11]</sup> showed that collateral vessels enter the liver peripherally after ligation of HA, and the blood fills the branches of HA to the occluded portion in a retrograde fashion. It is presumed that a breakdown of the bilioenteric anastomosis does not occur because sufficient arterial blood flow can reach the bile duct stump *via* the intrahepatic shunts which mainly come from the IPA. Because the left and right IPA contact the bare area of the liver segments 1, 2, and 7<sup>[14]</sup>, this method is useful not only for the left trisegmentectomy with resection of the right hepatic artery but also for the right trisegmentectomy with resection of the left hepatic artery.

In conclusion, stepwise hepatic arterial embolization is one of the useful methods for performing resection of locally advanced hilar tumor invading HA, although the safety of the procedure needs to be confirmed in other cases.

### INTRODUCTION

Ischemic colitis, an acute abdominal disease, is caused by various predisposing factors. Although patients with connective tissue disorders, such as systemic lupus erythematosus (SLE), are at risk for various forms of colonic ischemia due to impairment of small vessel circulation to the large bowel caused by widespread vasculitis, ischemic colitis is an uncommon gastrointestinal complication in patients with SLE<sup>[1-8]</sup>. We report a case of ischemic colitis associated with intestinal vasculitis and presented with increased SLE activity.

### CASE REPORT

A 32-year-old male with a history of SLE was admitted to our department due to a two-day history of abdominal pain and bloody stool. He was diagnosed as having SLE. He had received cyclophosphamide and steroid, had been in clinical remission since last 13 mo. At 3 mo before admission, immunologic tests showed stable SLE disease activity. On the day of admission, the vital signs were normal except for body temperature of 37.8°C. Physical examination revealed mild tenderness of the left lower abdomen but no peritoneal signs or organomegaly. Initial laboratory test results were as follows: white blood cell count,  $8.7 \times 10^9/L$  (normal,  $4.5 \times 10^9/L$ - $10.5 \times 10^9/L$ ); hemoglobin, 14.7 g/dL; platelet count,  $195 \times 10^9/L$  (normal,  $150 \times 10^9/L$ - $350 \times 10^9/L$ ); blood urea nitrogen, 27 mg/dL; creatinine, 1.1 mg/dL. The results of electrolytes and coagulation were normal. Immunologic test showed increased activity of SLE: ESR, 48 mm/h (normal, 0-20 mm/h); CRP, 6.79 mg/dL (normal, 0-0.3 mg/dL); antinuclear antibody (ANA), a titer of 1:200 (normal, < 1:50); C3, 108 mg/dL (normal, 84-151 mg/dL); C4, 23 mg/dL (normal, 17-40 mg/dL), antiphospholipid antibody, 2.0 U/mL (normal, < 10 U/mL); anti-Smith antibody, positive; anti-double stranded DNA antibody, 43.91 IU/mL (normal, < 5.30 IU/mL). Flexible sigmoidoscopy demonstrated severe inflammation of the mucosa extending from rectosigmoid junction to the splenic

### Abstract

Ischemic colitis is an uncommon complication in patients with systemic lupus erythematosus (SLE). In previously reported cases of colitis caused by SLE, intestinal vasculitis is implicated as the causative process, but is rarely confirmed histologically. We described a case of a 32-year-old man with increased activity of SLE, who presented with hematochezia and abdominal pain due to ischemic colitis with small vessel vasculitis which was proven by sigmoidoscopic biopsy. The clinical course of the patient was improved after steroid and conservative management.

**Figure 2** Microscopy of colon biopsies shows the thickening of small vessel wall and lymphocyte infiltration around vessels (HE, x 400).

flexure, with contact bleeding and irregularly shaped ulceration (Figure 1). Rectum appeared relatively free from disease. Biopsy specimens from the sigmoid colon revealed inflammatory cell infiltration and hemorrhage in the mucosa, and small vessel wall thickening with lymphocyte infiltration, and vasculitis was considered (Figure 2). An ischemic colitis with increased SLE activity was confirmed and conservative management was done with fluids, intravenous antibiotics and intravenous steroid therapy. Clinical improvement was observed over the next three days, with stopped bloody stool and loss of abdominal pain. On the seventh day, follow-up flexible sigmoidoscopy demonstrated marked improvement of inflammation and ulceration in the sigmoid colon. On the ninth day, the patient was discharged.

## DISCUSSION

The development of ischemic colitis in patients with SLE is an uncommon complication<sup>[1-8]</sup>. But widespread fibrinoid vasculitis, typical of SLE, is thought to be a likely predisposing factor<sup>[1]</sup>. If this vasculitis involves the colon, ischemic colitis occurs. Gastrointestinal vasculitis is one of the most serious complications of SLE, even though the occurrence of colonic lesions is rare (0.2%)<sup>[4-6]</sup>. The gastrointestinal vasculitis of SLE is consequence of tissue damage from vasculopathy mediated by immune complexes, and has been associated with SLE activity<sup>[4,5]</sup>.

There are no pathognomic and histopathologic findings in SLE; however, pathologic changes associated with gastrointestinal vasculitis occur in the small vessels of the intestinal wall rather than in medium-sized mesenteric arteries<sup>[4,6]</sup>. Ischemic colitis in patients with SLE is caused by decreased blood perfusion of mesenteric vasculatures. The predisposing factors are embolism, thrombosis, vasospasm, drugs (steroids and immunosuppressive agents), vasculitis, performed colonoscopy, and enema<sup>[1,7,8]</sup>. Management of abdominal manifestations of SLE, in the absence of compelling radiographic or clinical findings suggestive of infarction or perforation, are steroid, antibiotics, and fluid therapy<sup>[2]</sup>.

The present case reveals ischemic change of edematous, erythematous mucosa and ulcerations with normal mucosa except for lesions on flexible sigmoidoscopy<sup>[9,10]</sup>. Even though the patient has received immunosuppressive agents, he had stable disease activity during last 13 mo without using immunosuppressant or steroid and no procedure, such as colonoscopy or enema has been performed. Comparing with previous laboratory findings, several tests concerned with SLE disease activity demonstrated increased activity; elevated ESR, elevated CRP, positive antinuclear antibody, elevated anti-double strand DNA antibody. Under this condition, we could diagnose ischemic colitis associated with increased SLE activity and vasculitis by histopathology. Generally, a typical pattern of vasculitis is quite difficult to prove by endoscopic biopsy<sup>[11]</sup>. Therefore, some literature used the term "lupus enteritis" rather than "gastrointestinal vasculitis" in SLE patients<sup>[5]</sup>.

In conclusion, the present case is ischemic colitis associated with intestinal vasculitis and increased SLE activity, and the patient showed clinical improvement with steroid and conservative treatment. In fact, there is no simple gauge to assess the extent and degree of intestinal ischemia<sup>[2]</sup>. However, if there are abdominal manifestations, such as pain or bloody stool in patients with active SLE, ischemic colitis should be considered and suspected.

## Abstract

Ascites is not an uncommon manifestation of certain solid tumors like gastrointestinal malignancies, ovarian cancer and breast cancer. However, it is unusual to encounter ascites in patients with hematological malignancies especially chronic leukemia. The patient described here presented with massive ascites and blood lymphocytosis. Further studies confirmed the diagnosis of chronic lymphocytic leukemia with ascites. The ascitic fluid was exudative, consisting of mature-looking B-lymphocytes, which were morphologically and immunophenotypically similar to peripheral blood and bone marrow cells. The patient was treated with chemotherapy and achieved a good response and diminution of ascitic fluid accumulation.

## INTRODUCTION

Chronic lymphocytic leukemia (CLL) is the most common hematological malignancy in the elderly. The disease is often indolent or slowly progressive. Approximately 40% of the patients are asymptomatic in the initial stages and the diagnosis is first made on the basis of a complete blood count when more than  $5 \times 10^9/L$  lymphocytes are found on differential white cell count and confirmed by a characteristic immunophenotyping pattern of peripheral blood or bone marrow lymphocytes. The common clinical features of the disease are lymphadenopathy, hepatosplenomegaly, malaise and weight loss. Bacterial infections, most often pneumonias, are fairly common in these patients. Less common complications are infiltration of various organs and transformation of the leukemia into other hematological malignancies. Ascites, however, is very rare in CLL patients particularly at the time of initial diagnosis. Development of ascites in CLL has been described at the time of relapse or transformation into prolymphocytic leukemia or Richter's syndrome<sup>[1-3]</sup>. It was only once reported as an initial manifestation of the disease and also as a case of chylous ascites<sup>[4]</sup>.

## CASE REPORT

A 75-year-old man was referred to our institute in March 2004 because of progressively increasing abdominal distension over a four-month period. More recently, he had also noticed weight loss, fatigue and night sweats. There was no history of change in bowel or bladder function, use of tobacco or alcohol. There was no history of diabetes mellitus, hypertension or heart disease. He had never required hospitalization prior to this admission.

Physical examination revealed an elderly man in obvious discomfort due to abdominal distension. He had generalized symmetrical lymphadenopathy including bilateral cervical, axillary and inguinal lymph nodes. There was minimal peripheral edema. His abdomen was protuberant with bulging flanks and a positive fluid thrill. There was no hepatosplenomegaly and no stigmata of chronic liver disease.

On admission, his complete blood count revealed a white blood cell count of  $45.2 \times 10^9/L$ , hemoglobin of 119 g/L, and platelet count of  $62 \times 10^9/L$ . The absolute lymphocyte count was  $33 \times 10^9/L$ . Peripheral blood smear examination showed lymphocytosis with

**Figure 1** Peripheral blood film showing lymphocytosis and several smear cells.

**Figure 2** Cytospin of ascitic fluid showing infiltration by a large number of small, mature looking lymphocytes (DQ staining,  $\times 400$ ).

mature lymphocytes and many smear cells (Figure 1). The lymphocytes were of variable small to medium size and most revealed round nuclei with some displaying nuclear irregularity. Prolymphocytes were only 8%. Flow cytometry performed on the peripheral blood showed the lymphocytes to be positive for CD5, CD19, CD20, CD23 and FMC7 and negative for CD10 and CD7. Bone marrow examination showed diffuse infiltration of the marrow with around 95% of the cells being lymphocytes. Many smear cells were seen. Normal hematopoiesis was markedly reduced. Cytogenetic studies did not reveal any chromosomal abnormalities. Serum protein electrophoresis disclosed low total protein with a normal percentage of albumin (56%). Serum immunoelectrophoresis revealed a decrease in both the serum IgG level (6.88 g/L; normal, 8-18) and IgM level (0.30 g/L; normal, 0.6-2.5).

His electrocardiogram was normal and a chest X-ray showed mediastinal lymphadenopathy. CT scan of the thorax and abdomen disclosed multiple enlarged lymph nodes in the axilla, mediastinum, abdomen and inguinal region. There was gross ascites with edema of the abdominal wall. Liver, spleen and the peritoneum appeared normal with no evidence of portal hypertension. At this stage, two liters of clear yellowish ascitic fluid was removed for symptomatic relief and laboratory analysis. Biochemistry of the ascitic fluid revealed the total protein was high, 13 g/L, and glucose

**Figure 3** A: Lymph node section in low power showing total effacement of normal architecture (HE staining,  $\times 40$ ); B: Lymph node section in higher power showing infiltration with small lymphocytes (HE staining,  $\times 400$ ).

and lactate dehydrogenase were normal. Thus, the fluid was exudative with a low serum ascitic albumin gradient. On microscopic evaluation, it was a highly cellular specimen consisting of numerous non-cohesive, small monomorphic lymphoid cells containing hyperchromatic nuclei with coarsely granular chromatin and mesothelial cells seen in the background (Figure 2). Morphological picture and immunophenotyping by flow cytometry of the ascitic fluid were consistent with small lymphocytic lymphoma/leukemia cells similar to blood and bone marrow. The gram-staining, culture and acid fast bacilli were negative.

Upper and lower gastrointestinal endoscopies were performed to rule out a coexisting gastrointestinal malignancy as a cause of ascites. The endoscopic findings along with serum  $\alpha$ -fetoprotein were normal. Hepatitis B and C studies were negative.

The lymph node biopsy showed total nodal effacement, with perinodal tumor infiltration and diffuse proliferation of small lymphoid cells (Figure 3). These cells were small and round with minimal degree of nuclear irregularity and scant cytoplasm. Several proliferating centers containing paraimmunoblasts were also present. These paraimmunoblasts were larger in size than the background lymphocytes having round nuclei with a vesicular chromatic pattern and medium to large nucleoli. These were found in aggregates that appeared pale and scattered in between the small lymphocytes.

Based on CD5/CD19 positive lymphocytosis, lymphadenopathy and thrombocytopenia, a diagnosis of chronic lymphocytic leukemia, Rai stage V was made<sup>[5]</sup>.

It was interesting to notice that the peripheral blood, bone marrow and ascitic fluid studies showed a clonal proliferation of mature lymphocytes.

In view of the above diagnosis, the patient was commenced on cyclophosphamide, vincristine and prednisolone (CVP) chemotherapy. He received three cycles of chemotherapy with a good response. His blood count normalized with disappearance of the lymph nodes and there was a remarkable reduction in the rate of accumulation of ascites. Unfortunately, after the third cycle of therapy, the patient failed to attend the oncology clinic (having had to travel more than 1000 kilometers on each occasion) and was lost to follow-up.

## DISCUSSION

In 1982, May and Costanzi reported a known case of CLL whose relapse was heralded by development of splenomegaly with massive ascites<sup>[6]</sup>. The ascitic fluid was a transudate with polymorphonuclear leukocytes and mononuclear cells. On cytopathology, there were no lymphocytes or abnormal cells. They attributed the cause of ascites to be periportal infiltration of the liver and marked infiltration of the spleen leading to portal hypertension. A similar case of portal hypertension caused by intra-hepatic block in CLL was later reported by Mouly<sup>[7]</sup>.

Clonal evolution is common in CLL during the course of the disease. This disease may convert to prolymphocytic leukemia, diffuse large-cell lymphoma or acute leukemia. "Prolymphocytoid" transformation of CLL is characterized by appearance of increasing number of large cells with irregular nuclei, i.e., prolymphocytes and development of hepatosplenomegaly. Ascites and pleural effusion have occasionally been described in this setting<sup>[2]</sup>. The ascitic fluid consists of prolymphocytes and is an exudate with low albumin gradient. Our patient had a very small population of prolymphocytes in the peripheral blood and none in the ascitic fluid, therefore transformation of CLL to "prolymphocytic leukemia" was not considered.

About 3%-10% cases of CLL may transform to diffuse large-cell lymphoma when it is called "Richter's syndrome". This is usually a terminal event with very poor prognosis. A few cases of ascites developing at the time of Richter's transformation have been described in the literature<sup>[3,8,9]</sup>. The ascitic fluid in these cases showed large blast-like lymphoma cells similar to the cells in the lymph node biopsy. In our patient, the ascitic fluid consisted of mostly small mature-looking lymphocytes consistent with CLL and not diffuses large cell lymphoma or acute leukemia.

Other possible causes of ascites which could be related to CLL are infection leading to subacute bacterial peritonitis, another malignancy or portal hypertension. Although patients with CLL are at high risk of infection, in this patient there was no evidence of a specific organism causing bacterial peritonitis, nor was there any indication of tuberculous peritonitis. There have

been some reports of increased incidence of second solid tumors in patients with CLL. Carcinoma of gastrointestinal tract and lung were ruled out in our patient by normal results of endoscopies and CT scans. Since serum  $\alpha$ -fetoprotein was normal and there was no hepatic lesion on CT, hepatocellular carcinoma was also unlikely as a cause of ascites in this patient. The remaining differential diagnosis in this patient may be hepatic cirrhosis, heart failure, or renal disease. However, all of these possibilities were systematically screened and excluded.

In conclusion, the patient described here had an unusual presentation of CLL. The ascitic fluid consisted of mature B-cell type lymphocytes, morphologically and immunophenotypically similar to the peripheral blood and bone marrow cells. The mechanism of ascites in this case can only be speculated. It is possible that despite the normal radiological studies, there may be microscopic peritoneal deposition by leukemia cells or portal system lymphatic obstruction due to extensive lymphatic infiltration. The fact that the ascitic fluid was sterile and most of the cells were mature lymphocytes, like in the blood, suggests that the ascites in this patient was due to infiltration of the peritoneum and was malignant ascites not significantly different from that found in solid tumors. A liver biopsy in this case might have been helpful in confirming a normal histology but it was not done as it was not indicated in the opinion of the managing team. It is interesting to note that there was a good response to chemotherapy with marked reduction in ascites. Unfortunately, nothing further can be commented in this regard because of the lack of follow-up after three cycles of chemotherapy. In view of the continued increase in the number of cases diagnosed with CLL, a greater awareness of the possibility of development of ascites as a presenting manifestation of this disease may be beneficial to the physicians caring for patients with ascites.

## INTRODUCTION

Gastric varices have been increasingly recognized as a major cause of gastrointestinal bleeding in patients with portal hypertension. Compared with esophageal variceal bleeding, hemorrhage caused by gastric varices is usually more severe and hemostatic control is reported to be more difficult<sup>[1]</sup>.

Management for gastric varices usually include vasoactive agents, endoscopic therapy and surgery<sup>[2]</sup>. Rupture of gastric fundal varices is often lethal because of massive bleeding<sup>[3,4]</sup>. Three-channel double-balloon catheter might be ineffective for gastric fundal varices when acute bleeding occurs. Endoscopic injection with tissue adhesives such as histoacryl can effectively control active bleeding<sup>[5,6]</sup>. However, gastric varices cannot disappear due to the unsatisfactory control of inflammation and fibrous organization caused by adhesives. Although endoscopic variceal ligation therapy (EVL) has shown its benefit for esophageal varices, it cannot achieve a similar success in the management of gastric varices<sup>[6]</sup>. It was reported that balloon retrograde transvenous obliteration (B-RTO) is a useful treatment for gastric fundal varices, but it requires a gastroduodenal shunt as the draining vein<sup>[7]</sup>. We report two cases of marked gastric varices with no gastroduodenal shunt, who were successfully treated with endoscopic therapy with combined adhesives and sclerosants.

## Abstract

Two patients with liver cirrhosis and portal hypertension related to hepatitis infection were admitted to Shanghai Ruijin Hospital due to recurrent melena and hematemesis. Isolated gastric varices were observed in the gastric fundus during the retroflexion of gastroscopy. We carried out endoscopic sclerotherapy successfully for bleeding gastric varices with combined cyanoacrylate and aethoxysklerol, which disappeared dramatically several months after two courses of sclerotherapy for each patient. No complication and clinical signs of gastrointestinal re-bleeding were observed during the 6-mo endoscopic follow-up. CT portal angiography (CTPA) has been widely used in the assessment of variceal treatment and improves the results of endoscopic injection therapy.

Shi B, Wu W, Zhu H, Wu YL. Successful endoscopic sclerotherapy for bleeding gastric varices with combined

## CASE REPORT

Patient one was a 69-year-old male suffering from recurrent melena for 3 mo. He had a 20-year history of hepatitis B virus (HBV) infection and a 8-year history of hepatitis C virus (HCV) infection and was diagnosed having viral liver cirrhosis and portal hypertension two years ago. His Child-Pugh was class B. Patient two was a 61-year-old female with liver cirrhosis and portal hypertension. She was admitted to the gastroenterology ward due to the onset of hematemesis. Her Child-Pugh was class A. Upper gastrointestinal (GI) endoscopy

**Figure 1** Subsequent chest X-ray on the 69-year-old male demonstrating marked retention of the cyanoacrylate/lipiodol mixture within the variceal bed in gastric fundus (arrow) (A), CTPA-reconstructed image showing abundant portal venous collaterals with no gastroduodenal shunt and gastric fundal varices (arrow) communicating with the confluence through the left gastric vein (B) and shrinkage of gastric fundal varices and deposition of cyanoacrylate/lipiodol mixture (arrow), blocking the draining veins (C) after sclerotherapy.

showed massive isolated gastric varices of the gastric fundus with red flat spots on their surface in both patients. No esophageal varices were observed. CTPA revealed dilated portal vein and tortuous splenic vein in both patients while gastric fundal varices were noticed to communicate with the confluence through the left gastric vein. No evidence of gastroduodenal shunt was shown. Written informed consent was obtained from the two patients before endoscopic sclerotherapy.

Both patients received endoscopic injection sclerotherapy with combined cyanoacrylate and aethoxysklerol. Routine preparation was carried out and anti-foam agent, simethicone, was administered 20 min before endoscopy. An intravenous infusion of somatostatin at 250 µg/h was performed 2 h before and 72 h after the therapy. The endoscopic therapy procedure required a retroflex view for variceal visualization. During the treatment, 10 mL of 1% aethoxysklerol (Polidocanol, Germany) was injected into the varix followed by conventional endoscopic injection sclerotherapy with a mixture of 1.5 mL  $\alpha$ -cyanoacrylate alkyl (Compoint, China) and 1.5 mL iodinated oil (Lipiodol, French). When no active bleeding or oozing of the varix occurred, the procedure was terminated.

Both patients tolerated the procedure well with no immediate complication. Subsequent chest X-ray one day after sclerotherapy demonstrated a marked collection of cyanoacrylate/lipiodol mixture within the variceal bed in the gastric fundus, but no sign of ectopic infarction. CTPA 3 wk after sclerotherapy showed shrinkage of gastric fundal varices and deposition of cyanoacrylate/lipiodol mixture blocking the draining veins (Figure 1). A repeated sclerotherapy was performed 3 wk later. A 6-mo endoscopic follow-up after the second treatment revealed dramatic disappearance of gastric varices in both patients (Figure 2). The two patients were free from re-bleeding after the last endoscopic treatment.

## DISCUSSION

The incidence of gastric variceal bleeding is lower than that of esophageal varices. However, rupture of gastric

varices usually results in more severe hemorrhage and a higher mortality<sup>[1]</sup>.

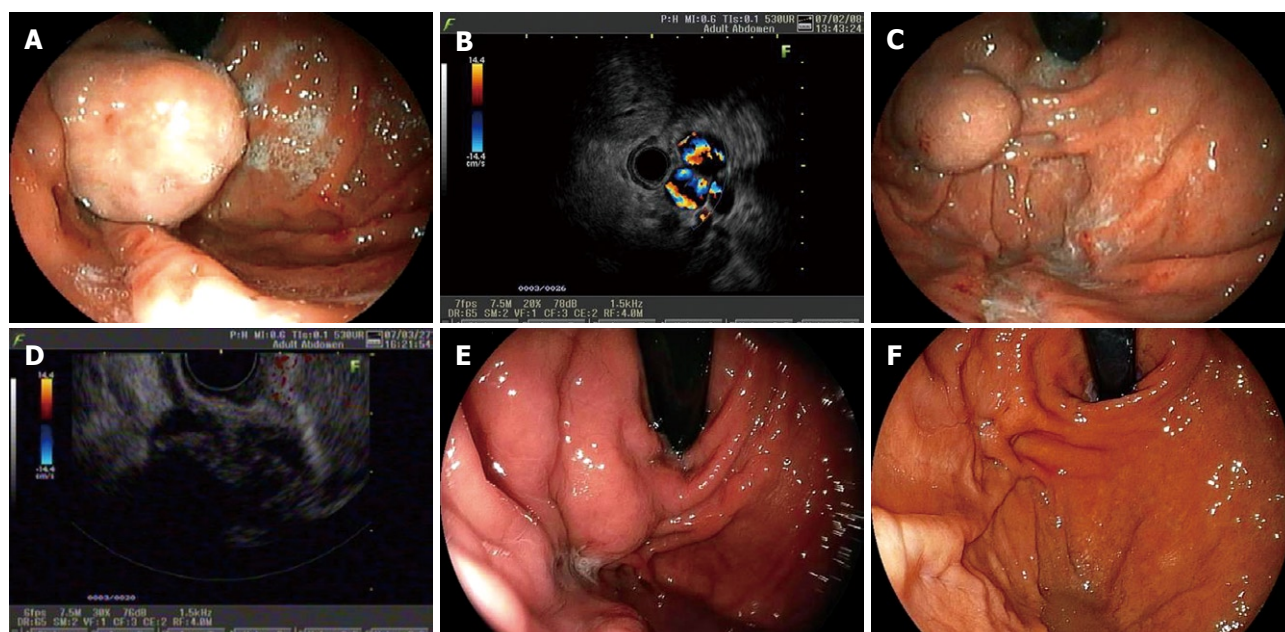

Since the description of experience with the use of cyanoacrylate compounds in endoscopic treatment of gastric varices in an experimental dog model in 1975<sup>[8]</sup>, adhesives such as N-butyl-2-cyanoacrylate (histoacryl) have been proved safe and efficient in the treatment of active bleeding of gastric varices. N-butyl-2-cyanoacrylate has not been approved for its use in treatment of variceal bleeding by China State Food and Drug Administration (SFDA). In our cases,  $\alpha$ -cyanoacrylate alkyl, an analogue of N-butyl-2-cyanoacrylate approved by SFDA, showed a similar pharmaceutical effect to N-butyl-2-cyanoacrylate. The adhesive polymer, an unabsorbable foreign body in the bed of varices after injection, could block the ruptured vein yet had a weak effect on promoting organization of the veins. Ulceration may occur and the polymer extrudes from the vessel bed several weeks after injection, during which fatal re-bleeding may occur<sup>[9]</sup>. The similar extrusion process was performed for the 69-year-old male patient during the endoscopic follow-up period (Figure 3).

Polidocanol is a well-accepted sclerosant for obliteration of gastric varices. It can produce significant thrombosis, inflammatory reaction and fibrous degeneration, thus finally eliminating the varices. Though sclerosing agents are widely used in the treatment of esophageal varices, they are far less promising for the treatment of gastric varices<sup>[10,11]</sup>. In Japan, ethanolamine oleate (EO) remains the first choice of sclerotherapeutic agents for eradicating esophageal varices, yet it has not been greatly used in the management of gastric varices. Oho and colleagues<sup>[12]</sup> reported that the rate of initial hemostasis is significantly lower in patients with bleeding gastric varices treated with EO than in those treated with butyl cyanoacrylate.

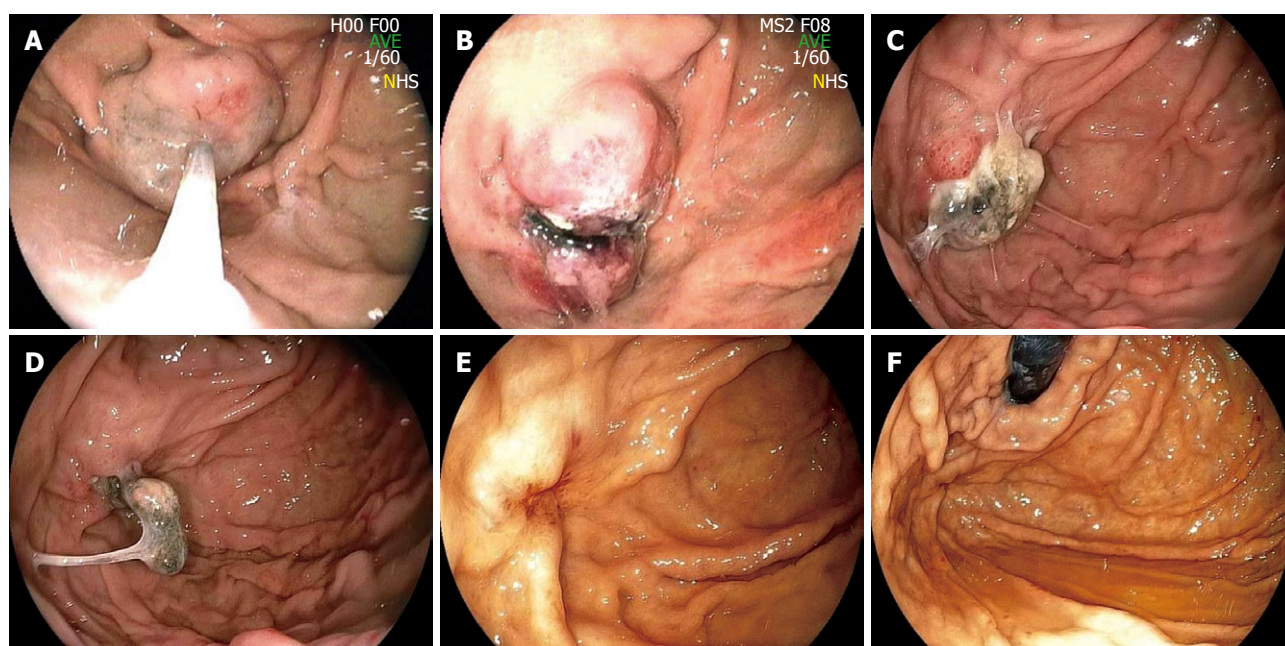

In our cases, the effect of  $\alpha$ -cyanoacrylate alkyl and aethoxysklerol on gastric varices was satisfactory and their gastric varices disappeared six months after treatment.

Rare but serious complications of endoscopic sclerotherapy may include cerebral stroke, pulmonary

**Figure 2** Endoscopy showing isolated gastric varices in gastric fundus (A) and abundant blood flow (B) in gastric varices before treatment, and shrinkage of gastric varices (C) and no blood flow signals (D), flat gastric varices with slight red spots on the top (E), and eradication of gastric varices (F) in the 69-year-old male patient after treatment.

**Figure 3** Endoscopic findings after the first injection treatment with combined cyanoacrylate and aethoxysklerol (A), an marked ulcer noticed on the surface of varices 3 d after the first injection with no stigmata bleeding (B), an adhesive extrusion process 3 wk after the initial treatment (C), adhesive found on the surface of flat gastric varices 3 wk after the secondary injection (D), disappearance of the former massive gastric varices three and a half months after the secondary injection (E, F).

embolism, portal vein embolism and splenic infarction<sup>[13,14]</sup>. Gastric varices are characterized by an enlarged caliber of the vessel bed, large draining veins and rapid blood flow, which may exacerbate the situation. Fortunately, no complication was found in these two patients.

After sclerotherapy, both patients were given antacids to suppress the secretion of gastric acid, thus protecting the gastric mucosa and promoting the healing of ulcer. The dosage of rabeprazole, a proton-pump inhibitor,

may be increased to 20 mg once a day per oral depending on the severity of ulcer on the surface of varices. Meanwhile, the patients were given propranolol and isosorbide mononitrate to reduce their portal pressure. After sclerotherapy, re-bleeding, especially during the process of adhesive extrusion, should be prevented.

CTPA can serve as an important supplement and an alternative technique for gastric varices. It can be applied in choosing appropriate candidates, evaluating and following up patients with gastric varices<sup>[15]</sup>. We detected

the varices and made assessments of portosystemic collaterals through CTPA before sclerotherapy, which demonstrated the afferent and efferent vessels of gastric varices. Willmann and colleagues<sup>[16]</sup> demonstrated that CTPA is able to differentiate between submucosal and perigastric fundal varices, which is of paramount interest since only the former may cause gastrointestinal hemorrhage. CTPA revealed the vessels blocked by adhesive polymer, obliteration and elimination of gastric varices, suggesting that injection of adhesives in combination with sclerosants is an effective treatment modality for gastric varices.

In conclusion, although the optimal treatment for gastric fundal variceal bleeding remains controversial, sclerotherapy with combined  $\alpha$ -cyanoacrylate alkyl and aethoxysklerol is an alternative and feasible treatment modality for gastric fundal varices.

### Abstract

Bombesin and neurotensin are neuropeptides which exert a wide spectrum of biological actions on gastrointestinal tissues influencing intestinal growth and adaptation, intestinal motility, blood flow, secretion, nutrient absorption and immune response. Based mainly on their well-established potent enterotrophic effect, numerous experimental studies investigated their potential positive effect on the atrophic or injured intestinal mucosa. These peptides proved to be effective mucosa-healing factors, but the potential molecular and cellular mechanisms for this action remained unresolved. In a recently published study (*World J Gastroenterol* 2008; 14(8): 1222-1230), it was shown that their protective effect on the intestine in experimentally induced inflammatory bowel disease was related to anti-inflammatory, antioxidant and antiapoptotic actions. These results are in close agreement with our previous studies on jaundiced and hepatectomized rats that showed a regulatory effect of bombesin and neurotensin on critical cellular processes such as enterocyte proliferation and death, oxidative stress and redox equilibrium, tight junctions' formation and function, and inflammatory response. The pleiotropic effects of bombesin and neurotensin on diverse types of intestinal injury may justify their consideration for clinical trials.

### TO THE EDITOR

We read with great interest the recently published article (*World J Gastroenterol* 2008; 14(8): 1222-1230) by Dr. Akcan and colleagues<sup>[1]</sup>, on the effect of neuropeptides Bombesin (BBS) and Neurotensin (NTS) on trinitrobenzene sulphonic acid-induced colitis in rats, an experimental model of colonic inflammatory bowel disease. In this nice set of experiments, the authors demonstrated the beneficial effects of both BBS and NTS on the preservation of intestinal macroscopic and microscopic integrity in experimental colitis. Most importantly, it was shown that this positive effect on the intestinal mucosa was related to anti-inflammatory, antioxidant and antiapoptotic actions.

It has been two decades since the issue of the potential beneficial role of BBS and NTS on preservation of intestinal homeostasis arose, based on peptides' well-established potent enterotrophic effect<sup>[2,3]</sup>. Up to now, numerous experimental studies have demonstrated the protective effect of BBS and NTS against diverse types of intestinal injury, such as administration of elemental diets or methotrexate, induction of chemical colitis, burns, radiation therapy, ischemia/reperfusion and small bowel resection<sup>[3-9]</sup>. However, the molecular and cellular mechanisms implicated in their intestinal mucosa-healing effect remained unresolved for a long period. Our recent studies with jaundiced and hepatectomized rats showed

that BBS and NT exert regulatory effects on critical cellular processes of enterocytes such as proliferation and death, oxidative stress, redox equilibrium, tight junctions' formation and function, and inflammatory response<sup>[10-13]</sup>. The results presented in this study by Dr. Akcan *et al* are in close agreement with those previously reported by us and add further support to the hypothesis of a multifactorial mode of action of BBS and NT on the intestinal mucosa, beyond their trophic effect. The pleiotropic (mitogenic, antioxidant, antiapoptotic, anti-inflammatory and tight-junction modulating) effects of BBS and NT on intestinal mucosa and the wide range of intestinal injuries that could be healed or prevented by these peptides render BBS and NTS potential pivotal "gut-regulatory peptides" for many intestinal diseases. Although the authors very precisely state that the results of laboratory experiments are not readily applicable to the clinical situation, we feel that there is already a substantial experimental body of evidence supporting their consideration for clinical trials.

### Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

## Instructions to authors

### GENERAL INFORMATION

*World Journal of Gastroenterology* (*World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly open access peer-reviewed journal supported by an editorial board consisting of 1215 experts in gastroenterology and hepatology from 60 countries. The aim of the journal is to deliver the most clinically relevant original and commentary articles to readers, and to make the full text publicly available to all clinicians, scientists, patients and biomedical students on an unrestricted platform, so that they can access and learn about the most recent key advances in the field.

In addition to the open access nature, another key characteristic of *WJG* is its reading guidance for each article which includes background, research frontier, related reports, breakthroughs, applications, terminology, and comments of peer reviewers for the general readers.

*WJG* publishes articles on esophageal, gastrointestinal, hepatobiliary and pancreatic tumors, and other esophageal, gastrointestinal, hepatic-biliary and pancreatic diseases in relation to epidemiology, immunology, microbiology, motility & nerve-gut interaction, endocrinology, nutrition & obesity, endoscopy, imaging and advanced hi-technology.

The main goal of *WJG* is to publish high quality commentary articles contributed by leading experts in gastroenterology and hepatology and original articles that combine the clinical practice and advanced basic research, to provide an interactive platform for clinicians and researchers in internal medicine, surgery, infectious diseases, traditional Chinese medicine, oncology, integrated Chinese and Western medicine, imaging, endoscopy, interventional therapy, pathology and other basic medical specialties, and thus eventually improving the clinical practice and healthcare for patients.

### Indexed and abstracted in

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/Science Edition, Index Medicus, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

### Published by

The WJG Press

### SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

### Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://wjg.wjgnet.com>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to [submission@wjgnet.com](mailto:submission@wjgnet.com), or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

### MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

#### Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was carried out; author contributions; disclosure of any financial support for the research; and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (remove all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s), and full family name.

**Author contributions:** The format of this section should be like this: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed research; Wang CL, Zou CC, Hong F and Wu XM performed research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed data; and Wang CL, Liang L and Fu JF wrote the paper.

**Peer reviewers:** All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

#### Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipment, and the experimental procedures should be included. RESULTS: The observed and experimental results, including data, effects, outcome, *etc.* should be included. Authors should present *P* value where necessary, and also include any significant data. CONCLUSION: Accurate view and the value of the results should be included.

The format for structured abstracts can be found at: <http://www.wjgnet.com/wjg/help/11.doc>.

#### Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

#### Text

For articles of these sections, original articles, rapid communication

and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, should be found at: <http://www.wjgnet.com/wjg/help/instructions.jsp>.

### Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ... *etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

### Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

### Notes in tables and illustrations

Data that are not statistically significant should not be noted. <sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01 should be noted (*P* > 0.05 should not be noted). If there are other series of *P* values, <sup>c</sup>*P* < 0.05 and <sup>d</sup>*P* < 0.01 are used. A third series of *P* values can be expressed as <sup>e</sup>*P* < 0.05 and <sup>f</sup>*P* < 0.01. Other notes in tables or under illustrations should be expressed as <sup>1</sup>F, <sup>2</sup>F, <sup>3</sup>F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

### Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

## REFERENCES

### Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability<sup>[1,2]</sup>". If references are cited directly in the text, they should be put together within the text, for example, "From references<sup>[19,22-24]</sup>, we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

### PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information for journal citations is very important. Using the reference testing system, the authors and editor should check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in an ASP file so that the readers can immediately access the abstract of the citations online.

### DOI requirement

A CrossRef DOI® (Digital Object Identifier) name is a unique string created to identify a piece of scholarly content in the online environment. The author should supply the DOIs for journal citation (doi:10.3748/wjg.13.6458). This link (<http://www.crossref.org/SimpleTextQuery/>) allows you to retrieve Digital Object Identifiers (DOIs) for journal articles, books, and chapters by simply cutting and pasting the reference list into the box. You may use the form with any reference style, although the tool works most reliably if references are formatted in a standard style such as shown in this example: Assimakopoulos SF, Scopa CD, Vagianos CE. Pathophysiology of increased intestinal permeability in obstructive jaundice. *World J Gastroenterol* 2007; 13(48): 6458-6464

The accuracy of the information of journal citations is very important. We will interlink all references with DOI in ASP file so that readers can access the abstracts of cited articles online immediately.

### Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

### Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

## Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those linked with a hyphen when the difference between the two numbers is greater than five. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered inappropriate references. Authors should not cite their own unrelated published articles.

## Statistical data

Write as mean  $\pm$  SD or mean  $\pm$  SE.

## Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as  $\chi^2$  (in Greek), related coefficient as *r* (in italics), degree of freedom as *v* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

## Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4  $\pm$  2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5  $\mu$ g/L; CO<sub>2</sub> volume fraction, 50 mL/L CO<sub>2</sub>, not 5% CO<sub>2</sub>; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: <http://www.wjgnet.com/wjg/help/15.doc>.

## Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of

Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

## Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kho I*, *Kpn I*, etc.

Biology: *H pylori*, *E coli*, etc.

## SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

## Editorial Office

### World Journal of Gastroenterology

Editorial Department: Room 903

Ocean International Center, Building D

No. 62 Dongsihuan Zhonglu

Chaoyang District, Beijing 100025, China

E-mail: [wjg@wjgnet.com](mailto:wjg@wjgnet.com)

<http://www.wjgnet.com>

Telephone: +86-10-59080039

Fax: +86-10-85381893

## Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

## Copyright assignment form

Please download a Copyright assignment form from <http://www.wjgnet.com/wjg/help/9.doc>.

## Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: <http://www.wjgnet.com/wjg/help/10.doc>.

## Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

## Links to documents related to the manuscript

*WJG* will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

## Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

## Publication fee

Authors of accepted articles must pay a publication fee.

EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

# WJG

## World Journal of Gastroenterology®

### Indexed and Abstracted in:

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health.

## Contents

### EDITORIAL

- 3609 Minimal hepatic encephalopathy matters in daily life

*Bajaj JS*

- 3616 Cystic tumors of the liver: A practical approach

*Del Poggio P, Buonocore M*

### REVIEW

- 3621 Extended-therapy duration for chronic hepatitis C, genotype 1: The long and the short of it

*Pearlman BL*

- 3628 Is there a place for serum laminin determination in patients with liver disease and cancer?

*Rosa H, Parise ER*

### GASTRIC CANCER

- 3633 Adipokines and ghrelin in gastric cancer cachexia

*Kerem M, Ferahkose Z, Yilmaz UT, Pasaoglu H, Ofluoglu E, Bedirli A, Salman B, Sahin TT, Akin M*

### LIVER CANCER

- 3642 Secretory Transactivating Transcription-apoptin fusion protein induces apoptosis in hepatocellular carcinoma HepG2 cells

*Han SX, Ma JL, Lv Y, Huang C, Liang HH, Duan KM*

### CLINICAL RESEARCH

- 3650 Partial overlap of anti-mycobacterial, and anti-*Saccharomyces cerevisiae* mannan antibodies in Crohn's disease

*Müller S, Schaffer T, Schoepfer AM, Hilty A, Bodmer T, Seibold F*

- 3662 Methylenetetrahydrofolate reductase C677T genotype affects promoter methylation of tumor-specific genes in sporadic colorectal cancer through an interaction with folate/vitamin B<sub>12</sub> status

*Mokarram P, Naghibalhossaini F, Saberi Firoozi M, Hosseini SV, Izadpanah A, Salahi H, Malek-Hosseini SA, Talei A, Mojallal M*

### BASIC RESEARCH

- 3672 Ellagic acid induces apoptosis through inhibition of nuclear factor  $\kappa$ B in pancreatic cancer cells

*Edderkaoui M, Odinkova I, Ohno I, Gukovsky I, Go VLW, Pandol SJ, Gukovskaya AS*

Contents	World Journal of Gastroenterology Volume 14 Number 23 June 21, 2008
3681	<p>Experimental treatment of pancreatic cancer with two novel histone deacetylase inhibitors</p> <p><i>Haefner M, Bluethner T, Niederhagen M, Moebius C, Wittekind C, Mossner J, Caca K, Wiedmann M</i></p>
3693	<p>Negundoside, an irridiod glycoside from leaves of <i>Vitex negundo</i>, protects human liver cells against calcium-mediated toxicity induced by carbon tetrachloride</p> <p><i>Tasduq SA, Kaiser PJ, Gupta BD, Gupta VK, Johri RK</i></p>
3710	<p>Hepatitis B virus DNA is more powerful than HBeAg in predicting peripheral T-lymphocyte subpopulations in chronic HBV-infected individuals with normal liver function tests</p> <p><i>You J, Sriplung H, Geater A, Chongsuvivatwong V, Zhuang L, Chen HY, Huang JH, Tang BZ</i></p>

Bajaj JS. Minimal hepatic encephalopathy matters in daily life. *World J Gastroenterol* 2008; 14(23): 3609-3615 Available from: URL: <http://www.wjgnet.com/1007-9327/14/3609.asp> DOI: <http://dx.doi.org/10.3748/wjg.14.3609>

### Abstract

Minimal hepatic encephalopathy is a neuro-cognitive dysfunction which occurs in an epidemic proportion of cirrhotic patients, estimated as high as 80% of the population tested. It is characterized by a specific, complex cognitive dysfunction which is independent of sleep dysfunction or problems with overall intelligence. Although named “minimal”, minimal hepatic encephalopathy (MHE) can have a far-reaching impact on quality of life, ability to function in daily life and progression to overt hepatic encephalopathy. Importantly, MHE has a profound negative impact on the ability to drive a car and may be a significant factor behind motor vehicle accidents. A crucial aspect of the clinical care of MHE patients is their driving history, which is often ignored in routine care and can add a vital dimension to the overall disease assessment. Driving history should be an integral part of care in patients with MHE. The lack of specific signs and symptoms, the preserved communication skills and lack of insight make MHE a difficult condition to diagnose. Diagnostic strategies for MHE abound, but are usually limited by financial, normative or time constraints. Recent studies into the inhibitory control and critical flicker frequency tests are encouraging since these tests can increase the rates of MHE diagnosis without requiring a psychologist. Although testing for MHE and subsequent therapy is not standard of care at this time, it is important to consider this in cirrhotics in order to improve their ability to live their life to the fullest.

### INTRODUCTION

Minimal hepatic encephalopathy is a neuro-cognitive dysfunction which occurs in an epidemic proportion of cirrhotic patients, estimated as high as 80% of the population tested. It is characterized by a specific, complex cognitive dysfunction which is independent of sleep dysfunction or problems with overall intelligence<sup>[1]</sup>. Although named “minimal”, minimal hepatic encephalopathy (MHE) can have a far-reaching impact on quality of life, ability to function in daily life and progression to overt hepatic encephalopathy (OHE)<sup>[2]</sup>. Importantly, MHE has a profound negative impact on the ability to drive a car and may be a significant factor behind motor vehicle accidents. Research in this field is expanding rapidly, but little consensus has emerged regarding standard diagnostic strategies or therapeutic options<sup>[3]</sup>. The current editorial will focus on the relevance of MHE as an important clinical entity that is ready for evaluation and regular detection not only in research centers but in routine hepatology practice.

### PREVALENCE AND IMPORTANCE

With improving management of cirrhotic patients, including those with end-stage liver disease, the neuro-psychological care of these patients is being recognized as an unmet need<sup>[4-6]</sup>. The importance of MHE has been recognized by hepatologists worldwide and of late an explosion of research in this field has occurred<sup>[7,8]</sup>.

Since its first description in the 1970s, MHE has been diagnosed in several countries around the world at a rate of 30%-80%<sup>[9,10]</sup>. The European experience has shown a high prevalence of MHE in patients who are predominantly non-alcoholic and without any psychoactive drug use<sup>[11,12]</sup>. The diagnostic methodologies were a combination of neuro-psychometric and neuro-physiologic testing strategies<sup>[11-13]</sup>. In the United States, the rate of MHE in several research series has been reported to

be 60%-80%, again using a combination of psychometric and neuro-physiologic techniques<sup>[14,15]</sup>.

Experience in Asian countries, especially India, Japan and China, has reconfirmed the high prevalence using locally modified tools<sup>[10,16-22]</sup>. The diagnostic tools were adapted to the local language and to include illiterate subjects<sup>[17,19]</sup>. The patient population in these series has included a higher number of patients with viral hepatitis compared to Western series<sup>[21,22]</sup>.

## CHARACTERIZATION OF MINIMAL HEPATIC ENCEPHALOPATHY

The importance of MHE lies in its specific deficits. As outlined by Weissenborn *et al*, patients with MHE have defects in attention, vigilance and orientation<sup>[23]</sup>. These attention deficits in turn lead to learning impairment and difficulties in working memory<sup>[12,24]</sup>. Psychometric testing in patients with MHE has consistently demonstrated a preservation of overall IQ compared to age-matched controls, indicating that the defects are restricted to certain aspects only<sup>[11]</sup>. Patients with cirrhosis can also exhibit motor impairments that include Parkinsonian features and features of hepatic myelopathy<sup>[25,26]</sup>. However, these motor deficits are not included in the typical impairment seen in MHE.

Importantly, deficits in MHE do not extend to the verbal and communication spheres<sup>[11]</sup>. Similar to OHE patients, there is evidence that patients with MHE have poor insight into their psychometric impairments<sup>[27-29]</sup>. The preservation of communication skills, lack of symptoms and the poor insight make MHE patients a difficult group to identify with simple questioning in the office.

## CONTRIBUTION OF CONCOMITANT DISEASES TO MHE

Patients with specific etiologies of cirrhosis are more likely to exhibit psychometric impairment, specifically chronic hepatitis C. Investigations in the chronic hepatitis C infected groups (both with and without cirrhosis) show a worse psychometric performance compared to patients without chronic hepatitis C in selected studies<sup>[30-33]</sup>. However, other studies have not demonstrated a difference in psychometric performance of cirrhotics with chronic hepatitis C compared to those without it<sup>[30,34]</sup>. In addition, a recent detailed study before and after interferon therapy in chronic hepatitis C cirrhotics failed to find an improvement or deterioration during and after therapy completion<sup>[35]</sup>.

Diabetes mellitus is an important correlate of patients with cirrhosis, with the increasing importance of non-alcoholic steatohepatitis, and is also correlated with chronic hepatitis C in the general population<sup>[36]</sup>. Diabetes mellitus, possibly due to its adverse effect on gastrointestinal motility, has been associated with hepatic encephalopathy<sup>[34,37]</sup>.

Most studies of MHE exclude patients with alcoholic liver disease; therefore, excluding patients with chronic

hepatitis C and diabetes mellitus will seriously hinder the generalization of the study. Therefore, a subgroup analysis of chronic hepatitis C and diabetes mellitus within the cirrhosis group or regression adjustment would be necessary for MHE investigation.

## CONCOMITANT SLEEP DISTURBANCES

Hepatic encephalopathy is associated with adverse effects on the sleep-wake cycle, especially causing fragmentation of sleep, sleep deprivation and reports of drowsiness during the day<sup>[38]</sup>. Sleep deprivation *per se* can result in impaired psychometric test performance and as is evidenced in the case of obstructive sleep apnea, and can independently lead to poor driving outcomes<sup>[39]</sup>. There is debate whether the MHE-associated psychometric impairment is partly due to the inherent sleep-wake cycle disturbances in this condition. Validated sleep and quality of life questionnaire such as Sickness Impact Profile (SIP) sleep scales, Pittsburgh Sleep Quality index and Epworth Sleepiness scale evaluation demonstrate a worse sleep quality and effect on quality of life in patients with MHE<sup>[17,38,40]</sup>. Steindl *et al* demonstrated a disrupted melatonin cycle in patients with cirrhosis and MHE which was independent of psychometric performance<sup>[41]</sup>. However, reports have demonstrated that cirrhotics with MHE and sleep disruption do not have worse psychometric performance compared to those who do not have sleep disruption<sup>[38,42,43]</sup>. This implies that although there is a significant disruption of the sleep-wake and circadian rhythm in patients with MHE, this phenomenon co-exists with the psychometric impairment and is not the cause of it.

## QUALITY OF LIFE AND MHE

Quality of life is an essential assessment component of patients with chronic diseases. Issues pertaining to quality of life are also central to most patient complaints in cirrhosis<sup>[44]</sup>. Groeneweg *et al* studied the Sickness Impact Profile (SIP) in a cohort of cirrhotics being tested for MHE (Medical Outcomes Trust, Boston, MA)<sup>[40]</sup>. The SIP consists of 136 items which questions patients about 12 sections; sleep and rest, eating, work, home management, recreation and pastimes, ambulation, mobility, body care and movement (the last three generate a physical sub score), social interaction, alertness behavior, emotional behavior, and communication (comprising the psychosocial sub score). All scales were significantly impaired in MHE patients compared to others. A recent study by Prasad *et al* confirmed these findings in MHE patients in all spheres apart from communication, which was similar between patients with or without MHE<sup>[17]</sup>. Impaired quality of life has also been demonstrated using the Short Form 36 (SF-36) in MHE populations in several studies across the world<sup>[45,46]</sup>.

Short form-36 (SF-36) is a 36-part questionnaire that has been used in several studies to characterize chronic liver disease and the chronic liver disease questionnaire

has also been used in patients with liver disease<sup>[44-47]</sup>.

The SIP is an extensive survey which requires several minutes to complete, in contrast to the relatively short SF-36. The SF-36, therefore, may be a better tool for clinical practice. However, since quality of life changes in MHE are subtle, the SIP is perhaps the questionnaire better suited for research studies since it can differentiate between small changes in several aspects of QOL.

## WORK CAPACITY AND MHE

The specific nature of cognitive dysfunction in MHE results in a disproportionate impairment of workers engaged in “blue-collar” professions compared to “white-collar” professionals. This is essential to remember because cirrhotics engaged in professions that require constant vigilance and coordination, e.g. machinery operators and drivers are affected by MHE more severely compared to those who have predominantly verbal and intellectual functions, such as administrative and company executives<sup>[29]</sup>. Therefore, MHE not only has the potential to endanger the patients and co-workers during complex occupational tasks, it also can adversely affect their socio-economic status by interfering with work performance<sup>[48]</sup>.

## MHE AND PROGRESSION TO OVERT HEPATIC ENCEPHALOPATHY

Overt hepatic encephalopathy portends a poor prognosis and overall survival<sup>[49,50]</sup>. Patients with MHE have a higher likelihood of development of OHE<sup>[14,49,51,52]</sup>. Specific subgroups that are more likely to progress to OHE are males, those with a history of OHE, those with alcoholic etiology of cirrhosis and those with varices<sup>[19,53,54]</sup>. Positive responders to the glutamine tolerance test are also more likely to develop OHE<sup>[53]</sup>. It is not clear, however, which individual MHE patient will go on to develop OHE. The relative contributions of precipitating factors, such as gastrointestinal bleeding, for OHE development in the context of MHE *versus* no MHE have also not been fully elucidated. Therefore, patients with MHE may be a subgroup requiring close follow-up clinically for OHE development, especially when potential precipitating factors are encountered.

## MHE AND DRIVING CAPABILITY

The ability to drive a motor vehicle requires coordination of visual, auditory and vestibular inputs and has the potential to be impaired by metabolic encephalopathies<sup>[55]</sup>.

MHE affects attention, psychomotor function and working memory, all of which are essential for safe driving<sup>[56]</sup>. Most studies of driving ability using on-road driving tests have demonstrated that MHE patients have significant defects in reaction time, resulting in their pronouncement as unsafe drivers in studies from Germany and Japan<sup>[49,57]</sup>. Wein *et al* studied the driving ability and rating of driving behavior of 44 patients with cirrhosis

using instructors masked to their status. Fourteen of these patients had been diagnosed with MHE<sup>[58]</sup>. Results showed that patients with MHE required interventions by the driving instructor to prevent an accident at a rate 10 times higher compared to those with MHE and controls. Specific driving behaviors were also rated worse in patients with MHE, especially car handling, adaptation, cautiousness and maneuvering<sup>[58]</sup>.

Another essential skill required for safe driving is navigation, which ensures that the subject is in the right place at the right time<sup>[55]</sup>. Given the working memory abnormalities in cirrhotic patients, the study of navigation in MHE is important<sup>[24]</sup>. Our group recently published a study evaluating the performance of cirrhotics to age and education-matched controls on a driving simulator. Navigation skills in MHE are adversely affected<sup>[59]</sup>. All patients underwent a driving simulation which also included a navigation task. This task consisted of driving through a “virtual city” and illegal turns off the marked path were recorded. There was a significantly higher rate of illegal turns in the MHE group compared to those without MHE and controls. Illegal turns were proportionate to impairment in psychometric performance in cirrhotic group<sup>[59]</sup>. Therefore, driving difficulties in patients with MHE are likely multi-dimensional and includes impairment in reaction time and navigation skills.

## DRIVING OUTCOMES IN PATIENTS WITH CIRRHOSIS AND MHE

Traffic accidents are one the leading causes of death worldwide, especially in young adults, the most productive age group of any society. It is important to determine whether patients with MHE also have poor driving outcomes compared to those without MHE and controls. This would be essential in formulating public health decisions regarding licensing and therapy for MHE. A study published by our group sent an anonymous driving outcome questionnaire to controls, cirrhotics tested for MHE and cirrhotics not tested for MHE due to concurrent psychoactive drug use<sup>[60]</sup>. As many as 33% of MHE patients reported having a traffic accident or violation within the last year compared to only 4% of MHE negative patients and 12% of the patients using psychoactive drugs. When 5 year data were analyzed a significant majority of MHE patients (53%) reported a traffic accident or violation compared to only 23% of MHE negative patients and 22% of those on psychoactive drugs. This is even more significant since none of the MHE patients were drinking alcohol. On multi-variate analysis, MHE emerged as the sole factor associated with traffic violations [odds ratio 6.0 (CI 1.2-31.3)], motor vehicle accidents [odds ratio 7.3 (CI 2.1-33.2)] and both [odds ratio 7.6 (CI 1.5-37.3)]<sup>[60]</sup>. However, despite these striking numbers, there is still the need to analyze driving data prospectively using identified records before making specific recommendations regarding driving capability<sup>[3]</sup>.

Patients with cirrhosis have a poor prognosis after trauma and surgery, especially with increasing Child-

Pugh score<sup>[61]</sup>. A combination of coagulation impairment, sepsis and hepatic dysfunction has been noted as contributing factors to this worse prognosis<sup>[61]</sup>. A study of a large inpatient sample from the United States showed that patients with cirrhosis who were involved in a motor vehicle crash had a higher mortality than those who were admitted for motor vehicle crashes only<sup>[62]</sup>. Despite a younger average age, patients with cirrhosis and crash had a similar mortality compared to those admitted with cirrhosis only. Hospitalization charges and inpatient stay were also significantly higher in cirrhotics with crash compared to patients admitted for cirrhosis only and those admitted for motor vehicle accidents only. On multi-variate regression within the patients admitted with motor vehicle accidents, age > 65 years and cirrhosis were the variables most significantly associated with mortality<sup>[62]</sup>.

Therefore, not only are patients with MHE more likely to get into an accident, they are also more likely to die from it and utilize greater resources as a result of the accident. All these factors make it essential for a clinician to take a driving history when evaluating patients for cirrhosis and chronic liver disease.

## MHE: INSIGHT INTO THE DISEASE PROCESS AND DRIVING SKILLS

Insight into personal deficits is essential in patients in order to seek medical intervention. Anosognosia, defined as the unawareness of a disease, is a key component of the disease process in several metabolic and vascular cerebral disorders<sup>[63,64]</sup>. This phenomenon is clearly observed in patients with OHE, in which it is the persons in the environment who detect changes in the patients' sensorium rather than the patient<sup>[27]</sup>. A recent report extended this lack of insight into driving impairment. This study demonstrated that patients with MHE rated themselves as significantly better drivers compared to those without MHE and controls when they were evaluated by independent observers<sup>[28]</sup>. Therefore, similar to patients with OHE, it may be important to elicit a complete driving history and assessment from relatives familiar with the MHE patients' driving rather than relying on the patients' history alone.

## THE HISTORY NOT TAKEN: DRIVING HISTORY

The standard of care of patients with cirrhosis without any ongoing acute issues is focused on strategies aimed to prevent decompensation. These strategies are aimed at reducing mortality and morbidity from a liver disease standpoint. However, as evidenced by recent reports, patients with cirrhosis and MHE also are at risk for developing morbidity and mortality behind the steering wheel<sup>[58,60]</sup>. An objective driving history, including confirmation from the local supervisory agency, and corroboration of driving skills by relatives is also an essential aspect of patient care. The driving history to the clinical

history would arguably be a vital addition to the overall understanding of the disease severity from a clinical and psychosocial view in cirrhosis.

## TESTING FOR MHE DURING CLINIC VISITS

Although the majority of surveyed hepatologists in Spain and the United States agreed that MHE was a significant problem requiring testing, the minority were able to actually test for MHE as part of their clinical practice<sup>[7,8]</sup>. Main barriers to MHE testing were inability to get tests paid for by insurance, adding time to clinic visits and lack of standardized norms for the United States<sup>[8]</sup>.

The psychometric battery recommended by the Working Group on Hepatic Encephalopathy is the PSE-syndrome test published by Weissenborn *et al*<sup>[2,11]</sup>. This test battery, although quite efficient in diagnosing MHE, requires a psychologist and valid population norms. The difficulty of applying these tests in the United States is the lack of background population norms and the need for a licensed psychologist to order and administer these tests. In addition, these are still not routinely covered by private health care insurance. These logistic barriers have effectively prevented routine clinic diagnosis of MHE.

The AASLD survey also highlighted the need for simpler and rapid testing that can take the place of cumbersome and copyrighted psychometric testing<sup>[8]</sup>. The inhibitory control and the critical flicker frequency have emerged as tests that can be applied in clinical practice without the need for psychological expertise<sup>[3,13,14,20,65]</sup>. However, detailed validation studies are still underway for these tests.

## POPULATION TO BE TESTED

Patients with cirrhosis who are ambulatory and capable of independent living are the ones most affected by MHE and should definitely be tested. Previous recommendations have been split regarding the specific population to be targeted for testing. Ortiz *et al* and Stewart *et al* have specifically recommended certain patient populations be tested<sup>[1,48]</sup>. Psychometric performance can be affected by current alcohol use, use of psychoactive drugs and pre-existing neurological disorders<sup>[11]</sup>. In cirrhotics who do not fulfill these criteria, it is in the best interest of the patient to be offered testing at the initial visit regardless of their subsequent activities. There is no consensus regarding the frequency of testing, but experience has shown relative similarity in psychometric scores at 6 mo intervals in the absence of acute clinical and neurological events such as development of OHE<sup>[19]</sup>.

## THERAPY FOR MHE

Treatment of MHE improves psychometric performance and quality of life<sup>[16,17]</sup>.

A recent consensus conference promulgated lactulose as the first choice of therapy for MHE in concor-

dance with the previous study data and the AASLD survey<sup>[3,8]</sup>. However, whether this would have any effect on development of OHE, driving capability or overall survival remains to be investigated. Since driving and psychometric impairments are highly correlated, it is reasonable to expect that driving performance would also improve after MHE therapy.

However, the adherence rate of lactulose in patients with OHE is low; therefore, to expect an MHE patient, who does not have any specific symptoms and lacks insight into their problems, to be adherent on a medication that could cause diarrhea and flatulence is difficult<sup>[3,66]</sup>. Therefore, alternatives to lactulose have also been studied for MHE. Liu *et al* showed that fiber and fiber with probiotics improved psychometric function and importantly the Child class of patients<sup>[21]</sup>. Similar studies have been published using various formulations of probiotics with good improvement in psychometric tests<sup>[67-71]</sup>. Our group has recently completed a randomized control trial of a probiotic yogurt that resulted in a significant reversal of MHE in the yogurt-randomized group compared to the group randomized to no treatment<sup>[72]</sup>. The adherence was excellent and none of the yogurt-treated group developed OHE. Although probiotics are attractive options that spare the patients from the poor palatability of lactulose, difficulties in the availability and the standardization of probiotic organisms remain. However, these preliminary data suggests that dietary intervention may be considered in addition to probiotics for amelioration of MHE.

Therefore, although treatment options for MHE are evolving, it is still important to test patients to offer them the available therapeutic options.

## CONCLUSION

MHE is an epidemic cognitive dysfunction in patients with cirrhosis which is gaining importance in clinical and research spheres due to improved survival in cirrhotic patients.

MHE patients exhibit a specific cognitive impairment that negatively impacts their driving capability and work performance and importantly is not evident to the patients themselves.

A crucial aspect of the clinical care of MHE patients is their driving history, which is often ignored in routine care and can add a vital dimension to the overall disease assessment. Driving history should be an integral part of care in patients with MHE.

The lack of specific signs and symptoms, the preserved communication skills and lack of insight make MHE a difficult condition to diagnose.

Diagnostic strategies for MHE abound, but are usually limited by financial, normative or time constraints. Recent studies into the inhibitory control and critical flicker frequency tests are encouraging since these tests can increase the rates of MHE diagnosis without requiring a psychologist.

Although testing for MHE and subsequent therapy is not standard of care at this time, it is important to con-

sider this in cirrhotics in order to improve their ability to live their life to the fullest.

## Abstract

With pegylated interferon and ribavirin, more than half of all chronically-infected hepatitis C patients can achieve a sustained virologic response; however, patients with genotype 1 infections and those with other poor prognostic factors have relatively inferior treatment response rates. Since new therapies are still years away from approval, it is incumbent upon providers to maximize the therapeutic efficacy of today's treatment. The later the virus is undetectable in serum during treatment, the less likely it will be eradicated. Patients with a delayed or slow virologic response to therapy (at least a 2-log<sub>10</sub> decrease in baseline hepatitis C RNA yet detectable viremia at 12 wk of therapy and undetectable virus 12 wk subsequently) may, therefore, benefit from an extended therapy course beyond one of standard duration. Although higher rates of treatment discontinuation may plague this approach, 72 wk of treatment for genotype 1-infected slow-responders may improve response rates and diminish relapse rates relative to those of 48 wk. Based on data from both viral kinetic and clinical studies, therapy prolongation in slow responders may be a reasonable strategy to improve response rates in these treatment-refractory patients.

## INTRODUCTION

One hundred and seventy million persons worldwide are infected with the hepatitis C virus (HCV)<sup>[1]</sup>, and liver-related deaths from the virus are expected to nearly triple by the year 2020<sup>[2]</sup>. Three years prior to the virus' identification in 1986, interferon alpha-2b was first utilized for the treatment of non-A, non-B hepatitis<sup>[3]</sup>. Although sustained virologic response (SVR) rates to interferon monotherapy for 6 mo were only about 8%, treatment extension to 12 mo nearly doubled response rates<sup>[4]</sup>. With the advent of the nucleoside analog ribavirin, used in combination with interferon, rates of SVR more than doubled again<sup>[5,6]</sup>. Whereas 48 wk of standard interferon with ribavirin achieved sustained response rates as high as 43%<sup>[6]</sup>, 48 wk of the newer pegylated interferons plus ribavirin improved rates of SVR to 54%-56% as shown in two multinational, randomized controlled trials<sup>[7,8]</sup>.

Nevertheless, SVR rates are inferior for patients with genotype 1 infection<sup>[7-9]</sup> despite a 48 wk recommended treatment course of peginterferon with weight-based ribavirin<sup>[10,11]</sup>. Although preliminary evidence indicates that small molecule inhibitors in combination with peginterferon and ribavirin may improve response rates even further for genotype 1-infected patients with merely 24 wk of therapy<sup>[12,13]</sup>, the combination of peginterferon and ribavirin alone is likely to remain the recommended treatment regimen for chronic HCV for the next 3-5 years<sup>[14]</sup>. Thus, it is incumbent upon clinicians to maximize their patients' chance of treatment success with existing therapy.

Methods utilized to improve the treatment response in genotype 1-infected patients include the bolstering of patient adherence through aggressive side effect management and increasing the dose of therapy through induction dosing of interferon or through higher doses

**Figure 1** Relationship between hepatitis C viremia and sustained virologic response with pegylated interferon alpha-2a and ribavirin therapy<sup>[19]</sup>. The later the virus becomes undetectable on therapy, the less likely it will be ultimately cleared. Data are from retrospective analysis<sup>[19]</sup> of a registration trial for peginterferon alpha-2a plus ribavirin involving over 1000 chronic, treatment-naïve hepatitis C-infected patients<sup>[8]</sup>. Neg: Undetectable RNA; > 2 log: At least a 2 log<sub>10</sub> decrease in viral RNA compared to pre-treatment value; < 2 log: Less than a 2 log<sub>10</sub> decrease in viral RNA compared to pre-treatment value.

of either interferon or ribavirin. Another strategy is to lengthen duration of treatment in those that are slow-responders to standard doses of peginterferon and ribavirin. The purpose of this survey is to review the justification for therapy prolongation in appropriate patients using viral kinetic data and to summarize the clinical trials supporting this approach.

## VIRAL KINETICS DURING TREATMENT

An initial decrement in HCV RNA level, referred to as phase 1, occurs hours after the administration of interferon; it represents the blocking of viral replication. A subsequent, slower decrease in viremia (phase 2) represents the clearance of HCV-infected hepatocytes and typically occurs days to months after interferon therapy is initiated. The phase 2 decline in virus is the better predictor of ultimate HCV clearance<sup>[15,16]</sup>. Phase 2 decline is significantly slower in genotype 1-infected patients than in those infected with genotypes 2 and 3<sup>[17,18]</sup>. Thus, by measuring virus concentrations of various points along a slope of a phase 2 decline in viremia, treatment outcome may be better predicted, and ultimately modified, based on an individual patient's response to therapy.

HCV-infected patients who achieve undetectable viremia as early as 4 wk into standard therapy have excellent sustained response rates; these rapid virologic responders achieve SVR about 90% of the time<sup>[19]</sup>. In fact, support exists for truncating therapy duration for genotype 1-infected rapid responders with low baseline HCV viral loads<sup>[20]</sup>. Conversely, patients who show undetectable virus for the first time 24 wk into therapy have less than one-third chance of ultimately achieving SVR<sup>[8]</sup>. Therefore, the earlier the HCV is undetectable in serum during treatment, the greater the likelihood of a successful treatment response (Figure 1).

Similarly, longer durations of viral suppression

on treatment may improve virologic response rates. Investigators have sought to determine if the standard 48 wk treatment duration of patients with genotype 1 infection is adequate. Using data from the peginterferon alpha-2b and ribavirin phase III trial<sup>[7]</sup>, Drusano and Preston developed a prediction model based on the duration of viral suppression on therapy<sup>[21]</sup>. The model was built on the basis of eleven covariables including demographics and virologic characteristics from 771 HCV-infected patients. Among the variables, the durations of viral clearance had the strongest bearing on the likelihood of a SVR. When the model was applied to a validation group of 229 patients, it predicted SVR with a positive predictive value of 97% and a negative predictive value of 91%. To achieve an 80% chance of SVR in genotype 1-infected patients, an undetectable HCV RNA was required for at least 32 wk on therapy, and to achieve a 90% chance of SVR, RNA undetectability was necessary for 36 wk. Since the average time to clear genotype 1 viremia was 30 wk, the authors concluded that the standard 48 wk treatment course for this genotype is inadequate. Problems with this study are its retrospective analysis and the model's requirement for monthly viral loads which may be cost-prohibitive. Furthermore, the model was based on the use of suboptimal ribavirin dosing (800 mg daily) which limits its applicability in genotype 1 infection. However, the study suggests that patients who don't achieve undetectable virus at certain time points may enjoy improved rates of SVR with treatment extension.

A failure to achieve an early virologic response (EVR), defined by an undetectable HCV RNA level or at least a 2-log<sub>10</sub> decrement in RNA from baseline at 12 wk of therapy, has excellent negative predictive value for treatment success<sup>[22,23]</sup>. An analysis of the peginterferon with ribavirin registration trials<sup>[7,8]</sup> suggests that patients who do not achieve a 12 wk EVR have a 3% or lower chance of ultimately achieving SVR<sup>[23]</sup>. Nonetheless, there is a large disparity in treatment response between patients who, at 12 wk, have at least a 2-log<sub>10</sub> decrease in baseline HCV RNA yet still have detectable virus (partial EVR) compared to those who achieve undetectable viremia (complete EVR). In the registration trial for peginterferon alpha-2b with ribavirin, patients in the latter group achieved SVR about four times more frequently than those in the former<sup>[23]</sup>. These former patients are said to be slow or late responders to therapy. Patients have also been characterized as slow responders to therapy if they have detectable virus at 4 wk; either definition necessitates undetectable virus at 24 wk of treatment, since detectable viremia at this time point virtually guarantees treatment failure.

In genotype 1 infection with the standard therapy duration of 48 wk, slow responders have higher relapse rates compared to those that clear virus earlier in treatment<sup>[19]</sup>. High rates of relapse in slow responding patients may indicate that therapy was of insufficient duration; therefore, it has been hypothesized that extending therapy in these patients may improve rates of SVR (Figure 2).

**Figure 2** Virologic responses of slow-responders to 48 wk vs 72 wk of therapy. Treatment extension may improve chance of SVR by lessening the chance of relapse. Slow-responders to standard duration therapy (48 wk) may see relapse after an end-of-treatment response is achieved; those receiving extended duration therapy (72 wk) are not as apt to relapse after treatment is completed.

## EXTENDED DURATION THERAPY WITH STANDARD INTERFERON

Several years before the term slow-responder was popularized, investigators attempted to improve response rates by extending therapy duration utilizing older medications. Using standard interferon monotherapy, authors have demonstrated improved biochemical, histologic and virologic responses with treatment ranging from 60 to 76 wk compared to treatments of shorter durations<sup>[24,25]</sup>. In one of these studies<sup>[24]</sup>, the investigators noted a reduced tendency for patients to relapse after treatment cessation when therapy was extended to 60 wk relative to previously published studies with shorter durations.

The first randomized, controlled trial to show that prolongation of interferon-based therapy combined with ribavirin for 18 mo reduced rates of relapse was performed in the Netherlands and Belgium<sup>[26]</sup>. Three hundred treatment-naïve chronic HCV patients were randomized to 6 or 18 mo of standard-interferon (3 million units thrice weekly) plus ribavirin (1000-1200 mg daily) or to 18 mo of the same dose of standard interferon monotherapy plus placebo. The majority of patients were genotype 1-infected with high viral loads. Although end-of-treatment responses were similar in the two combination therapy arms (55% and 41% in 6 and 18 mo arms, respectively), relapse rates were significantly lower in the 18 mo combination arm (13%) compared to those in the 6 mo treatment arm (38%,  $P = 0.006$ ). It should be noted that the rate of relapse in the group treated with 18 mo of monotherapy was still high at 38%; these results demonstrate that extending the duration of interferon alone is inadequate to decrease relapse rates and attests to ribavirin's effect on relapse diminution. In an intention-to-treat analysis, SVR rates were 16% for 18 mo monotherapy, 34% for 6 mo combination therapy and 43% for 18 mo of combination therapy ( $P < 0.05$ ). Although 25% of patients withdrew from both 18 mo treatment arms prematurely, this withdrawal rate is similar to those from standard interferon plus ribavirin treatment trials of 48 wk duration (21%-27%)<sup>[5,6]</sup>. Prolongation of combination therapy had no significant effect on rates

of relapse or SVR in genotype 2- or 3- infected patients; nevertheless, extension of treatment from 6 to 18 mo had an independent effect on relapse and SVR rates in patients infected with genotype 1 virus (SVR: OR 4; CI: 2-10,  $P = 0.004$ ). Slow responders, those with detectable viremia at 12 wk, enjoyed a decline in relapse rate from 70% to 30% when treatment was prolonged from 24 to 72 wk. The study's major limitation was the absence of a 12 mo treatment arm.

## EXTENDED DURATION THERAPY WITH PEGYLATED INTERFERON

Investigators from Spain and Israel were the first to report successful treatment extension to 72 wk for slow responders to peginterferon and ribavirin<sup>[27]</sup>. Slow responders were defined as those patients with at least a 2 log<sub>10</sub> decline in HCV RNA from baseline, yet detectable viremia at 12 wk after receipt of 1.0 mcg of peginterferon alpha-2b weekly and 800 mg ribavirin daily. Although only 8 patients were treated in this fashion, 7 of the 8 (88%) achieved an SVR, which is a profound improvement relative to a SVR of 21% in slow responders treated for 48 wk in the phase III trial of peginterferon alpha-2b and ribavirin<sup>[23]</sup>. The suboptimal dosing of ribavirin and the paucity of patients studied are the limitations of this analysis.

Furthermore, results from a large, prospective, multicenter trial from Germany support the extension of therapy duration in slow responders to peginterferon and ribavirin<sup>[28]</sup>. 459 treatment-naïve genotype 1-infected patients were randomized to 48 wk *vs* 72 wk of peginterferon alpha-2a, 180 mcg weekly and ribavirin, 800 mg daily. 22% of patients were slow virologic responders to therapy, defined by virus detectability at 12 wk of treatment, but with viral undetectability at 24 wk. Slow responders in the 72 wk group had lower relapse rates than did slow responders treated for 48 wk (40% *vs* 64%, respectively;  $P = 0.021$ ) and had similar end-of-treatment responses; thus, rates of SVR for this subgroup of patients were significantly higher when treated for 72 wk compared those treated for 48 wk (29% *vs* 17%, respectively;  $P = 0.04$ ). Patients with low levels of viremia (less than 6000 IU/mL) at 12 wk of treatment derived the greatest benefit from extended duration therapy. Thus, the investigators concluded that in slow virologic responders to treatment, relapse rates could be reduced and rates of SVR could be augmented by extending therapy to 72 wk. Nonetheless, the slow responders represented only a subgroup of those randomized, and the conclusions were garnered retrospectively. Moreover, the 800 mg ribavirin used in the trial is an inadequate dose for most genotype 1-infected patients<sup>[9]</sup>. It should also be emphasized that, for the majority of patients randomized to 72 wk of therapy, there was no statistical benefit relative to 48 wk of treatment. Overall, SVR rates were 54% and 53%, respectively ( $P = 0.8$ ), and relapse rates were likewise statistically similar. Thus, extended duration

therapy is generally not recommended for all treatment-naïve patients with genotype 1 infection and should be considered only for those with the slow responding phenotype. Finally, although patients in both the standard and extended duration treatment arms had similar rates of medication dose reduction and adverse events, the rate of premature therapy discontinuation was higher in the extended treatment arm compared to that in the standard treatment arm (41% and 24%, respectively).

Another randomized, multicenter clinical trial from Spain, the TeraViC-4 study, prospectively evaluated the effects of extended therapy duration with peginterferon alpha-2a (180 mcg weekly) and ribavirin (800 mg daily)<sup>[29]</sup>. Treatment-naïve patients with detectable HCV RNA levels at week 4 ( $n = 326$ ) were randomized to a therapy duration of 48 wk ( $n = 165$ , 149 of whom were genotype 1-infected) or to 72 wk ( $n = 161$ , 142 of whom were genotype 1-infected). Thus, in this case, a slow responder was defined by absence of a rapid virologic response, and only slow responders were randomized to extended therapy. In TeraViC-4, the 12 wk virologic responses were not reported. Although end-of-treatment responses for patients with genotype 1 infections were statistically similar in both extended and standard treatment arms (62% *vs* 58%, respectively;  $P = 0.53$ ), SVR rates were superior in the extended treatment arm (44% *vs* 28%, respectively;  $P = 0.003$ ), by virtue of a diminution of relapse rate (17% *vs* 53%, respectively;  $P = 0.002$ ). The incidence of adverse events and dose reductions were similar in both groups; yet, treatment discontinuation was more frequent in the extended therapy arm compared to the standard duration arm (36% *vs* 18%, respectively;  $P = 0.0004$ ). In fact, one of the study's limitations was this inordinate number of premature terminations in those randomized to prolonged therapy, largely because of patient preference. Other limitations were the lack of central testing for viral load measurements and the inclusion of patients with other genotypes besides one. Like that of the German study, the primary weakness of this trial may have been the suboptimal dose of ribavirin utilized (800 mg for genotype 1 virus).

In another prospective study from the United States, we randomized genotype 1-infected slow-responders to 48 or 72 wk of peginterferon alpha-2b (1.5 mcg/kg weekly) and weight-based ribavirin (800 to 1400 mg daily)<sup>[30]</sup>. In our trial, slow response was defined by achieving at least a 2 log<sub>10</sub> decrement in HCV RNA from baseline, yet having detectable viremia at 12 wk but undetectable virus at 24 wk (PCR, lower limit of detection 10 IU/mL). One hundred twelve of our treatment-naïve patients were deemed slow-responders who represented about 30% of our patients. This percentage was felt to be high secondary to difficult-to-treat baseline characteristics: 26% had bridging fibrosis or cirrhosis on pre-treatment liver biopsy; 48% were African American; 34% were obese defined by greater than or equal to 30 kg/m<sup>2</sup>; 78% had high baseline viral load (more than 800 000 IU/mL) and 18% had impaired fasting glucose, pre-treatment. Similar to the

aforementioned European trials, we did not observe a higher number of adverse events or therapy reductions in the extended treatment arm relative to the control arm. However, unlike in the other studies, we did not see a greater treatment cessation rate in the prolonged therapy arm; in fact, none of the therapy terminations occurred between weeks 48 and 72. Growth factors were prohibited, yet peginterferon dose reductions for neutropenia were made only if counts were less than 500/mm<sup>3</sup>. Similar to those of the slow-responders in Spain, our randomized patients saw equivalent end-of-treatment response rates in the 72 wk arm *vs* the 48 wk arm (48% *vs* 45%, respectively;  $P = 0.75$ ), yet enjoyed improved relapse rates with therapy prolongation (20% *vs* 59%, respectively;  $P = 0.004$ ). Overall, rates of SVR in slow-responders were superior with treatment extension (38%) compared to those of standard duration therapy (18%,  $P = 0.03$ ). The primary limitation of our analysis is it was conducted in a single medical center.

African Americans, a group with inferior responses to interferon-based therapy<sup>[31-33]</sup>, may likewise benefit from a treatment extension strategy if slowly responsive to treatment. When compared to non-Hispanic whites receiving combination therapy, African Americans showed smaller phase 1 and phase 2 declines in viral load<sup>[34]</sup>; thus, it was unclear if African Americans' viral kinetics on therapy would be analogous to those of white "late" responders. Nearly half of our slow responders were self-identified as African American ( $n = 48$ ) and were randomized to 48 and 72 wk treatment arms in our Atlanta study described above<sup>[30]</sup>. Although overall, African American slow responders had expected inferior SVR rates to those of whites (17% and 39%, respectively), the former group still benefited from treatment extension because of reduced relapse rates. End-of-treatment response rates were 24% *vs* 26% for 48 and 72 wk of treatment, respectively ( $P > 0.05$ ), and SVR rates were 12% *vs* 21%, respectively ( $P = 0.02$ ). Results should be interpreted with caution, however, because this ethnic group's response rates were derived from subgroup analysis.

Preliminary results are available from a multicenter trial in Europe that also utilized extended therapy for slow-responders to peginterferon alpha-2a (180 mcg weekly) with weight-based ribavirin (1000-1200 mg daily)<sup>[35,36]</sup>. Of the 373 patients treated, 11% were slow-responders to therapy, defined by having detectable virus at 12 wk ( $> 50$  IU/mL), yet still at least 2 log<sub>10</sub> below baseline, and thus randomized to complete standard duration therapy of 48 wk or extended treatment to 72 wk. None of these slow-responders had achieved undetectable virus at 4 wk. Over 90% of patients had genotype 1 infections, and the remainder was infected with genotype 4 virus. As in the previously described studies, extended therapy compared to that of standard duration improved SVR rates in slow-responders (69% *vs* 52%, respectively;  $P$  value not available) by virtue of a decrease in relapse rates (18% *vs* 32%, respectively;  $P$  value not available). Although treatment discontinuation data are not available for slow-responders specifically,

**Table 1** Studies of extended therapy for treatment-naïve, genotype 1-infected slow responders to pegylated interferon with ribavirin

Country(ies) in which studies performed	Number of subjects studied	Treatment duration (wk)	Definition of slow response (assay sensitivity)	Pegylated interferon type and weekly dose	Ribavirin daily dose (mg)	End-of-treatment responses	Relapse rates	Sustained virologic response rates	P value (sustained response)	Major study limitation (s)

<sup>1</sup>Detectable viremia at 12 wk and undetectable viremia at 24 wk required; <sup>2</sup>Less than 10% genotype 4 infections; <sup>3</sup>One of twenty patients had an end-of-treatment response, but relapsed; <sup>4</sup>Not statistically significant.

patients who received extended duration therapy had a greater number of treatment discontinuations (17%) compared to those on standard duration therapy (4%). Limitations of this study are the small numbers of slow-responders analyzed (41 patients) and the mixture of genotype 1- and 4- infected patients.

Finally, a recently published, randomized, multicenter study from Italy assessed the utility of variable therapy duration, including a treatment extension strategy, based on the time to a patient's first undetectable HCV RNA<sup>[37]</sup>. 696 genotype 1-infected treatment-naïve patients were randomized to a standard duration or a variable duration therapy arm in a 2:1 ratio. Patients were treated with either peginterferon alpha-2a (180 mcg weekly) or peginterferon alpha-2b (1.5 mcg/kg weekly), both with weight-based ribavirin (1000-1200 mg daily). Irrespective of first time to viral undetectability in serum (< 50 IU/mL), 237 patients in the standard therapy arm received treatment for 48 wk, unless patients did not achieve EVR at week 12 or had detectable virus at week 24, at which time therapy was discontinued. However, in the variable duration arm, patients were treated for 24, 48 or 72 wk if serum HCV RNA were negative at 4, 8, or 12 wk, respectively. Patients were likewise treated for 72 wk in the variable duration arm if they had at least a 2 log<sub>10</sub> decline in serum RNA from baseline yet detectable viremia at 12 wk of therapy (slow-responders).

Overall, based on the rates of SVR, the standard and variable duration treatment arms were statistically equivalent. Nonetheless, the study proved prospectively

that the longer the virus is undetectable on therapy, the better the chance of achieving a SVR, regardless if a patient had received treatment of a standard or variable duration. In the standard duration arm, 87%, 70% and 38% of patients first attaining undetectable viremia at 4, 8 or 12 wk, respectively, achieved SVR; in the variable duration group, corresponding SVR rates were 77%, 72% and 64%.

More pertinent to this discussion is the fact that the study's slow-responders in the standard treatment duration arm ( $n = 21$ ) did not achieve SVR in a single case (0%), and those slow-responders treated for 72 wk ( $n = 53$ ) saw an SVR of only 7.5%; nonetheless, the results were not statistically significant ( $P = 0.3$ ). Moreover, 10 of the slow-responders treated for 72 wk voluntarily withdrew from the study compared to only 3 patients treated for 48 wk, suggesting that prolonged therapy was not well-tolerated. Most intriguing, patients who achieved undetectable virus for the first time at 12 wk of therapy (having detectable viremia at week 8), enjoyed improved SVR rates when treated for 72 wk compared to 48 wk in 64% and 38% of cases, respectively (difference -25.4, CI: 22.3-28.4). Extended therapy, even in these "complete" early virologic responders, seemed to have improved SVR rates because of a decline in relapse (43% in standard group, and 15% in variable group). The authors deemed this difference "...substantial, (and) may warrant a prospective trial."

The most important limitations of this last study are the large number of patients in the variable treatment duration arm who discontinued therapy because of poor

compliance (49% of all treatment discontinuations), and the relative paucity of patients on which subgroup analysis was performed. For example, only 21 slow-responders were treated for 48 wk.

The Study to Assess Treatment with Pegylated Interferon Alpha-2b and Ribavirin in Treatment-Naïve Patients with Chronic hepatitis C and slow virologic response (SUCCESS) is a multinational study in 133 centers across Europe, Canada and Israel designed to compare response rates of slow-responders to either 48 or 72 wk of therapy<sup>[38]</sup>. Slow-response is again defined by patients with genotype 1 infection who had at least a 2 log<sub>10</sub> reduction, albeit detectable, HCV RNA levels at 12 wk compared to baseline and undetectable virus at week 24. As of late 2006, 126 patients were deemed slow-responders and were randomized into standard and extended therapy duration arms (Table 1). Final results should be available sometime later in 2008 or in early 2009.

## CONCLUSION

Treatment extension has been attempted with varying degrees of success using alternative interferons<sup>[39,40]</sup>, in those with relapse<sup>[40]</sup> or non-response to peginterferon-based therapies<sup>[41]</sup> and in those who are HCV-HIV coinfectd<sup>[42,43]</sup>. Details of these analyses are beyond the scope of this review.

Certainly, not every treatment-naïve patient with genotype-1 infection benefits from therapy prolongation. However, a subgroup with a delayed or slow response to therapy (approximately 15% of patients) may enjoy improved rates of SVR with treatment extension to 72 wk, largely because of a relapse diminution. Data on therapy prolongation in slow-responders are summarized in Table 1. Compared to patients receiving therapy of standard duration, those in extended treatment groups have experienced higher discontinuation rates in most, but not all, studies to date; however, the numbers of adverse events and dose reductions appear to be equivalent. Clearly, if treatment prolongation is utilized, adherence to therapy is paramount. Finally, the use of 72 wk for slow virologic responders to peginterferon and ribavirin may be cost-effective compared to 48 wk, or standard duration therapy<sup>[44]</sup>. Thus, therapy extension in slow-responders seems to be a reasonable strategy to ameliorate response rates in a group with notoriously poor treatment results.

## Abstract

Biliary cyst tumors (cystadenoma and cystadenocarcinoma) are an indication for liver resection. They account for only 5% of all solitary cystic lesions of the liver, but differential diagnosis with multiloculated or complicated biliary cysts, atypical hemangiomas, hamartomas and lymphangiomas may be difficult. The most frequent challenge is to differentiate biliary cyst tumors from hemorrhagic cysts. Computerized tomography (CT) and magnetic resonance imaging (MRI) are often not diagnostic and in these cases fine needle aspiration (FNA) is used to confirm the presence of atypical biliary cells. FNA, however, lacks adequate sensitivity and specificity and should always be used in conjunction with imaging. Pre-operative differentiation of cystadenoma from cystadenocarcinoma is impossible and surgery must be performed if a biliary cyst tumor is suspected. When multiple cystic lesions are observed throughout the liver parenchyma, it is important to exclude liver metastasis, of which colonic cancer is the most common primary site. Multiple biliary hamartomas (von Meyenburg complex) can appear as a mixture of solid and cystic lesions and can be confused with cystic metastasis. Strong and uniform T2 hyperintensity on MRI is usually diagnostic, but occasionally a percutaneous biopsy may be required.

## INTRODUCTION

Although rare, cystic neoplasms of the liver may represent a diagnostic challenge in everyday practice. Cystic tumors may be solitary or multiple and vary from the most benign (e.g. simple cysts, hamartomas) to potentially malignant (cystadenoma) or overtly malignant (cystadenocarcinoma). There are also atypical cystic presentations of normally non-cystic tumors, like cystic hemangiomas or cystic hepatocarcinomas and congenital diseases presenting as diffuse cyst-like involvement of the liver (Caroli's disease and von Meyenburg complex) that must be differentiated from cystic metastasis. The most important issue in the case of solitary cystic tumors is to distinguish biliary cystadenoma and cystadenocarcinoma from other benign conditions that require only observation of the patient.

## SOLITARY CYSTIC TUMORS

Cystadenoma is a biliary cyst tumor arising from biliary epithelium. With its malignant counterpart (cystadenocarcinoma), it accounts for less than 5% of all cystic lesions of the liver; but it is dangerous for its propensity toward local recurrence and malignant change<sup>[1,2]</sup>. These tumors usually present in middle aged women with a mean age of 50 years and have a great variability in size, ranging from 1.5 cm to 30 cm. The majority of patients are asymptomatic, but in the case of large tumors they may present with a palpable mass and cause symptoms<sup>[3]</sup>. Cystadenocarcinoma can arise *de novo* or from a pre-existent cystadenoma, from which it is difficult to differentiate since both have a multiloculated appearance at ultrasound (US), computerized tomography (CT) and magnetic resonance imaging (MRI). Cystadenoma has thinner septa and a less thick and more regular walls than cystadenocarcinoma<sup>[4]</sup>. However, internal papillary projections and foldings with arterial enhancement of the external wall at dynamic CT scan and MRI may be present in both tumors, so that imaging itself cannot reliably differentiate these

**Figure 1** T1 weighted MR image (A) and ultrasound examination (B) showing a large cystic lesion of the left liver lobe with a thick and irregular septum, raising the suspicion of a biliary cystadenoma, and Doppler ultrasound (C) showing vascular signals within the septum disclosing a focus of cystadenocarcinoma confirmed in the surgical specimen.

neoplasms. Internal septa and papillary projections are more often hypovascular in the case of cystadenoma, and the demonstration of vascular signals at color Doppler can be a sign of its malignant transformation (Figure 1). The diagnosis of cystadenocarcinoma is straightforward only when ultrasound, CT scan or MRI shows nodular septa and thick, irregular walls with strong contrast enhancement, but in many cases there are overlapping features. Intracystic hemorrhage and fine punctuate calcifications may present in both conditions and can also be observed in complicated hemorrhagic cysts, their role as diagnostic criterion are, therefore, doubtful<sup>[5]</sup>. Fine needle aspiration can be used to differentiate a biliary cyst from other benign conditions and from a single metastasis, but is totally unreliable in differentiating cystadenoma from cystadenocarcinoma, since small neoplastic foci are undetectable by fine needle aspiration and may be revealed only in the surgical specimen<sup>[6]</sup>.

In conclusion, there is no definite, reliable criterion for differentiating cystadenoma from cystadenocarcinoma and the correct diagnosis is often made only in the surgical specimen.

The majority of biliary cyst tumors do not usually communicate with the bile ducts, although direct luminal communication is occasionally observed. In these cases, dysplastic mucinous epithelium itself may proliferate within the bile ducts and cause obstruction<sup>[7]</sup>. This variant is considered an intraductal papillary neoplasm with prominent cystic dilatation rather than a true biliary cyst neoplasm and must be differentiated from biliary papillomatosis and cholangiocarcinoma of intraductal growth type. CT and MRI are insufficient to show the luminal communication, probably because the communication is too narrow, while intraoperative cholangiography can establish the correct diagnosis. Intraductal spreading of neoplastic cells into the bile duct portends a poorer prognosis of this variant of biliary cyst tumor.

If it is practically impossible to distinguish pre-operatively cystadenoma from cystadenocarcinoma, every effort should be made to differentiate these neoplasms from biliary cysts and other benign tumors without malignant potential. In case of simple cysts, without internal septa or papillary projections,

cystadenoma can be reliably excluded and the patient can only be observed. In case of multiloculated biliary or complicated biliary cyst (hemorrhagic cyst), imaging is often not reliable in ruling out cystadenoma. The most challenging differential diagnosis is hemorrhagic cysts where ultrasound can visualize internal clots as papillary excrescences or nodular and irregular septal images. CT scan is less sensitive than ultrasound in visualizing intracystic blood clots and at times it can only depict homogeneous low density areas inside a huge cyst. In these cases, a discrepancy between US and CT may suggest the correct diagnosis of hemorrhagic cysts. Recently MRI has been shown to be helpful. It was reported that high signals from clot formation could be detected both in T1 and in T2 weighted sequences, and are useful in differentiating it from cystadenocarcinoma, which usually exhibits low signals<sup>[8]</sup>. It should be noted that if a hemorrhagic cyst is suspected, MRI should not be delayed because hemorrhagic signal intensity becomes rapidly low when clots are liquefied<sup>[9]</sup>. History, on the contrary, is totally unreliable to suspect a hemorrhagic cyst since intracystic hemorrhage can occur in the absence of any symptom<sup>[10]</sup>. In the presence of a complicated or multiloculated hepatic cyst, a fine needle aspiration (FNA) of intracystic fluid can be performed to rule out a biliary cyst neoplasm. The presence of atypical cells, mucinous material and elevated levels of CEA and CA19-9 in the cystic fluid has been typically observed both in cystadenoma and in cystadenocarcinoma, but not in hepatic cysts<sup>[11,12]</sup> although CA19-9 is equally expressed in paraffin-embedded tissues from both hepatic cysts and biliary cyst neoplasms<sup>[13]</sup>. To complicate things further, high CA19-9 cyst-fluid levels have been occasionally found in complicated hepatic cysts<sup>[14]</sup> and data on CA19-9 serum levels are scanty and inconclusive<sup>[13,15]</sup>. The macroscopic appearance of the intracystic fluid is likewise useless since in biliary cyst tumors it can be mucinous, but also bile stained or clear, as it occurs when there is abundance of ovary stroma<sup>[16]</sup>. On the whole, FNA alone does not have adequate sensitivity and specificity to confirm or exclude biliary cyst tumors and should be always evaluated together with imaging.

Similar to intracystic bleeding, non suppurative, granulomatous infection of a biliary cyst may simulate cystadenoma and cystadenocarcinoma by the presence

of a thickened wall and a solid component infiltrating the peri-cystic surrounding tissue, thus mimicking a neoplastic lesion<sup>[17]</sup>. On the other hand, suppurated hepatic cysts and echinococcal cysts do not generally pose diagnostic problems. Sonography can easily differentiate the mobile internal debris typical of abscess formation or the multilayered appearance of the echinococcal cystic wall, and only an unexperienced sonographer can confuse the multiloculated appearance of cystadenoma with multiple daughter cysts of echinococcus<sup>[18]</sup>. When in doubt, the presence of anti-echinococcal antibodies is diagnostic.

Mesenchymal hamartoma is an uncommon benign lesion composed of bile ducts, immature mesenchymal cells and hepatocytes and may appear as a multiseptated cyst, causing confusion with biliary cystadenoma. Isolated septal calcification can be observed in both lesions and does not aid in the correct diagnosis<sup>[19]</sup>. Most of the cases are diagnosed in childhood when it presents as a large cystic mass<sup>[20]</sup> and very few cases have been reported in adults<sup>[21]</sup>. FNA can be diagnostic by showing clusters of both epithelial and mesenchymal spindle-shaped cells with pieces of loose connective tissue<sup>[22]</sup>.

Ciliated hepatic foregut cyst is a very rare benign lesion arising from an abnormal budding of the primitive foregut and lined by stratified ciliated columnar cells, similar to the bronchial epithelium. These cysts are often anechogenic, but at times they may show internal echoes and can reach considerable dimensions posing differential diagnostic problems of cystadenoma. The typical subcapsular location in segment IV and the presence of a strong T2 hyper-intensity with T1 signal variability on MRI are quite characteristic. Another helpful clue may be the presence of scattered hyperechogenic spots within the cystic wall with no acoustic shadowing, which are related to cartilaginous remnants<sup>[23]</sup>.

Abdominal lymphangioma may be occasionally located in the liver and appear as a single multiseptated lesion<sup>[24]</sup>. If this diagnosis is suspected, fine needle aspiration is not recommended due to the risk of massive lymphorrhea<sup>[25]</sup> and complete surgical resection should be accomplished, even without a precise pre-operative diagnosis.

Differential diagnosis with cystic hemangioma may also be a problem, especially in the case of a giant hemangioma, with large hypoechogenic central areas simulating the giant cystadenoma. CT and magnetic resonance imaging point out to the correct diagnosis by showing an enhancing rim with globular vessels and centripetal filling, with sparing of the large central lacunar areas<sup>[26]</sup>.

Hepatocellular carcinoma and cholangiocarcinoma may occasionally present as a large hypodense and multiseptated mass at CT scan, simulating a cystic lesion or a biliary cyst tumor. In these cases, arterial phase enhancement on dynamic CT and washing out of the contrast material in the portal phase, are diagnostic<sup>[27]</sup>.

Isolated mucin producing metastasis from melanoma

or colon adenocarcinoma may at times simulate biliary cyst tumors and even benign hepatic cysts. These metastases may be associated to segmental dilatation of the peripheral bile ducts, caused by the presence of mucin casts occluding the bile ducts themselves<sup>[28]</sup>.

Once a diagnosis of cystadenoma is made, surgery should be performed in any case, because differential diagnosis with cystadenocarcinoma is unreliable and cystadenoma itself has a malignant potential. If the pre-operative diagnostic work up, including cytologic aspiration of the lesion, has not produced a definitive diagnosis and surgery is performed because of a suspected bile cyst tumor, an intraoperative biopsy of the lesion is recommended since an extensive lymph node resection would be required if the tumor is proved to be a cholangiocarcinoma<sup>[14]</sup>. It is important that final decisions regarding indications and type of intervention are jointly discussed by the surgeon and a radiologist expert in liver tumor imaging, particularly in the case of cystic liver tumors, the most frequent mistake is the resection of a complicated biliary cyst incorrectly diagnosed as a cystadenoma.

## MULTIPLE CYSTIC TUMORS

When multiple cystic lesions are observed throughout the liver parenchyma, the most important diagnostic problem is to exclude cystic liver metastases. The primary tumor is usually colonic adenocarcinoma, melanoma, carcinoid, breast or renal or ovarian cancer. Colonic cancer is the common, accounting for about 50% of all hepatic metastases<sup>[27]</sup>. The presence of intra- or peritumoral calcifications may suggest a specific diagnosis, being more frequent in the case of gastrointestinal, ovarian, breast and renal metastases compared to other types of tumors<sup>[29]</sup>. The cystic nature of the metastasis is secondary to the rapid growth and insufficient hepatic arterial supply of the lesion, leading to a large central necrosis simulating a cyst<sup>[30]</sup>.

The differential diagnosis with polycystic liver disease and multiple liver abscesses is usually an easy task on US and CT scan. In case of cystic metastases, the borders of the cystic lesions are heterogeneous and ill-defined, the cystic wall is irregular and the vessels are amputated, but not displaced as in polycystic liver disease. In addition, cystic metastasis has a peripheral enhancing rim on the arterial phase of CT scan and MRI<sup>[27]</sup>, while polycystic liver disease does not show any type of enhancement<sup>[31]</sup>. Another helpful sign may be the presence of peribiliary cysts, such as small cysts with a diameter of less than 10 mm, located within the hilum and adjacent to the hepatic ducts, more frequently on the left. These small cysts are typically observed only in polycystic liver disease and should not be confused with the segmental biliary dilatations occasionally observed in the case of metastasis or macronodular cirrhosis, which are less regular and never adjacent to the main ducts<sup>[32]</sup>.

Multiple hepatic pyogenic microabscesses are easy to differentiate from metastasis by clinical symptoms and

**Figure 2** T1 weighted images showing the left multiple hypo-intense focal lesions of the liver parenchyma simulating metastases (A) and T2 weighted images showing a strong hyper-intensity in Von Meyenburg complex disclosing its cystic nature (B).

the presence of a late faint enhancing peripheral rim on CT scan and MRI<sup>[33]</sup>. This rim is quite different from the early arterial enhancing ring observed in the case of metastasis. An additional sign pointing to liver abscesses is the presence of air densities inside the lesions, which is almost never observed in the case of cystic metastasis.

The differential diagnosis with other types of ductal plate malformations, such as Caroli's disease, Caroli's syndrome and von Meyenburg complex, may at times be more difficult. Caroli's disease is a congenital autosomal recessive malformation characterized by diffuse or segmental cystic dilation of the intrahepatic biliary system. In Caroli's syndrome, periportal congenital fibrosis or multicystic renal diseases are observed in addition to biliary dilations. In both cases, these dilations are less regular than in polycystic liver disease and have intraluminal protrusions or may be associated to segmental dilation of the intrahepatic bile ducts, thus simulating cholangiocarcinoma or multiple cystic metastases. The presence of the "dot signs", such as an intracystic portal branch, surrounded by the dilated bile duct and the demonstration of a communication of the cysts with the biliary system on MR cholangiography, is diagnostic and excludes liver metastasis<sup>[34]</sup>.

Von Meyenburg complex and bile duct hamartoma are small focal developmental lesions composed of innumerable dilated bile ducts mixed with a dense collagenous stroma. The dilated bile duct foci, contrary to those observed in Caroli's disease and Caroli's syndrome do not communicate with the biliary system<sup>[16]</sup>. Depending on the prevalence of fibrous stroma or biliary dilation, these lesions can appear as predominantly solid and cystic or intermediate and may be easily confused with metastases, microabscesses and even biliary cystadenocarcinoma<sup>[35]</sup>. Occasionally, the differential diagnosis may be a real dilemma. Although biliary hamartomas are more uniform in size and measure less than 1 cm in diameter, CT scan and ultrasound are often not specific. MRI, on the contrary, can be very helpful by identifying strong hyper-intensity in biliary hamartomas on heavily T2 weighted images (Figure 2), often with a signal intensity similar to that of the spleen<sup>[36]</sup>. These features, however, are not always sufficient to make a precise diagnosis, especially in intermediate or predominantly solid von Meyenburg complex and a percutaneous or even surgical biopsy is

occasionally required<sup>[37]</sup>. The issue is further complicated by very rare reports on malignant transformation of these hamartomas to cholangiocarcinoma, making this type of cystic malformation the most challenging to differentiate from cystic neoplastic lesions.

### INTRODUCTION

Laminin was initially identified by TIMPL and MARTIN in 1979<sup>[1]</sup>, from a murine fibrosarcoma, the Engelbreth-Holm-Swan (EHS) tumor. Its molecule is a large complex (approximately 850 kilodaltons) made up of three polypeptidic chains called  $\alpha 1$  (with approximately 440 kDa),  $\beta 1$  e  $\gamma 1$  (each one with approximately 200 kDa). These chains are intertwined by disulphide bridges, forming a characteristic cross-shaped asymmetrical structure<sup>[1-3]</sup>.

Laminin is one of the main glycoproteins of the basement membrane and participates in a series of such biological phenomena as adhesion, migration, cellular differentiation and growth, inflammatory response and the maintenance of the cytoskeleton upon its binding to several components of the matrix, such as collagen type IV, heparan-sulphate and entacin<sup>[3-7]</sup>.

Laminin receptors are also found on the surface of a wide range of cells, such as platelets, muscle cells, neutrophils, endothelial cells and hepatocytes<sup>[3,6]</sup>. Recently, the existence of a class of transmembrane receptors for laminin known as integrins has been demonstrated. These integrins are involved in the mechanisms of cell-cell, cell-matrix and, more recently, pathogen-cell adhesion<sup>[3,7,8]</sup>. Laminin binding proteins have been described in a number of such pathogenic agents as *Staphylococcus aureus*, *Escherichia coli*, *Helicobacter pylori* (*H pylori*), and *Candida albicans*.

### LAMININ IN THE LIVER

In normal liver, laminin is found around the vessels and biliary ducts, where basement membranes are identified. Little or only a slight reaction for antibodies against laminin can be observed in the hepatic sinusoids<sup>[9,10]</sup>. In this organ, glycoprotein is also involved in intracellular activities, such as the normal differentiation of the biliary ducts, genetic expressions for albumin messenger RNA in hepatocyte, and regeneration with normal

### Abstract

Laminin is a glycoprotein which has an important role in the mechanism of fibrogenesis and is, thus, related to hepatic fibrosis in addition to presenting increased levels in several types of neoplasias. However, its determination is not routinely considered in the study of hepatic fibrosis. In this review, the authors critically comment on the role of this glycoprotein compared to other markers of fibrosis through non-invasive procedures (Fibroscan). They also consider its clinical investigational potential and believe that the continuation of these investigations might contribute to a better understanding of the fibrogenic mechanism, which could in turn either lead to the identification of patients at risk of developing fibrosis non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH) or at least be used as an indicator for hepatic biopsy in such patients. Finally, the authors believe that serum laminin determination might contribute to the diagnosis of epithelial tumor metastasis and peritoneal carcinomatosis.

lobular organization following partial hepatectomy<sup>[11-14]</sup>. Laminin is thought to be synthesized by hepatocytes and sinusoidal cells<sup>[14,15]</sup>. Among all cellular types in the sinusoids, special attention should be given to stellate cells or lipocytes, which produce the largest amount of serum laminin.

With the development of hepatic cirrhosis, laminin and collagen deposition occurs both along the fibers of septal fibrosis and subendothelial sinusoids or Disse's space. At the latter site, laminin deposition, together with collagen deposition, determine the formation of a true basement membrane along sinusoids. This phenomenon is called capillarization of Disse's space<sup>[16]</sup>. Besides the increased production of laminin in the liver an additional effect due to a lack of degradation of this protein by liver endothelial cells should also be taken into consideration. As demonstrated by Smedsrod *et al*<sup>[17]</sup> in an experimental model, apart from an increase in tissue deposition or turnover, there would be a decrease in the liver's ability to degrade this protein. With the development of anti-laminin antibodies, directed against the laminin P1 portion, increased levels of this circulating protein were observed in the more advanced stages of fibrosis in patients with hepatic disease<sup>[18-22]</sup> and as expected these serum levels have a positive correlation with portal pressure<sup>[21-26]</sup>. Kropf *et al* have proposed laminin serum concentration as a sensitive screening test for hepatic fibrotic disease and portal hypertension, if the test is carried out together with hyaluronic acid determination<sup>[21,22]</sup>. Laminin as an isolated parameter was found to be highly sensitive, but with low specificity to detect portal pressure above 5 mmHg.

We have assessed laminin serum levels in patients with alcoholic liver cirrhosis and with preserved hepatic function in an attempt to evaluate its predictive value for the risk of variceal bleeding, which is assessed through a portal pressure level equal to or higher than 12 mmHg<sup>[26]</sup>. In these patients, serum laminin levels were significantly correlated with portal pressure levels ( $r = 0.70$ ). Such correlation enabled us to find a cut-off level for serum laminin that could correspond more closely to a portal pressure of 12 mmHg, accepted as a threshold for esophageal rupture in those patients. As it was found by others, these laminin levels presented very low specificity and negative predictive values to identify those patients with increased portal hypertension. In fact, patients presenting laminin serum concentration of less than 2.20 U/mL have almost 50% chance of having or not a portal pressure of 12 mmHg or higher.

This low specificity of serum laminin determination in portal hypertension could be related to the fact that laminin levels reflect only structural changes and do not take into account changes in the systemic and portal blood flow, which contribute significantly to portal pressure.

On the other hand, due to the great distribution of laminin in the body's basement membranes, and its limited participation in the liver's extracellular matrix, some issues need to be further investigated and clarified as for the origin of this protein. A study of concentrations of

serum laminin in different vascular territories showed that its levels in supra-hepatic veins were higher compared to those found in the renal and femoral veins of patients with fibrosis or hepatic cirrhosis<sup>[27]</sup>, which would be indicative of its hepatic synthesis. Similar findings were also demonstrated in control and carbon tetrachloride treated animals; there was also a significant correlation found between laminin serum levels and the degree of hepatic fibrosis<sup>[28]</sup> and an important increase was observed in the concentration of this glycoprotein in the supra-hepatic vein when compared to its amount in portal blood<sup>[29]</sup>. However, the hepatic contribution was much smaller in cirrhotic animals than in those with fibrosis as the sole condition. This fact could point towards decreased hepatic extraction of the protein or an increase in laminin synthesis in other organs of the splanchnic circulation, secondary to the venous congestion of this system. The latter possibility seems to be reinforced by studies with patients infected by *Schistosoma mansoni*. In the hepatosplenic form of the disease portal hypertension is due to periportal fibrosis, which determines pre-sinusoidal portal hypertension with large splenomegaly. Because these patients do not present hepatic cirrhosis, collagenization and capillarization of with Disse's space are not usually found. In these patients, initial studies revealed a significant increase in the levels of circulating laminin, when compared to patients presenting hepatointestinal form and the control group<sup>[30-32]</sup>. This increase correlated with the levels of portal pressure measured *via* the splenic vein<sup>[30, 31]</sup>. But, when these patients were submitted to splenectomy, a significantly decrease in the levels of type IV collagen and laminin in the serum of these patients was observed<sup>[32]</sup>. Since an increased synthesis of basement membrane in the spleen of such patients has been reported, the reduced levels of laminin after splenectomy strongly suggest an important participation of an extra-hepatic source for the serum levels of laminin in these patients<sup>[33,34]</sup>.

Thus, not only might circulating levels of laminin reflect the hepatic processes of synthesis and degradation, but also the increase of the synthesis of basement membranes, as a result of the congestion observed in other splanchnic organs.

Hence, the use of serum laminin as a marker of portal hypertension for clinical use suffers from other extra-hepatic factors which might influence its blood concentration. In addition, recent studies with Fibroscan have found sensitivity and specificity for the diagnosis of portal hypertension in cirrhotic patients far higher than those found through the determination of serum laminin<sup>[35,36]</sup>.

Due to this relationship between laminin tissue deposition and advanced fibrosis, serum levels of laminin have been used by several authors as a non-invasive parameter to assess liver fibrosis in alcoholic patients as well as in those presenting with viral hepatitis and hemochromatosis<sup>[37]</sup>. Such determination, however, was progressively discontinued as it did not demonstrate to be superior to those of other such components of the extracellular matrix as TIMPs and hyaluronic acid. However,

in recent studies laminin determination has been included in a set of test together with PIIINP, hydroxyproline, prothrombin activity, and AST/ALT in the diagnosis of advanced fibrosis in chronic hepatitis C<sup>[35,38-41]</sup>.

In non-alcoholic fatty liver disease (NAFLD), however, laminin serum levels should be further investigated. In this condition, the fibrogenic stimulus in the perisinusoidal region occurs earlier, with the detection of pericellular and perisinusoidal fibrosis in the early stages of fibrosis<sup>[39]</sup>.

We have more recently been able to assess serum laminin values in NAFLD, and to measure collagen type IV and hyaluronic acid<sup>[42]</sup>. Ballooning and hepatic fibrosis in these patients is associated with the progression of the disease<sup>[43]</sup>. In this preliminary study, we analyzed the discriminative ability of serum laminin, type IV collagen and hyaluronan and hepatic enzymes levels to predict the presence of fibrosis in 30 overweight patients divided into two groups according to the absence or presence of fibrosis upon liver biopsy. All the three biochemical markers of fibrosis were able to differentiate between these two groups, but laminin presented the best correlation ( $r_s = 0.65$ ) with hepatic fibrosis and the best diagnostic performance, with 87% accuracy. When compared with the BAAT criteria proposed by Ratzliff *et al*<sup>[44]</sup>, laminin values presented a better diagnostic accuracy for the diagnosis of septal fibrosis (83%  $\times$  70%) and for the presence of any fibrosis.

Although laminin was not evaluated, in a study with 112 patients with NAFLD, 70 of whom with at least grade 1 fibrosis, Sakugawa *et al*<sup>[38]</sup> were able to confirm our findings that hyaluronic acid and type IV collagen were useful in discriminating the patients with fibrosis from those with steatosis only. The subtle differences in diagnostic accuracy performance for these biochemical markers of liver fibrosis found in our study and that by Sakugawa *et al*<sup>[38]</sup> might be attributable to the fact that their study included a higher number of patients with any given degree of fibrosis (62%  $\times$  37%) or advanced fibrosis (37%  $\times$  10%). On the other hand, Lydatakis *et al*<sup>[36]</sup> showed that HA determination was more useful in the diagnosis of fibrosis than serum laminin and type IV collagen. No correlation was observed among laminin level and the grade of hepatic fibrosis, possibly due to the method and patients selection. It's important to take into account the small number of studies on fibrosis markers by indirect method.

In studies by Sakugawa *et al*<sup>[38]</sup> HA serum levels have been well demonstrated to significantly increase in cirrhotic patients when compared to the other degrees of fibrosis. In this manner, the determination of serum laminin values can not only play a useful role in the identification of NAFLD patients with a certain degree of fibrosis, but also in the distinction between patients with simple steatosis and those with non-alcoholic steatohepatitis (NASH) and a certain degree of fibrosis. Finally, the determination of serum laminin values might become a selection parameter of patients for the indication of fibrosis. A study bearing this purpose is currently being conducted in our laboratories.

## SERUM LAMININ IN NEOPLASTIC DISEASES

Not only have serum laminin levels been studied in patients with liver diseases, but also in patients with cancer, especially in cases where tumor proliferation and invasion are found. Serum values tend to increase significantly with the emergence of metastases, irrespective of tumor lineage or the organ originating the neoplasm<sup>[45-48]</sup>.

Hence, serum laminin could be regarded as a tumoral marker in cases of alterations in the basement membrane, proliferation and tumoral invasion<sup>[48]</sup>. In fact serum laminin concentration is increased in metastatic cancer of different origins as melanoma, gastric adenocarcinoma, hepatocellular carcinoma, colorectal cancer, epithelial ovarian tumor<sup>[49-52]</sup>.

Grounded on these observations and the findings by Byers *et al*<sup>[53]</sup> and Chu *et al*<sup>[54]</sup>, who observed increased concentrations of laminin in the ascites of metastatic breast tumors, we decided to study the discriminative ability for this glycoprotein in serum and in ascites to (differentiate) discriminate between ascites due to peritoneal carcinomatosis and hepatic cirrhotics<sup>[55]</sup>. By using polyclonal antibodies against laminin isolated from human placenta, a significant increase in serum and ascitic laminin levels was observed in patients with peritoneal carcinomatosis when compared to patients with hepatic cirrhosis with or without hepatocellular carcinoma.

Although immunohistochemical studies have shown important laminin deposition in cases of neoplastic transformation of hepatocytes<sup>[56,57]</sup> and despite the considerable representation of the group of patients with HCC once they presented advanced disease with large tumor masses with high serum alpha-fetoprotein levels, blood and ascites laminin values did not distinguish these patients from those with liver cirrhosis without tumor complication. In benign and malignant ascites, serum laminin values were higher and showed excellent correlation with its value in the ascitic fluid ( $r = 0.93$ ,  $P < 0.0001$ ). Thus, these findings indicated that serum laminin levels can also be a marker of neoplastic ascites. Indeed serum laminin showed high discriminative ability for the diagnosis of malignant ascites, with 75% sensitivity, 100% specificity and 91% accuracy<sup>[43]</sup>.

So, considering the potential of laminin for clinical investigation, it seems to us that more studies are needed in order to clarify if there are still a place for serum laminin determination in the diagnosis of hepatic fibrosis in NAFLD and in the diagnosis of epithelial tumors metastasis and peritoneal carcinomatosis.

### Abstract

**AIM:** To investigate the roles of the adipocytokines, ghrelin and leptin in gastric cancer cachexia.

**METHODS:** Resistin, ghrelin, leptin, adiponectin, insulin and insulin-like growth factor (IGF- I ), were measured in 30 healthy subjects, and 60 gastric cancer patients of which 30 suffered from cancer-induced cachexia and 30 served as a control group. The relationships between hormones, body mass index (BMI) loss ratio, age, gender, and Glasgow Prognostic Score (GPS) were investigated.

**RESULTS:** Cachexia patients had higher tumor stage and GPS when compared with non-cachexia patients ( $P < 0.05$ ). Ghrelin, resistin, leptin, adiponectin and IGF- I , showed a significant correlation with BMI loss ratio and GPS ( $P < 0.05$ ). A strong correlation was seen between GPS and BMI loss ( $R = -0.570$ ,  $P < 0.0001$ ). Multivariate analysis indicated that BMI loss was significantly independent as a predictor of ghrelin, resistin, leptin and IGF- I ( $P < 0.05$ ). Existence of an important significant relationship between resistin and insulin resistance was also noted.

**CONCLUSION:** These results showed that serum ghrelin, leptin, adiponectin, and IGF- I play important roles in cachexia-related gastric cancers. No relationship

### INTRODUCTION

Cachexia, characterized by marked weight loss, anorexia, asthenia and anemia, is often associated with the presence and growth of a tumor and leads to malnutrition secondary to the induction of anorexia or decreased food intake<sup>[1]</sup>. As major mediators of metabolism; growth hormone (GH) and insulin-like growth factor- I (IGF- I ) have attracted many researchers in the field of cachexia associated gastrointestinal cancer<sup>[2,3]</sup>. Recent evidence suggests that an intricate interplay between multiple hypothalamic effector pathways and afferent hormonal signals of diverse systemic origin (resistin, leptin and adiponectin from adipocytes, ghrelin and polypeptides from the gastrointestinal tract, and insulin from the pancreas) is important in the regulation of energy intake and expenditure<sup>[4]</sup>.

Ghrelin was discovered as the peptide hormone that stimulates the release of GH from the anterior pituitary and has crucial roles in the regulation of food intake and energy homeostasis in both humans and rodents<sup>[5]</sup>. It is produced primarily by the mammalian gastric enteroendocrine cells of the oxyntic mucosa, likely the

X/A-like cells<sup>[6]</sup>. It has been reported that there was an increase in the levels of total ghrelin in cachectic lung<sup>[7]</sup>, breast and colon<sup>[8]</sup> cancer patients. Ghrelin infusion has recently been shown to increase appetite in subjects with cancer-induced cachexia<sup>[9]</sup>. Data on the association between ghrelin levels and gastric cancer cachexia are contradictory.

Leptin is a member of a group of adipocyte-secreted proteins, collectively known as the adipocytokines. Leptin acts in the central nervous system, particularly in the hypothalamus, to suppress food intake and stimulate energy expenditure<sup>[4]</sup>. Leptin levels were reported to be low in gastrointestinal<sup>[10]</sup> and pancreatic cancers<sup>[11]</sup>, and high in breast and gynecologic cancer patients<sup>[12]</sup>.

Resistin which is an 108-amino acid, 12.5-kDa peptide hormone member of the cysteine-rich secreted protein family, is also referred to as resistin-like molecules or "found in inflammatory zone" molecules. Resistin has mainly been studied in mice, in which there is compelling evidence linking the protein to insulin resistance, obesity, and type 2 diabetes mellitus<sup>[13]</sup>. There is only 55% amino acid homology between human and murine resistin, and findings have been inconclusive regarding a potential role of resistin in human insulin regulation, obesity and type 2 diabetes mellitus<sup>[14]</sup>. There is no information about the role of resistin in cancer cachexia.

Adiponectin is a member of the adipocytokine family. It is induced during adipocyte differentiation, and its secretion is stimulated by insulin and IGF- I<sup>[4]</sup>. A negative correlation between obesity and circulating adiponectin has been well established and adiponectin concentrations increase concomitantly with weight loss<sup>[15,16]</sup>. Although low adiponectin levels were reported among patients with weight-loss in advanced lung cancer<sup>[16]</sup>, there was no correlation between adiponectin levels and cachexia in breast and colon cancer patients<sup>[8]</sup>. A more recent study demonstrated that an impaired response of adiponectin, ghrelin, and leptin may play a role in the pathogenesis of cancer cachexia with breast and colon cancer<sup>[8]</sup>. However, the role of adiponectin in gastric cancer patients is not clearly understood.

There is increasing evidence that the presence of a systemic inflammatory response, as evidenced by elevated concentrations of C-reactive protein (CRP), is a prognostic factor independent of stage, performance status and weight loss in patients with advanced cancer. Recently, Forrest *et al*<sup>[17,18]</sup> have shown that an elevated CRP and hypoalbuminemia may be combined to form a score, the Glasgow Prognostic score (GPS), which has prognostic value in patients with inoperable non-small-cell lung cancer.

The aim of the present study was to investigate: (1) the nature of the relationship between serum levels of resistin, leptin, adiponectin, ghrelin, and cancer related cachexia; (2) the relationship of these three hormones, insulin, IGF- I and insulin-resistance; and (3) to evaluate the relation between the hormones and GPS.

## MATERIALS AND METHODS

The protocol was approved by the Gazi University

Medical Faculty Ethics Committee and was conducted between October 2005 and December 2006. All clinical investigations described in this paper were conducted within the guidelines mentioned in The Declaration of Helsinki. Patients with a histopathological diagnosis of gastric adenocarcinoma were included in the study, while patients with gastric lymphoma and malignant stromal tumors were excluded from the study for homogenization. The contributors were informed of the nature of the study and informed consent was obtained.

### Exclusion criteria

Patients were excluded if there was evidence of drug or alcohol abuse defined as any use of reactional drugs or more than two drinks per day; presence of congestive heart failure (ejection fraction < 35% on a echocardiogram or signs such as edema, dyspnea, or jugular venous distension); severe liver disease; severe chronic obstructive pulmonary disease; diabetes with hemoglobin A1c levels greater than 7%; fasting plasma glucose greater than 160 mg/dL or random glucose levels greater than 200 mg/dL; presence of thyroid diseases or renal failure; active infection (temperature > 38°C or other signs or symptoms of infection); history of neuroendocrine tumor; use of glucocorticoids, progesterone, testosterone or other orexigenic agents; history of eating disorders or dysphagia; treatment by chemotherapy, radiotherapy, or a major operation within the last 6 mo prior to hospitalization; malignancy with an obstructing lesion in the cardia or antrum together or if patients refused consent.

Control group patients were chosen from healthy people over 40 years of age, because the majority of the patients were over 50 and most of the parameters studied in the study were affected by age.

### Demographic findings and anthropometrical measurements

Clinical parameters obtained in the study included age, gender, BMI, cancer localization and staging, cachexia, performance status, and GPS. All pathology reports were evaluated and data on tumor histology were recorded. The extent of tumor spread was recorded using the American Joint Cancer Committee TNM Classification and Stage System. Patient height and weight were measured and BMI was calculated as body weight divided by height squared (kg/m<sup>2</sup>). Patients were defined as cachectic, based on > 10% reduction in BMI within 6 mo prior to admission, as calculated from reported weight differences given by these subjects<sup>[1]</sup>. Performance status was evaluated by using the World Health Organization (WHO) performance status.

### Analytical methods

Blood samples were drawn from each subject between 8 and 9 AM, after an overnight bed rest for measurement of the hormones, CRP, and fasting sugar, as well as a complete blood count and chemistry. All samples were stored at -80°C until analytical measurements were

performed, except for glucose, which was determined immediately after blood was drawn.

### Biochemical parameters

Routine laboratory measurements of hemoglobin, albumin and CRP were conducted. Serum glucose was measured using the glucose oxidase method. Homeostasis model assessment of insulin resistance (HOMA-IR) was calculated from fasting insulin and glucose levels [fasting glucose (millimoles per litre X fasting insulin microunits per millilitre)/22.5] as previously described<sup>[19]</sup>.

### Prealbumin

Prealbumin concentrations in the serum were determined using a commercial solid phase sandwich enzyme linked immuno-sorbent assay (ELISA) kit from Immundiagnostic® kit (Bensheim, Germany).

### Hormone determination

Resistin, leptin, adiponectin, IGF- I, and insulin concentrations in serum were determined using a commercially available ELISA kit from RayBiotech® (Norcross, GA, USA). The intra- and interassay coefficients of variation were less than 7%-10% for all parameters.

### Active ghrelin levels

For human ghrelin assessment, we used a RIA kit (Linco Research®, Missouri, USA) which incorporates an antibody that is specific for active ghrelin. The sensitivity was 100 pg/mL (in a 100 µL sample size) with a range of 100 to 10000 pg/mL. The intra- and inter assay coefficients of variation were 5.63% and 16%, respectively.

### Statistical analysis

All calculations and statistical tests were performed using SPSS (version 13.00 software, SPSS, Inc., Chicago, IL, USA). Descriptive data were expressed as mean  $\pm$  SD. Categorical parameters were expressed as percentage. The study variables were compared between the study groups using Student *t*-tests or ANOVA for continuous variables and Fisher exact test for categorical variables. For multiple comparisons, the Tukey test was used. Pearson or Kendall's tau-b correlation coefficient was used to determine the relationship between continuous variables. Multiple linear regression analysis was performed to ascertain independent effects of BM, after adjustment for age, gender, and differentiation of tumor on adiponectin, ghrelin, leptin, and IGF- I levels. All significance tests were two-tailed.

## RESULTS

### Subjects characteristics and demographic finding

Sixty patients (30 cachectic and 30 non-cachectic), who satisfied study criteria, were selected from 76 gastric cancer patients admitted to our unit between the study dates.

The patient demographic characteristics are presented in Table 1. There was no significant difference between the ages of cachectic ( $63.6 \pm 13.8$ ), non-cachectic ( $55.6 \pm 13.3$ ), and control patients ( $56.4 \pm 3.0$ ). There was no difference with respect to gender within the three groups. While 60% of non-cachectic patients had stage 1 and 2 cancers, this rate was only 10% in cachectic patients. The majority of cachectic patients were stage 3 (40%) or 4 (50%) and in non-cachectic patients, this ratio was 25% and 15%, respectively ( $P = 0.007$ ). None of the non-cachectic patients were inoperable. On the other hand, there were 2 inoperable patients (5%) in the cachectic group ( $P < 0.05$ ). There was no difference between the two groups according to tumor location and differentiation ( $P = 0.369$ ). While the WHO score for gastric cancer patients was significantly worse than the control group ( $P < 0.001$ ), there was no significant difference between the WHO scores of cachectic and non-cachectic groups ( $P = 0.108$ ). Baseline biochemical findings and changes in BMI and weights are listed in Table 2. Changes in BMI and weight were significantly higher in cachectic patients than the non-cachectic patients ( $P < 0.001$ ). Hb levels of cachectic patients were significantly lower than the levels of control and non cachectic patients ( $P < 0.001$ ). There were no significant differences in the levels of TSH, AST, creatinine, WBC or lymphocytes in the three groups.

### Ghrelin

Mean ghrelin levels were significantly elevated in cachectic patients compared with non-cachectic cancer patients and healthy control subjects ( $2305 \pm 818$  ng/mL *vs*  $1980 \pm 913$  ng/mL, and  $1332 \pm 620$  ng/mL, respectively,  $P = 0.013$ ; Table 3). No significant difference in ghrelin levels between non-cachexia and healthy control groups was observed.

A significant negative correlation was found between the serum ghrelin levels and BMI loss in the previous 6 mo ( $R = -0.439$ ,  $P = 0.008$ , Figure 1A). There was also a positive significant correlation between the serum ghrelin levels and age ( $R = 0.467$ ,  $P = 0.039$ , Table 4), and GPS ( $R = 0.327$ ,  $P = 0.002$ ).

### Resistin

Mean resistin levels were significantly elevated in cachectic patients compared with non-cachectic cancer patients and healthy control subjects ( $P = 0.013$ ). It was found that resistin levels in non-cachectic gastric cancer patients were significantly higher than the control group ( $P = 0.042$ , Table 3). A significant negative correlation was found between the serum ghrelin levels and BMI loss in the previous 6 mo ( $R = -0.574$ ,  $P < 0.001$ , Figure 1B), and GPS ( $R = 0.387$ ,  $P < 0.01$ , Table 4). There was also a significant correlation between the serum resistin levels and insulin ( $R = 0.348$ ,  $P = 0.016$ ), glucose ( $R = 0.418$ ,  $P = 0.0018$ ), and HOMA-IR ( $R = 0.518$ ,  $P = 0.0001$ , Table 4).

### Adiponectin

The average serum adiponectin levels were  $36.5 \pm 15.0$  µg/mL in patients with cachectic gastric cancer,

<sup>a</sup> $P < 0.05$  vs healthy controls and non cachexia; <sup>c</sup> $P < 0.05$  vs healthy controls.

22.6  $\pm$  12.4  $\mu$ g/mL in healthy controls, and 27.8  $\pm$  11.9  $\mu$ g/mL in the non-cachexia group. Thus, there was a significant difference between the cachexia group and healthy and non-cachexia groups ( $P = 0.006$ , Table 3). However, there was no significant difference between the serum adiponectin levels of healthy and non-cachectic controls.

The association between adiponectin levels and BMI loss in the last 6 mo is plotted in Figure 1C. A significant

negative correlation was found between the serum adiponectin levels and BMI changes in the previous 6 mo ( $R = -0.283$ ,  $P = 0.028$ ). Adiponectin showed a strong positive correlation with GPS ( $R = 0.241$ ,  $P = 0.008$ ).

### Leptin

Cachectic gastric cancer patients had significantly higher serum leptin levels than healthy controls and non-cachectic gastric cancer patients (3 405  $\pm$  640 pg/mL

**Figure 1** A: Correlation between serum ghrelin levels and BMI change in the 6 mo before recruitment; B: Correlation between serum resistin levels and BMI change in the 6 mo before recruitment; C: Correlation between serum adiponectin levels and BMI change in the 6 mo before recruitment; D: Correlation between serum leptin levels and BMI change in the 6 mo before recruitment; E: Correlation between serum IGF-1 levels and BMI change in the 6 mo before recruitment. R: Pearson correlation coefficient.

vs  $2623 \pm 665$  pg/mL and  $2810 \pm 818$  pg/mL, respectively,  $P = 0.003$ , Table 3). No significant differences in serum leptin levels between non-cachexia and healthy control groups were observed. A significant negative correlation was found between leptin levels and BMI loss in the previous 6 mo ( $R = -0.438$ ,  $P < 0.001$ , Figure 1D). Leptin also showed a strong positive correlation with GPS ( $R = 0.303$ ,  $P = 0.003$ ).

#### Albumin, prealbumin, CRP, and GPS

Albumin and prealbumin, markers of nutritional status, were lower in gastric cancer patients when compared with healthy and non-cachectic subjects ( $P = 0.03$ ,  $P = 0.001$ , respectively). The mean CRP levels were significantly higher in cachexia patients than the levels

of healthy and non-cachexia controls ( $P < 0.001$ ). CRP levels also increased significantly in non-cachectic and healthy subjects ( $P < 0.05$ , Table 3). The average GPS was significantly higher in cachexia patients than non-cachectic cancer patients and healthy controls ( $P < 0.001$ ). BMI loss in last 6 mo showed a strong negative correlation with GPS ( $R = -0.758$ ,  $P < 0.0001$ ) and CRP ( $R = -0.570$ ,  $P < 0.0001$ ), however, a positive correlation with prealbumin ( $R = 0.302$ ,  $P = 0.019$ ).

#### Glucose, insulin, and HOMA-IR

Fasting glucose levels increased borderline significantly in cachectic patients compared with the healthy and non-cachectic patients ( $P = 0.05$ ). Insulin levels were increased in non-cachectic gastric cancer patients when

**Table 3** All biochemical parameters in blood in whole subjects are shown

	Healthy controls ( <i>n</i> = 30)	Patients with gastric cancer		<i>P</i> -value (between groups) (ANOVA)

compared with cachectics (*P* = 0.04); however, there was no significant difference between non-cachectic cancer patients and healthy subjects (*P* > 0.05). After adjusting for the presence of diabetes mellitus, HOMA-IR values were not significantly different between groups. Only glucose showed an inverse significant correlation with BMI loss in 6 mo (*R* = -0.324, *P* = 0.012).

### IGF- I

IGF- I levels significantly decreased in cachectic subjects compared with healthy and non-cachectic subjects (43.8 ± 9.5 pg/mL vs 95.0 ± 30.1 pg/mL and 63.1 ± 13.1 pg/mL; *P* < 0.05). Moreover, there was a significant difference in IGF- I levels between healthy and non-cachectic cancer patients (63.1 ± 13.1 pg/mL vs 43.8 ± 9.5 pg/mL; *P* < 0.05, Figure 1E). IGF- I also showed a positive correlation with BMI loss in the previous 6 mo (*R* = -0.679, *P* < 0.0001, Figure 1E) and GPS (*R* = 0.363, *P* = 0.004); negative correlations with age (*R* = -0.331, *P* = 0.01) and fasting glucose (*R* = -0.358, *P* = 0.005, Table 4) were observed.

### Multivariate analysis results

Multiple regression analysis was used to evaluate the role of BMI loss as a continuous variable, along with

**Table 5** Multiple regression analysis with age, BMI change, gender, and tumor differentiation as predictors of ghrelin, leptin, adiponectin, and IGF- I in gastric cancer patients

	<i>P</i>	0.001 <sup>a</sup>	0.009 <sup>a</sup>	0.008 <sup>a</sup>	0.21	< 0.0001 <sup>a</sup>

*β*: Standardized coefficient. Significant regression analysis and <sup>a</sup>*P* < 0.05 are shown.

age, gender, and BMI change to predict ghrelin, resistin, leptin, adiponectin, and IGF- I levels. The results of the regression model indicated that age was not a significant predictor of hormone levels. Gender was a negative independent significant predictor for leptin, and BMI was found to be a negative independent significant predictor for all parameters, except adiponectin (Table 5).

## DISCUSSION

In this prospective study, BMI loss in gastric cancer patients negatively correlated with serum active ghrelin, resistin, adiponectin and leptin levels, but positively correlated with the level of serum IGF- I. It was also noted that there was a correlation between resistin which was found to be high in cachectic patients, and insulin resistance, insulin and blood glucose.

Ghrelin an anabolic hormone, has several roles in metabolism, appetite, nutrition, weight gain, gastric motility, and gastric emptying. In addition, it has an important role in the regulation of synthesis of GH, IGF- I, insulin, and leptin<sup>[4-6]</sup>. Total ghrelin levels in cachectic patients with colon, breast and lung cancer were significantly higher than the levels in non-cachectic patients<sup>[7,8]</sup>. Garcia *et al*<sup>[20]</sup> showed that the ratio of active to total ghrelin levels increased in cancer-induced cachexia. In the same study, it was stated that the increase in active ghrelin levels could have been explained by ghrelin resistance. As the ratio of active/total ghrelin levels were

in favor of active ghrelin in cancer cachexia, we evaluated active ghrelin levels. Our study showed that active ghrelin levels were higher in healthy subjects and non-cachectic cancer patients, especially females. Although we were not able to confirm the ghrelin resistance mentioned by Garcia *et al*<sup>[20]</sup>, we saw the indirect effects. Under normal conditions, endogenous ghrelin increases GH secretion and indirectly increases IGF- I by stimulation of its own receptors. However in our study, the existence of a negative correlation between decreased IGF- I and ghrelin may show that efficiency decreases while the levels of active ghrelin increase. These findings support the presence of ghrelin resistance. It is also possible that ghrelin levels could increase to compensate for the increased metabolic rate and energy need, which was hypothesized by Nagaya *et al*<sup>[21]</sup> Several experimental studies have shown that ghrelin has an important role in the regulation of insulin *via* controlling pancreatic endocrine functions<sup>[22,23]</sup>. No significant relationship between ghrelin and insulin, fasting glucose level and HOMA-IR were found in the present study.

Resistin is a member of the newly discovered family of cysteine-rich secretory proteins, called resistin-like proteins. The role of resistin in pathogenesis of insulin resistance remains questionable, with conflicting data in animal models and negative findings in clinical observation<sup>[13,14]</sup>. The role of insulin resistance in cancer cachexia occurrence is not fully understood<sup>[1,2]</sup>. From this point of view, it came to mind whether resistin can have effect in gastric cancer cachexia occurrence. There are no clinical studies of serum resistin levels in cancer cachexia. It has been shown that serum resistin levels are high in lymphoma patients<sup>[24]</sup>, but the resistin-tumor cachexia relationship was not investigated in this study. From this point of view, our study is the first study in the literature. We found that serum resistin levels in cachectic gastric cancer patients were significantly higher than the noncachectic patients and healthy controls. Resistin showed negative correlation with BMI loss. The effect of resistin on cachexia is probably due to insulin resistance and ineffective usage of glucose. The existence of a correlation between serum resistin levels and insulin, insulin resistance and blood glucose levels supports this idea<sup>[25]</sup>. The role of leptin in modulating the immune response and inflammation has become increasingly evident and has been reviewed recently<sup>[26,27]</sup>. Complex interactions among the nervous, endocrine and immune systems affect the leptin loop and the potential role of these mediators in cancer-related cachexia-anorexia syndrome<sup>[8,11,12]</sup>. Wallace *et al*<sup>[10]</sup> showed that serum levels of leptin did not differ between normal subjects and patients with gastrointestinal cancer. Other studies have shown that there is a relationship between cachexia and leptin levels in pancreatic, lung, breast, and colon cancer patients<sup>[8,11,12]</sup>. Wolf *et al*<sup>[8]</sup> showed that changes in leptin levels in cancer cachexia were significantly higher. Our results were similar to this last study. It is known that leptin receptors are found in  $\beta$  islet cells of the pancreas and inhibit insulin secretion<sup>[28,29]</sup>. However, our study revealed that there

was a reverse correlation between leptin and fasting glucose levels, whereas no relation was found between leptin, insulin resistance, and insulin levels.

It also has been showed that insulin resistance and low serum IGF- I levels are important factors for cancer cachexia. These hormones are strongly anabolic and increase muscle protein synthesis<sup>[11,2]</sup>. IGF- I concentrations increase with growth hormone and testosterone administration, thereby accounting for some of the effects of these hormones on muscle bulk and strength. Low IGF- I concentrations in malnourished humans suggest a role for IGF- I in the pathogenesis of cachexia<sup>[30]</sup>. These findings showed that IGF- I was one of the most important factors in the gastric cancer cachexia.

GPS was found to be an important parameter for determining the prognosis of advanced cancers<sup>[17,18]</sup>. In our study, besides the strong correlation between GPS and BMI loss, significant correlations were found between the GPS and the levels of hormones and cytokines which could be very important for clinical evaluation. GPS which is calculated using routine measurements of albumin and CRP can help us in evaluation and management of the cancer cachexia in clinical practice.

Adiponectin, which has an obvious anti-inflammatory effect, is inversely related to weight gain<sup>[4]</sup>. Serum adiponectin levels were low in cases with increased insulin resistance like obesity, type 2 diabetics, and non-alcoholic fatty liver diseases<sup>[30]</sup>. However, serum adiponectin levels decreased in patients who lost weight voluntarily. High adiponectin levels are risk factors for endometrial and breast cancer, whereas low levels are risk factors for gastric cancers<sup>[31,32]</sup>. No relationship was found between adiponectin and cachexia in breast and colon cancer. In our study, a significant positive correlation was found between adiponectin and BMI loss, but multivariate analysis did not show BMI loss as predictive for adiponectin. Adiponectin, which is predominantly secreted from adipose tissues, might have increased due to lipolysis which occurred with muscle loss in the catabolic state. No correlation was found between adiponectin, whose close relationship with insulin resistance was known, and insulin, blood glucose levels, HOMA-IR, or IGF- I<sup>[4]</sup>.

As a result, cachexia in gastric cancer is a complex process in which ghrelin, resistin, leptin, adiponectin, and IGF- I function. It is of note that these hormones have important roles in occurrence of cachexia in gastric cancer patients. This study will be one of the corner stones of the further studies about prevention and treatment of cachexia.

## COMMENTS

### Background

Adipocytokines are the peptide hormones secreted from adipocytes and have special roles in regulation of metabolism, glucose metabolism, and inflammation. Ghrelin which is secreted from especially from the gastric fundus has roles in regulation of blood glucose level, appetite and secretion of growth hormone. In this study, the role of adiponectin, ghrelin, and insulin like growth factor in gastric cancer patients with cachexia is evaluated.

## Research frontiers

Significant correlation between cachexia and ghrelin, leptin adiponectin and IGF- I can inform more sophisticated studies about the mechanism of cachexia. Despite sufficient nutritional support, cachexia is always an expected morbidity in cancer patients. This study will help future studies about the pathophysiology of the cachexia.

## Innovations and breakthroughs

Although there have been several studies concerning nutritional support and measurement of cachexia in cancer patients, there have not been many studies about the pathophysiology. It is important to understand the behaviour of cancer with cachexia and also to support the patient. Several factors contributing to cancer biology demand attention. However, this study is original for being the first evaluating the correlation between cancer cachexia and resistin. The relationship between adipocytokines and colon, lung and breast cachexia have been studied before. This study has investigated the relationship between gastric cancer cachexia and adipocytokines.

## Applications

To date, the treatment of cancer cachexia has gone no further than nutritional and fluid-electrolyte support. Alternative treatment modalities may be identified if the role of hormones and peptides in cachexia is well-understood. For example, administration of recombinant ghrelin induces growth hormone secretion and appetite.

## Terminology

Adipocytokines are secreted from adipocytes. They are peptide hormones that have systemic effect. For example: resistin, adiponectin, leptin, etc. Cachexia means loss of lipid, carbohydrate and protein in a short time.

## Peer review

This paper investigated resistin, ghrelin, leptin, adiponectin, insulin, IGF- I in gastric cancer subjects with and without cachexia and healthy controls. Ghrelin, resistin, adiponectin significantly differed between subjects with and without cachexia. The study was well described and appropriately presented. It's an important study.

## Abstract

**AIM:** To determine whether SP-TAT-apoptin induces apoptosis and also maintains its tumor cell specificity.

**METHODS:** In this study, we designed a secretory protein by adding a secretory signal peptide (SP) to the N terminus of Transactivating Transcription (TAT)-apoptin (SP-TAT-apoptin), to test the hypothesis that it gains an additive bystander effect as an anti-cancer therapy. We used an artificial human secretory SP whose amino acid sequence and corresponding cDNA sequence were generated by the SP hidden Markov model.

**RESULTS:** In human liver carcinoma HepG2 cells, SP-TAT-apoptin expression showed a diffuse pattern in the early phase after transfection. After 48 h, however, it translocated into the nuclear compartment and caused massive apoptotic cell death, as determined by 3-(4,5-dimethylthiazole-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay and annexin-V binding assay. SP-TAT-apoptin did not, however, cause any cell death in non-malignant human umbilical vein endothelial cells (HUVECs). Most importantly, the conditioned medium from Chinese hamster ovary (CHO) cells transfected with SP-TAT-apoptin also induced significant cell death

## INTRODUCTION

Apoptin or viral protein 3 (VP3), a protein of 13.6 kDa derived from the chicken anemia virus (CAV), represents a new anti-cancer tool with great potential<sup>[1,2]</sup>. It appears to have innate tumor-specific, *p53*-independent<sup>[3,4]</sup>, Bcl-2-enhanced proapoptotic activity<sup>[4,5]</sup>, and hence is of considerable interest for efficient targeting and specific elimination of cancer cells<sup>[3,4,6-8]</sup>. The antitumor activity of apoptin appears to be linked to its ability to localize in the nuclei of transformed cells, but not in those of primary or non-transformed cells<sup>[9]</sup>. Therefore, apoptin has been explored to achieve efficient targeting and specific elimination of cancer cells.

To use apoptin in cancer therapy, efficient delivery to or expression of apoptin in cancer cells is required. The Human Immunodeficiency Virus (HIV) Transactivating Transcription (TAT)-derived protein transduction peptide is a small basic peptide that has been successfully shown to deliver a large variety of materials, from small particles to proteins, peptides and nucleic acids, across

the cell membrane<sup>[10-12]</sup>. The region that conveys the cell-penetrating properties appears to be confined to a small (11 amino acids) stretch of basic amino acids (aa 47-57, YGRKKRRQRRR)<sup>[13]</sup>. This TAT transduction domain has been successfully used to deliver apoptin to cancer cells<sup>[14]</sup>.

In this study, we designed a secretory TAT-apoptin fusion protein by adding a secretory signal to the N-terminal of the recombinant molecule to gain an additive by-stander effect as an anti-cancer therapy. Secreted TAT-apoptin from transformed cells enters un-transformed cancer cells and causes apoptosis. We employed an artificial human secretory signal peptide (SP) whose amino acid sequence and corresponding cDNA sequences were generated by an SP hidden Markov model (SP-HMM)<sup>[15]</sup>. We demonstrated expression of the secretory fusion protein (SP-TAT-apoptin) and induction of apoptosis by the secreted protein in HepG2 cells.

## MATERIALS AND METHODS

### Generation and cloning of SP-TAT-apoptin

The human secretory SP was designed and optimized by an HMM that has been used to predict, identify and generate secretory SP sequences<sup>[15]</sup>. PCR was used to amplify the apoptin gene and to incorporate the TAT transduction domain and SP sequence upstream. The primers were designed based on the published sequences in GenBank (NC\_001427), and synthesized by Shanghai Sangon Biological Engineering Technology & Services (Shanghai, China). The first pair of designed primers were: 5'-AAGAATGAACGCTCTGCAGG AAGATACTCC-3' (sense) and 5'-CTGCAGTCTTA TACGCCITTTTGCGG-3' (antisense), with a product size of 406 bp. The sense primer contains the TAT transduction domain sequence. The second pair of primers, which incorporated the secretory signal sequence into the TAT-apoptin fusion protein, were: 5'-GCTGCTGCTGCTGCTGCTGTGGCCCATGGTG TGGGCCTATGGCAGG-3' (sense) and the same antisense primer as the first pair, with a product size of 466 bp. The templates used for generating recombinant TAT-apoptin and TAT-GFP in the first round PCR were the *apoptin* and *gfp* genes carried on pCDNA3.1-apoptin plasmid<sup>[16]</sup> and pEGFP plasmid, respectively. The conditions for both rounds of PCR were as follows: 30 cycles of 94°C for 40 s, 56°C for 40 s, and 72°C for 1 min. The PCR products obtained were TOPO<sup>®</sup> cloned into the pLenti6/V5-D-TOPO<sup>®</sup> vector (Invitrogen, USA) resulting pLenti6/V5-D-TOPO/SP-TAT-apoptin and pLenti6/V5-D-TOPO/SP-TAT-EGFP. The plasmids were transformed into Stbl3<sup>™</sup> *Escherichia coli* (*E. coli*) (Invitrogen) by electroporation. The SP-TAT-apoptin cDNA cloned in pLenti6/V5-D- TOPO<sup>®</sup> vector was confirmed by restriction enzyme digestion and by DNA sequencing.

### Cell lines and cell culture

HepG2 human hepatoma cells, human umbilical vein

endothelial cells (HUVECs) and Chinese hamster ovary (CHO) cells were purchased from Keygen Company (Nanjing, China). All cells were maintained and grown at 37°C in DMEM (Hyclone, USA), supplemented with 1% penicillin–streptomycin, and 10% fetal bovine serum in an incubator with CO<sub>2</sub> controlled at 5%.

**Conditioned medium:** The conditioned medium from Chinese hamster ovary (CHO) cells transfected with SP-TAT-apoptin. (CHO cells were cultured in a six-well plate. The cells were transfected with the pLenti6/V5-D-TOPO/SP-TAT-apoptin plasmid using the Lipofectamine<sup>™</sup> 2000 protocol according to manufacturer's instructions (Invitrogen). After 6 h incubation, the cells were washed with fresh culture medium and cultured for an additional 24 h. The culture supernatants were then collected and added, respectively, to the monolayers of HepG2 cells and HUVECs grown in 24-well plates.)

**Stbl3<sup>™</sup> *Escherichia coli*:** Stbl3<sup>™</sup> *E. coli* for transformation as this strain is particularly well-suited for use in cloning unstable DNA such as lentiviral DNA containing direct repeats.

### Reverse transcriptase-PCR (RT-PCR)

Cells were rinsed twice with PBS and total RNA was isolated from cells using a Simply P Total RNA Extraction Kit (Bioer, Japan) according to the manufacturer's instructions. One microgram of total RNA was reverse transcribed to first-strand cDNA with Superscript II reverse transcriptase (Invitrogen) at 46°C for 45 min. Synthesized first-strand cDNA was then subjected to PCR analysis using gene-specific primers. The primers used were: CMV forward 5'-CGCAAATGGGCGGTAGGCGTG-3' and V5(C-term) reverse 5'-ACCGAGGAGAGGGTTAGGGAT-3', with a product size of 700 bp. The PCR conditions were as follows: 30 cycles at 94°C for 40 s, 56°C for 40 s, and 72°C for 1 min for SP-TAT-apoptin; 25 cycles at 94°C for 30 s, 60°C for 45 s, and 72°C for 1 min for  $\beta$ -actin control. PCR products were run on 1.5% agarose gels containing ethidium bromide and photographed using a Syngene Gene Genius imaging system (Syngene, USA).

### Transient transfection and fluorescence microscopy

Cells were cultivated in 24-well culture plates. In each well, the cells were grown at 50%-80% confluency and transfected with 400 ng plasmid DNA pre-incubated with 1.4  $\mu$ L Lipofectamine<sup>™</sup> 2000 (Invitrogen), according to the manufacturer's instructions. Coverslips were placed at the bottom of the wells to allow the cells grow on the slides. Apoptin expression was detected with anti-V5-FITC antibody (Invitrogen) as green fluorescence, and the cell nuclei were stained by propidium iodide (PI) as red fluorescence. The cells were incubated with anti-V5-FITC antibody in the dark for 1 h and washed twice with PBS before staining with PI. Fluorescence images were recorded on a confocal imaging system equipped with krypton–argon laser (Leica SP2 Confocal System, Germany).

**Figure 1** SP-TAT-apoptin expression in HepG2 cells ( $\times 1000$ ). Cells transfected with plenti6/V5-D-TOPO/SP-TAT-apoptin plasmid and fixed at 24 h (A) and 48 h (B) post-transfection. Recombinant apoptin detected by anti-V5-FITC antibody is shown in green and cell nuclei stained by PI in red. Apoptin protein showed a diffuse pattern in the cytoplasm at 24 h post-transfection, and in the nucleus at 48 h.

### Flow cytometry

The loss of cell membrane asymmetry in apoptotic cells was determined by using an Annexin-V FITC Apoptosis Assay Kit (Keygen, China). Apoptin-expressing cells were stained with annexin-V FITC as green fluorescent cells, and the nuclei of the apoptotic cells were stained by PI with red fluorescence. After staining, the cell suspensions were analyzed on a Cytometric FC500 flow cytometer, and  $10^5$  events were collected for each sample. Viable cells were defined as annexin-V FITC and PI double-negative events.

### Cell viability assay

Cell viability was also determined by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) dye reduction assay which measures mitochondrial respiratory function<sup>[17,18]</sup>. Exponentially growing cells were plated in 96-well flat bottom plates (Corning, USA) and allowed to adhere for 24 h. At various times post-transfection with the recombinant plasmid, cells were incubated with MTT dye (1 mg/mL) for 2 h and solubilized with 20  $\mu$ L 10% SDS.  $A_{560}$  was then measured.

### DNA laddering assay

DNA fragmentation was detected using an Apoptotic DNA Laddering Kit (Keygen) according to the manufacturer's instructions. DNA was extracted, separated by 1.5% agarose gel electrophoresis, followed by ethidium bromide staining to visualize the ladder DNA.

### Immunocytochemical assay and DAPI staining

At various times post-transfection, cells grown in six-well plates were harvested and treated by trypsinization and resuspended in PBS. The cells were then spread on a slide, fixed by 100% methanol for 5 min at room temperature, stained by the Apoptotic/Necrotic Cell Detection Kit (Keygen), and embedded in resin, after permeabilization, for long-term storage.

Cytotoxicity of SP-TAT was also tested by 2,4-diamidino-2-phenylindole (DAPI) staining. Transfected cells grown on coverslips that were placed on the bottom of a 24-well plate were washed with PBS and fixed, and apoptotic cells were differentiated by staining with mounting medium containing DAPI, and visualized using an Olympus AX70 fluorescence microscope.

### Protein secretion and activity test

CHO cells were cultured in a six-well plate. The cells were transfected with the pLenti6/V5-D-TOPO/SP-TAT-apoptin plasmid using the Lipofectamine<sup>TM</sup> 2000 protocol according to manufacturer's instructions (Invitrogen). After 6 h incubation, the cells were washed with fresh culture medium and cultured for an additional 24 h. The culture supernatants were then collected and added respectively to the monolayers of HepG2 cells and HUVECs grown in 24-well plates. These cells had also been washed with PBS before adding the supernatants. At various times post co-culture, these cells were fixed and stained, and apoptin localization and apoptosis were analyzed.

**Figure 2** SP-TAT-apoptin-induced cell death. **A:** Cell viability measured by flow cytometry. **A1 and A2:** HUVECs at 48 and 72 h post-transfection; **A3-A6:** HepG2 cells at 24, 48, 72 and 96 h. HepG2 cells were susceptible to SP-TAT-apoptin-induced apoptosis in a time-dependent manner; **B:** Cell viability determined by MTT dye reduction assay; **C:** DNA fragmentation in HepG2 cells demonstrated by agarose gel electrophoresis. Lane 1: 1 kb DNA marker; Lanes 2-5: DNA from cells at 24, 48, 60 and 72 h post-transfection, respectively.

### Statistical analysis

ANOVA was performed for multiple group comparison. In conjunction with ANOVA, post hoc pairwise comparisons were performed by Bonferroni's test, with  $P < 0.05$  regarded as statistically significant.

## RESULTS

### Generation of SP-TAT-apoptin fusion construct and expression of SP-TAT-apoptin

The human secretory SP was constructed and optimized virtually by the HMM, which has been used to describe, predict, identify, and generate secretory SP sequences<sup>[13]</sup>. It was inserted at the N terminus of recombinant TAT-

apoptin to generate SP-TAT-apoptin fusion protein, and it contained a positively charged N region, a hydrophobic central region, and a C region that contained a cleavage site. Two rounds of PCR were carried out to amplify the apoptin gene and to fuse TAT and the synthetic SP into the construct to create recombinant secretory-TAT-apoptin.

To determine whether the SP-TAT-apoptin cDNA construct generated was expressed *in vivo*, the HepG2 cell line was transfected with the plenti6/V5-D-TOPO/SP-TAT-apoptin plasmid. Analysis by RT-PCR revealed that SP-TAT-apoptin was expressed 24 h after transfection (data not shown). The expression of SP-TAT-apoptin in HepG2 cells was confirmed by immunofluorescence microscopy (Figure 1).

**Figure 3** Cytotoxicity of SP-TAT-apoptin compared to SP-TAT. **A:** Micrographs of HepG2 cells transfected with SP-TAT-apoptin construct stained by Apoptotic/Necrotic Cell Detection Kit. An inverted microscope ( $\times 400$ ) was used. The nuclei of apoptotic cells were stained deep blue. **A1** and **A2:** HepG2 cells at 24 and 72 h post-transfection; **B:** HepG2 cells stained with DAPI and observed by fluorescence microscopy ( $\times 400$ ). **B1:** HepG2 cells 72 h after transfection with plenti6/V5-D-TOPO/SP-TAT-GFP plasmid; **B2:** HepG2 cells 72 h after transfection with plenti6/V5-D-TOPO/SP-TAT-apoptin. Arrow indicates apoptotic cells.

### Induction of apoptosis by SP-TAT-apoptin

To determine whether SP-TAT-apoptin induces apoptosis and also maintains its tumor cell specificity, HUVECs and HepG2 cells were transfected with the plenti6/V5-D-TOPO/SP-TAT-apoptin plasmid. SP-TAT-apoptin-induced apoptosis was investigated in these two cell lines. Three different assays were used to gauge apoptosis. In the first assay, cell viability was measured by co-staining with annexin-V FITC and PI, followed by flow cytometry. This assay was based on the loss of plasma membrane asymmetry (integrity) as a result of apoptosis. Viable cells were defined as annexin-V FITC and PI double-negative events. As shown in Figure 2A, only HepG2 cells were susceptible to SP-TAT-apoptin-induced apoptosis in a time-dependent manner. These results also confirm previous reports that apoptin has the ability to induce apoptosis specifically in tumor cells<sup>[3,4,7,19,20]</sup>. In the second assay, cells that were exponentially grown were inoculated in 96-well flat-bottom plates and allowed to adhere for 24 h. After transfection, cell viability was determined at various times by MTT dye reduction assay. Expression of the recombinant protein slightly decreased the viability of HepG2 cells at 24 h post-transfection, and the same was true in HUVECs (Figure 2B). At 48 h post-transfection, the viability of HUVECs was only slightly decreased compared to that at 24 h. However, the viability of HepG2 cells was significantly decreased at 48 h post-transfection. The presence of recombinant apoptin caused a decrease in HepG2 cell viability to

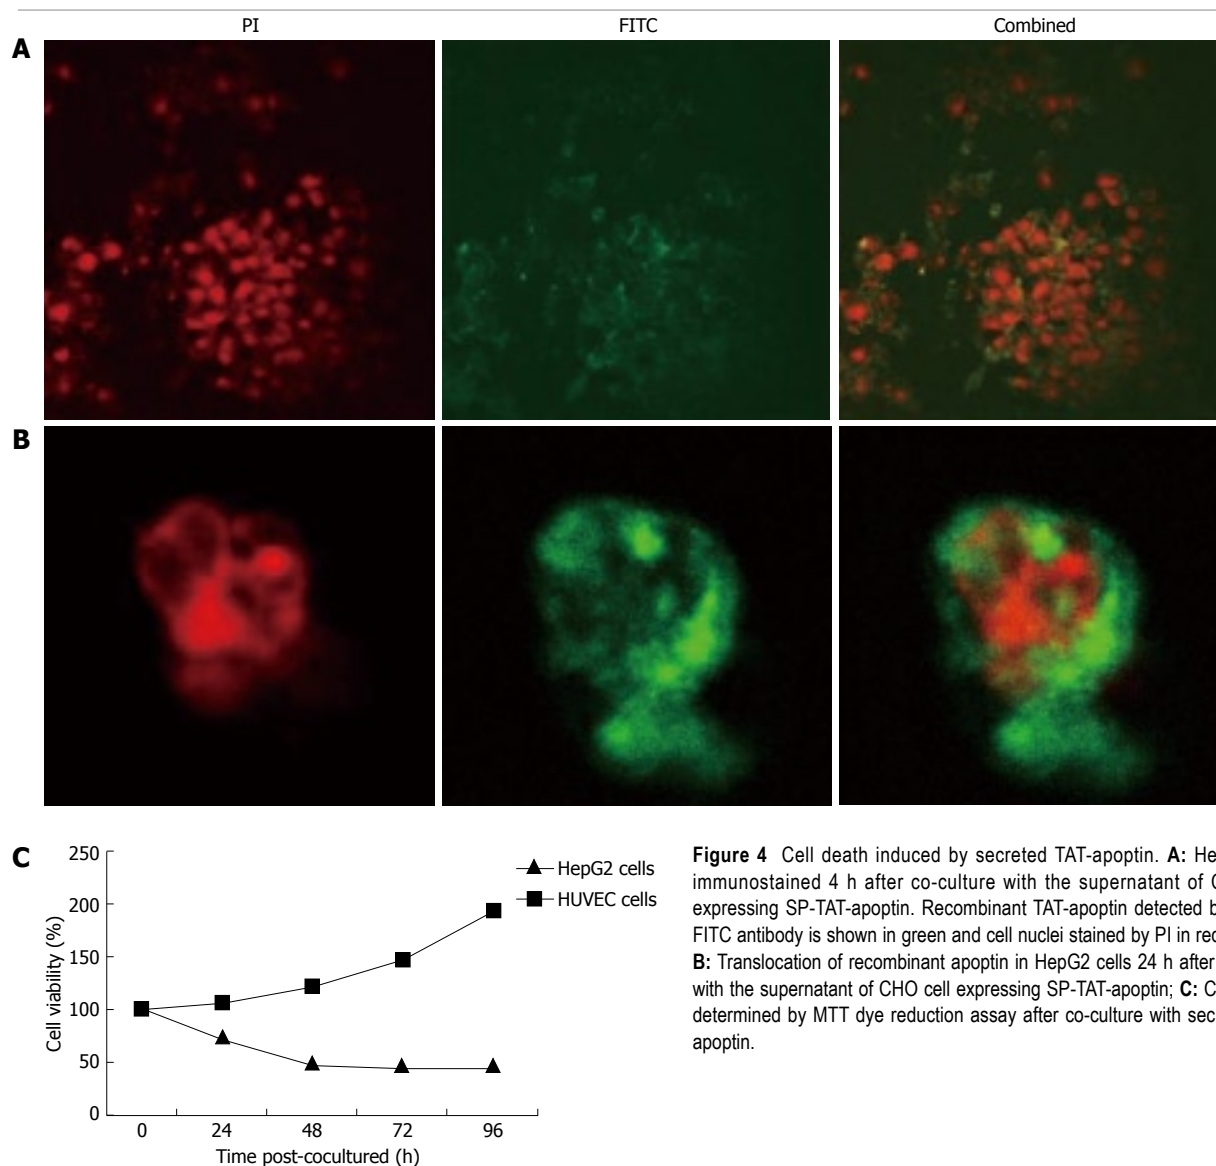

$< 60\%$  at 72 h and  $< 50\%$  at 96 h post-transfection (Figure 2B). In the third assay, genomic DNA fragmentation in HepG2 cells and HUVECs was investigated. As shown in Figure 2C, the apoptin fusion protein brought about significant DNA fragmentation in HepG2 cells at 72 h post-transfection. In contrast, detectable apoptotic DNA laddering in HUVECs was not seen during the experiment (data not shown).

### Lack of cytotoxicity of SP-TAT

In order to determine the cytotoxicity of SP-TAT, plenti6/V5-D-TOPO/SP-TAT-apoptin plasmid and plenti6/V5-D-TOPO/SP-TAT-GFP plasmids were transfected into HepG2 cells separately. Robust apoptosis of HepG2 cells was observed, as demonstrated by microscopy at different times after transfection, while in contrast, expression of SP-TAT-GFP did not induce noticeable apoptosis in these cells (Figure 3). Therefore, SP-TAT did not seem to exhibit cytotoxicity in HepG2 cells and apoptosis induced by SP-TAT-apoptin was due to apoptin.

### Secretion of SP-TAT-apoptin and the effect of secreted TAT-apoptin on HepG2 cells

The presence of synthesized SP enables TAT-apoptin to be secreted outside the transfected cells and re-enter adjacent un-transfected HepG2 cells, potentially increasing the efficacy of apoptin when used as cancer therapy. To test its feasibility, the recombinant construct was used to transfect CHO cells and the culture supernatant was collected. HepG2 cells and HUVECs

**Figure 4** Cell death induced by secreted TAT-apoptin. **A:** HepG2 cells immunostained 4 h after co-culture with the supernatant of CHO cells expressing SP-TAT-apoptin. Recombinant TAT-apoptin detected by anti-V5-FITC antibody is shown in green and cell nuclei stained by PI in red ( $\times 1000$ ); **B:** Translocation of recombinant apoptin in HepG2 cells 24 h after co-culture with the supernatant of CHO cell expressing SP-TAT-apoptin; **C:** Cell viability determined by MTT dye reduction assay after co-culture with secreted TAT-apoptin.

were then co-cultured with this supernatant. At 24 h post co-culture, TAT-apoptin had translocated from the cytoplasm to the nucleus (Figure 4A). At various times post co-culture, cell viability was also determined by MTT dye reduction assay. As shown in Figure 4B, the recombinant protein TAT-apoptin slightly decreased cell viability of HepG2 cells at 24 h post co-culture. In contrast, the viability of HUVECs was actually increased at 24 h, which continued during the course of the experiment. At 48 h post co-culture, viability of HepG2 cells was significantly decreased compared to that of HUVECs. The recombinant apoptin protein decreased HepG2 cell viability to  $< 50\%$  at 48 h post-transfection.

## DISCUSSION

New therapeutic approaches that facilitate selective targeting of cancer cells while sparing normal cells have emerged in recent years. Apoptin represents a new anti-cancer tool in such new approaches with great potential<sup>[21-25]</sup>. Two routes can be taken using apoptin or its encoding cDNA, i.e. as protein or gene therapy. In any case, efficient systems are required to facilitate

the delivery of apoptin to cancer cells or expression of apoptin within these cells<sup>[26-30]</sup>. The HIV TAT transduction domain has been successfully used to deliver apoptin into cancer cells<sup>[14]</sup>, and no apoptosis of normal cells (HUVECs) was observed with this TAT-apoptin fusion protein. In this study, we generated a cDNA construct of SP-TAT-apoptin. Cancer cells transfected with this construct expressed recombinant apoptin and apoptosis was induced. By incorporating a synthetic SP we also expected apoptin to be secreted from the transfected cells as TAT-apoptin fusion protein and re-enter adjacent untransfected HepG2 cells, which enabled the construct to act as both a protein and gene therapeutic agent, and increased the potency of apoptin in cancer therapy.

SP-TAT-apoptin was expressed in HUVECs and HepG2 cells, and the protein was initially located in the cytoplasm. At 48 h post-transfection, the protein was located in the nucleus of HepG2 cells, which indicated that SP-TAT-apoptin was capable of translocating to the nucleus. SP-TAT-apoptin was also functionally active and efficiently induced HepG2 cell apoptosis, in a time-dependent manner. In HUVECs, SP-TAT-

apoptin remained in the cytoplasm and no induction of apoptosis above the background level was observed. Meanwhile, no apoptosis was observed in cells in which SP-TAT-GFP was expressed, which indicates that SP-TAT alone is not cytotoxic for HepG2 cells. Therefore, SP-TAT-apoptin retained the characteristic expression pattern of apoptin and induced apoptosis in cancer cells.

Having a synthetic SP, recombinant apoptin was able to be secreted from transfected cells and re-enter adjacent untransfected HepG2 cells. The recombinant protein was detected in the cytoplasm in HepG2 cells and HUVECs shortly after co-culture of the cells with the cell-free supernatant of the transfected CHO cells. This indicated that the secreted TAT-apoptin fusion protein contained in the CHO cell culture medium was able to enter these cells. The fusion protein was later found in the nucleus of HepG2 cells and induced HepG2 apoptosis. The new secretory characteristic increased the possibility of apoptin being used in cancer gene therapy. However, there are still a large number of unanswered questions regarding the mechanisms and therapeutic usage of apoptin, and further studies are certainly required.

## ACKNOWLEDGMENTS

We thank Dr. Zhi-Xian Sun at the Academy of Military Medical Sciences, China, for providing plasmid pCDNA3.1-apoptin.

## COMMENTS

### Background

Apoptin is a protein encoded by Constant Angular Velocity (CAV) and it can cause apoptotic cell death. It has been shown to possess a striking specificity for cancer cells. Apoptin, therefore, has great potential for efficient targeting and specific elimination of cancer cells.

### Research frontiers

Human Immunodeficiency Virus (HIV)-Transactivating Transcription (TAT)-fused apoptin has been shown to possess a striking specificity for cancer cells. However, the cancer killing activity is limited in cells transfected with the apoptin expression construct, which spares the untransfected cancer cells. A secretory TAT-apoptin fusion protein with a secretory signal has an additive by-stander effect as an anti-cancer therapy. Secreted TAT-apoptin from transformed cells enters un-transformed cancer cells and causes apoptosis.

### Innovations and breakthroughs

The new secretory characteristic increased the possibility of apoptin being used in cancer gene therapy. However, there are still a large number of unanswered questions regarding the mechanisms and therapeutic usage of apoptin, and further studies are certainly required.

### Terminology

Apoptin or VP3 is a protein of 13.6 kDa derived from CAV, represents a new anti-cancer tool with great potentials. It appears to have innate tumor-specific, p53-independent, Bcl-2-enhanced pro-apoptotic activity.

### Peer review

The authors investigated the role of secretory TAT-apoptin fusion protein in HepG2 cells. They conclude that such a protein induces apoptosis in HCC cell lines, but not in non-cancer cell line HUVEC. This is a very interesting study, which may be applicable for the treatment of human liver cancer in the future.

of CD patients but only 0%-6% of controls were seropositive against different mycobacterial antigens. Anti-mycobacterial IgG correlated with ASCA ( $r = 0.37-0.64$ ;  $P = 0.003-P < 0.001$ ). ASCA-positivity and deficiency for mannan-binding lectin synergistically associated with anti-mycobacterial IgG. In some patients, anti-mycobacterial antibodies represent cross-reactive ASCA. Vice-versa, the predominant fraction of ASCA did not cross-react with mycobacteria. Finally, fistulizing disease associated with antibodies against *M avium*, *M smegmatis* and MAP ( $P = 0.024$ ,  $0.004$  and  $0.045$ , respectively).

**CONCLUSION:** Similar to ASCA, seroreactivity against mycobacteria may define CD patients with complicated disease and a predisposition for immune responses against ubiquitous antigens. While in some patients anti-mycobacterial antibodies strongly cross-react with yeast mannan; these cross-reactive antibodies only represent a minor fraction of total ASCA. Thus, mycobacterial infection unlikely plays a role in ASCA induction.

Partial overlap of anti-mycobacterial, and anti-*Saccharomyces cerevisiae* mannan antibodies in Crohn's disease. *World J Gastroenterol* 2008; 14(23): 3650-3661 Available from: URL: <http://www.wjgnet.com/1007-9327/14/3650.asp> DOI: <http://dx.doi.org/10.3748/wjg.14.3650>

### Abstract

**AIM:** To test whether humoral immune reaction against mycobacteria may play a role in anti-*Saccharomyces cerevisiae* antibodies (ASCA) generation in Crohn's disease (CD) and/or whether it correlates with clinical subtypes.

**METHODS:** The dominant ASCA epitope was detected by *Galanthus nivalis* lectin (GNL)-binding assay. ASCA and IgG against mycobacterial lysates [*M avium*, *M smegmatis*, *M chelonae*, *M bovis* BCG, *M avium ssp. paratuberculosis* (MAP)] or purified lipoarabinomannans (LAM) were detected by ELISA. ASCA and anti-mycobacterial antibodies were affinity purified to assess cross-reactivities. Anti-mycobacterial IgG were induced by BCG-infection of mice.

**RESULTS:** GNL bound to different extents to mycobacterial lysates, abundantly to purified mannose-capped (Man) LAM from *M tuberculosis*, but not to uncapped LAM from *M smegmatis*. Fifteen to 45%

### INTRODUCTION

Crohn's disease (CD) is a multifactorial disease that affects genetically susceptible hosts. The exact pathogenesis is still largely unknown. However, it is generally accepted that the disease, once established,

is driven by antigens of the intestinal flora, reflecting a loss of tolerance against commensal microorganisms<sup>[1,2]</sup>. The hypothesis that genetic predisposition, together with unfavorable environmental and commensal triggers cause CD with its various phenotypes contradicts the highly controversial idea of a single infectious origin of the disease<sup>[3]</sup>.

A number of serological markers have been detected that have a certain degree of specificity and sensitivity for CD<sup>[4,5]</sup>. Of the most intriguing antibodies are those directed against outer cell wall mannans of the baker's yeast *Saccharomyces cerevisiae* (anti-*Saccharomyces cerevisiae* antibodies, ASCA)<sup>[6-9]</sup>. These antibodies are found in more than 50% of CD patients, but rarely in healthy controls or patients with ulcerative colitis (UC)<sup>[8]</sup>. Yeasts are ubiquitous and ingested on a daily basis. Why an organism that, with a few reported exceptions of virulent mutants<sup>[10]</sup>, is not adapted to live or even grow in the human body elicits a strong IgG response in CD patients has not yet been conclusively answered. A recent report presented experimental data supporting the idea that the facultative opportunistic pathogen *Candida albicans* may be the inducer of ASCA<sup>[11]</sup>. However, our recent study showed that ASCA and anti-*C. albicans* antibodies correlate to a lower degree than ASCA with antibodies to mannans from other ubiquitous yeasts<sup>[12]</sup>. Thus, whether *C. albicans* infection may indeed represent the dominant trigger for ASCA cannot be definitively answered so far and there may be other cross-reactivities that play a role in ASCA induction. Potential candidates are mycobacteria since their cell wall contains lipoarabinomannans with similar mannose side chains as the cell wall mannans of yeast. The exact epitope recognized by ASCA has been demonstrated to be an  $\alpha$ -1,3 mannose-( $\alpha$ -1,2 mannose)<sub>n</sub> with  $n = 2$  or 3 by two independent studies<sup>[9,13]</sup>. Similar or equal oligo-mannose motives are found in other yeasts, as well as in the mannosylated side chains of mycobacterial lipoarabinomannans (LAM)<sup>[14,15]</sup>. Part of this motif, the terminal  $\alpha$ -1,3 linked mannose, can be detected by the *Galanthus nivalis* lectin (GNL)<sup>[16,17]</sup> and has been shown to be present in the lipo(arabino)mannan of *M. chelonae*<sup>[18]</sup>. Two other publications have demonstrated presence of the GNL-reactive motif in some mycobacterial species, including *M. bovis*, *M. avium* and *Mycobacterium avium* ssp. paratuberculosis (MAP)<sup>[19,20]</sup>. Hence, we were interested whether ASCA-positive CD patients may also more frequently contain antibodies against distinct mycobacterial strains and specifically against LAM, and whether these antibodies would be of cross-reactive nature.

In the case of MAP studies have shown a very high (77%-87%) prevalence of seroreactivity against the MAP antigens p35 and p36 in CD<sup>[21,22]</sup>. While this is intriguing, the interest in the possible relationship between CD and MAP mainly comes from the fact that Johne's disease in cattle which is caused by MAP infection in some aspects resembles CD.

The acute phase reactant mannose-binding lectin (MBL) specifically binds to mannose residues and is an

important first line of defense innate immune effector molecule<sup>[23-26]</sup>. We have previously shown that deficiency for MBL associates with the ASCA-positive subgroup of CD patients<sup>[27,28]</sup>. Thus, it was of interest, if in CD, deficiency for MBL might associate with elevated levels of anti-mycobacterial IgG as well. Finally, we correlated our findings regarding anti-mycobacterial antibodies with different clinical CD phenotypes.

## MATERIALS AND METHODS

### Patients and sera

Sera from 105 patients with CD, 45 patients with UC and 35 healthy controls were obtained with informed consent and with the approval of the local ethical authorities. Diagnosis of CD and UC was established by endoscopic, histological and clinical criteria. CD: 54 women and 51 men, mean age 40 years (19-73); UC: 22 women and 23 men, mean age 38 years (20-65); healthy controls: 21 women and 14 men, mean age 37 years (18-67). Disease activity was graded for CD according to the CD activity index (CAI), or for UC according to the Mayo-score<sup>[29,30]</sup>. At the time of blood collection, CD patients were treated as follows: no medical treatment ( $n = 29$ ), 5-ASA ( $n = 4$ ), steroids ( $n = 8$ ), antibiotics ( $n = 3$ ), infliximab ( $n = 4$ ), or immunomodulators such as 6-mercaptopurine or azathioprine (6-MP/aza,  $n = 47$ ), or methotrexate ( $n = 20$ ). Some patients had combined medication: infliximab + methotrexate ( $n = 1$ ), steroids + methotrexate ( $n = 4$ ), steroids + 6-MP/aza ( $n = 3$ ), infliximab + 6-MP/aza ( $n = 2$ ). CAI ranged between 75 and 380 (mean: 138 points). UC patients were treated as follows: no medical treatment ( $n = 9$ ), 5-ASA ( $n = 15$ ), steroids ( $n = 6$ ), immunomodulators 6-MP/aza ( $n = 20$ ), or tacrolimus ( $n = 2$ ). Some of these patients had combined medication: 5-ASA + 6-MP/aza ( $n = 4$ ), steroids + 6-MP/aza ( $n = 3$ ). CD patients were grouped according to the Montreal classification<sup>[31]</sup> into a UC-like (purely inflammatory, non-stenosing, non-fistulizing), a stenosing, or a fistulizing phenotype. The latter two are summarized as complicated disease phenotype.

### Mycobacteria, yeast and mannan

Mycobacterial strains used in this study were *M. avium*, *M. smegmatis*, *M. chelonae*, MAP (all strains are patients' isolates and property of the Institute of Infectious Diseases, University of Bern), and BCG (commercial vaccination strain). Strains were grown in Middlebrook 7H9 medium (Difco™ BBL™, BD Biosciences, San Jose, CA, USA) with 10% OADC enrichment (Difco™ BBL™, BD Biosciences), 1 mg/mL casein peptone (Merck, Glattbrugg, Switzerland) and 0.5% glycerin, and were collected during logarithmic growth phase. For MAP cultures, growth medium was supplemented with 2 mg/mL Mycobactin J (Synbiotics Europe SAS, Munich, Germany). Bacteria were heat-inactivated for 1 h at 80°C and then lysed in the presence of trypsin inhibitor and PMSF (Sigma, Buchs, Switzerland) by needle sonication (2 × 1 min. with 100 watts, on ice). The lysate was cleared by centrifugation and protein concentration determined.

Mannose-capped lipoarabinomannan (ManLAM) from *M. tuberculosis* and (non-mannose-capped) phosphomyo-inositol-capped LAM (PILAM, subsequently termed LAM) were kindly provided by J. Belisle, Colorado State University. *S. cerevisiae* Vita Gold was obtained from Deutsche Hefewerke, Nürnberg, Germany. The yeast was grown in 5% yeast peptone D-glucose (YPD, Sigma) and harvested during logarithmic growth. Mannan was extracted according to Kocourek and Balou<sup>[32]</sup>. Briefly, cells were resuspended in 20 mmol/L Na-citrate buffer (pH 7.0) and autoclaved for 3 h at 125°C. The supernatant was cleared by centrifugation and the pellet resuspended in Na-citrate buffer (1.5 × initial volume). After centrifugation, the supernatants were pooled and cleared from residual debris by centrifugation. The mannans were complexed with equal volumes of Fehling's solutions (Fehling I: 6.93 g CuSO<sub>4</sub> · 5 H<sub>2</sub>O/100 mL in H<sub>2</sub>O; Fehling II: 34.6 g C<sub>4</sub>H<sub>4</sub>KNaO<sub>6</sub> · 4H<sub>2</sub>O + 12 g NaOH/100 mL in H<sub>2</sub>O) and pelleted by centrifugation. The pellet was resolved in 3 mol/L HCl before precipitating the mannans off the CuSO<sub>4</sub> complex with a methanol/acetic acid 8:1 v/v solution while stirring. The precipitate was pelleted and washed repeatedly with methanol/acetic acid 8:1 v/v until the supernatant was colorless and clear and finally washed twice with methanol alone and dried in a desiccator at 4°C.

## ELISA

ELISA was performed in Nunc-Immuno™ Maxisorp 96-well plates (Nunc, Wiesbaden, Germany). For mycobacteria-specific ELISA, 50 µL of mycobacterial lysates, purified LAM or ManLAM at 5 µg/mL PBS was added per well and dried over night at 37°C. The next day plates were blocked with 1% skim milk in PBS. For ASCA, tetanus toxoid (TT) or galanthus nivalis lectin (GNL)-binding ELISA, plates were coated with the respective antigen at 0.25 µg/mL carbonate-bicarbonate (25 mmol/L Na<sub>2</sub>CO<sub>3</sub>, 25 mmol/L NaHCO<sub>3</sub>) coating buffer pH 9.6, overnight at 4°C. On the next day, plates were blocked with PBS + 0.5% BSA (PBS-BSA). Plates were washed and patients' sera added 1/500 (mycobacteria) or 1/1000 (ASCA, TT) PBS-BSA. Plates were incubated 1.5 h at room temperature (mycobacteria) or overnight at 4°C (ASCA, TT). For the GNL-binding ELISA, biotinylated GNL (Vector Laboratories, Burlingame, CA, USA) was added at 5 µg/mL to the blocked plates. Plates were washed with PBS-BSA + 0.05% Tween 20 (PBST-BSA). For ASCA and TT ELISA peroxidase-coupled anti-human IgG (Sigma) was added 1/5000 in PBST-BSA and plates incubated for 1 h at room temperature. The plates incubated with biotinylated GNL were further incubated with peroxidase-coupled streptavidin (BD Biosciences). After washing ELISA was developed with TMB substrate (Sigma) for 15-30 min. in the dark. Reaction was stopped with 0.5 mol/L sulphuric acid and plates read at 450 nm. A cut-off value discriminating between negativity and positivity for anti-mycobacterial IgG was defined using the average extinction values for the healthy population

(without the clearly positive individuals as defined by  $A_{450} \geq 0.3$ ) and addition of 3 standard deviations. To determine the MBL oligomer concentration sera were diluted 1/100 and assessed in an MBL-oligomer ELISA kit according to the manufacturer's instructions (The Antibodyshop, Gentofte, Denmark).

## Affinity purification of ASCA

*S. cerevisiae* mannan was separated on an 8% polyacrylamide gel. The separated mannan was transferred to Hybond-ECL nitrocellulose membrane (Amersham GE Healthcare Europe, Otelfingen, Switzerland) and the ASCA-reactive material was localized by Western blot on a small section of the membrane. The ASCA-reactive region of the remaining membrane was cut into 8 equal pieces and the pieces blocked in TBS + 2% BSA.

Eight highly ASCA-positive sera from Crohn's patients were diluted 1/5 in TBS + 2% BSA and incubated with one piece of the membrane overnight at 4°C, on a rocking platform. After incubation the membranes were thoroughly washed with TBS and 1× with H<sub>2</sub>O and bound antibodies eluted with 0.2 mol/L glycine, pH 2.8. The eluate was neutralized with Tris-base pH 8.0 and the eluted antibodies stabilized with 0.1% BSA.

## Affinity purification of anti-*M. smegmatis* antibodies

1 cm × 1 cm pieces of Hybond-ECL nitrocellulose membrane were decorated with *M. smegmatis* lysate and sequentially incubated overnight at 4°C and for 2 h at rt. Membranes were rinsed and blocked in TBS + 2% BSA. Incubation with sera and elution of bound antibodies was performed as described above.

## Immunization of mice

C57BL/6 mice were reared in individually ventilated cages (IVC) under specified pathogen-free conditions. Housing and experimental procedures were in accordance with the European regulations on animal experimentation (FELASA). BCG culture was adjusted to a density of  $A_{600} = 0.5$  MacFarland (10<sup>8</sup> cells per mL) with 0.9% sterile NaCl and 100 µL (10<sup>7</sup> viable bacteria) injected into the tail vein per mouse. Mice were 8 wk old and sex-matched. Viability of the mycobacteria was confirmed by reculturing the remaining bacterial suspension. Four weeks after infection serum was prepared from whole blood samples after clipping the tail tips. By week 5, the mice were boosted by iv with the same amount of mycobacteria and sera collected 4 and 13 wk later. Anti-BCG and ASCA IgM and IgG were determined by ELISA. To that end, samples were diluted 1/250 and anti mouse IgM and IgG HRP antibodies (Sigma) used 1/1000 and 1/500, respectively.

## Statistical analysis

Raw data were imported into a statistical package program (STATA Versiön 9.0, Texas). Results of numerical data are presented as mean ± SE. Categorical data are summarized as the percentage of the group total. Two-sided Fisher's exact test ( $n < 20$ ) or the Chi square test ( $n \geq 20$ ) was used to explore associations of

**Figure 1** Reactivity of *Galanthus nivalis* lectin (GNL) with mycobacterial lysates and purified LAM or ManLAM. ELISA plates were coated with yeast mannan, mycobacterial lysates, purified LAM or ManLAM or coating buffer alone without antigen (-), and binding of biotinylated GNL to these antigens assessed by further incubation with peroxidase-coupled streptavidin followed by TMB substrate reaction. Shown are mean values ± SE of 3 individual experiments.

categorical data in 2 independent groups. The Wilcoxon rank sum test was used to explore associations of numerical data in 2 independent groups. A  $P < 0.05$  was considered statistically significant. Associations between numerical data were evaluated using the Spearman rank correlation coefficient.

## RESULTS

### The dominant ASCA epitope terminal $\alpha$ -1,3 linked mannose is differentially present in lysates of different mycobacterial species

Phosphopeptidomannan with  $\alpha$ -1,3 mannose ( $\alpha$ -1,2 mannose  $\alpha$ -1,2 mannose)<sub>n</sub> ( $n = 1$  or  $2$ ) sugar residues represent a prominent epitope recognized by ASCA from CD patients<sup>[9,13]</sup>. The snowdrop lectin *Galanthus nivalis* agglutinin or lectin (GNL) has been shown to have high specificity for such terminal mannose sugar residues<sup>[16,17]</sup> and has been used to detect ASCA epitopes from microorganisms directly or in infected tissue<sup>[11,20]</sup>. After coating ELISA plates with mycobacterial lysates, purified LAM or ManLAM, or, as a positive control, yeast mannan, GNL differentially bound to these antigens. Besides yeast mannan, GNL strongly bound to lysate from *M chelonae* which is in perfect agreement with published observations<sup>[18]</sup>. Marked binding was further observed with lysates from BCG and MAP followed by *M avium* and *M smegmatis*. While no binding was observed to purified LAM, GNL strongly bound to ManLAM (Figure 1).

### Higher frequencies of anti-mycobacterial IgG-positive individuals among patients with IBD compared to healthy controls

$A_{450}$  extinction values of the anti-mycobacterial ELISA obtained with sera from the healthy population were used to define cut-off values for anti-mycobacterial IgG as described in the materials and methods section. According to these cut-off levels, between 13% (anti-LAM) and 45% (anti-*M smegmatis*) of CD patients were designated anti-mycobacterial IgG positive while in the group of healthy controls only 0 (anti-ManLAM) to 6% (anti-*M chelonae*, anti-MAP) were positive (Figure 2). Between 2% (anti-LAM) and 36% (anti-BCG) of UC patients were anti-mycobacterial IgG positive. Despite similar age groups, only one of the 35 healthy volunteers was tested positive for anti-BCG IgG while 42% of CD patients and 36% of UC patients were above the cut-off. Furthermore, while none of the healthy controls reached positivity for anti-ManLAM IgG, 19% of CD and 11% of UC patients did. Using the Chi-square test, differences in frequencies of positive individuals between the groups of CD patients and healthy controls were significant for IgG against all mycobacterial lysates tested and purified ManLAM. Differences between UC patients and controls were significant for *M chelonae*, BCG and ManLAM. Finally, compared to UC patients, CD patients were significantly more frequently positive for anti-*M avium* and anti-*M smegmatis* IgG (Figure 2).

### Anti-mycobacterial IgG correlate with ASCA

To test whether seroreactivity against mycobacterial antigens in general and mycobacterial mannans in particular may correlate with that against yeast mannans, we grouped CD patients into ASCA-negative and ASCA-positive categories. ASCA-positive CD patients showed the highest frequencies of seropositivities against all mycobacterial antigens tested. Between 21% (anti-LAM) and 65% (anti-*M smegmatis*) of ASCA-positive CD patients were anti-mycobacterial IgG positive, while only 5% (anti-LAM) to 29% (anti-*M smegmatis*) of ASCA-negative CD patients had anti-mycobacterial IgG titers above the cut-off (Figure 3A). Compared to healthy controls, even the proportion of anti-LAM-positive individuals was significantly elevated in ASCA-positive CD patients (21% *vs* 4%). In addition, ASCA-positive CD patients were also significantly more frequently positive for IgG against *M smegmatis*, *M chelonae*, BCG, MAP and purified ManLAM when compared with ASCA-negative CD patients. On the other hand, ASCA-negative CD patients were significantly more frequently positive than healthy controls only for anti-*M smegmatis* IgG. When ASCA-positive CD patients were further grouped according to the levels of their ASCA titers, we observed a weak trend of increasing titers of IgG against mycobacterial lysates with increasing ASCA titers (data not shown). In contrast, seropositivity against purified LAM or ManLAM was almost exclusively and strongly elevated in the highest ASCA-positive subgroup. While less than 20% of ASCA-negative, or weakly positive CD patients were positive for anti-LAM

**Figure 2** Determination of anti-mycobacterial serum IgG in IBD and healthy controls. ELISA for different mycobacterial lysates and purified LAM or ManLAM were performed with sera from 105 CD patients, 45 UC patients and 35 controls. A negative to positive discrimination level was defined by a cut-off value representing the average of all  $A_{450}$  values from the healthy controls (excluding the clearly positive individuals with an  $A_{450} \geq 0.3$ ) plus 3 standard deviations. With these cut-off values, individuals positive for antibodies against the various mycobacterial antigens were identified and are shown as a percent of the total population. Asterisks indicate significant differences between the populations. <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$ .

**Figure 3** Association of anti-mycobacterial IgG with ASCA. CD patients were grouped according to their ASCA status and their anti-mycobacterial IgG were determined in comparison with healthy controls ( $n = 25$ ). **A:** ASCA- ( $n = 42$ ), extinction values at 450 nm below the cut-off as determined by routine diagnostics (3 standard deviations above the average of 10 negative control sera); ASCA+ ( $n = 48$ ) extinction values above the cut-off. According to the legend of Figure 1, percentages of IgG-positive individuals per group were determined for each antigen. **B:** ASCA-positive CD patients were further grouped according to the levels of ASCA and compared to healthy controls and UC patients. ASCA+ ( $n = 28$ ),  $A_{450}$  clearly above, but less than double the cut-off value; ASCA++ ( $n = 10$ ),  $A_{450}$  2 to 3 times higher than the cut-off value; ASCA+++ ( $n = 10$ ),  $A_{450}$  higher than 3 times the cut-off value. According to legends of Figures 1 and 2A, percentages of anti-LAM and anti-ManLAM IgG-positive individuals in each group were determined. Asterisks indicate significant differences between the groups. <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$ .

and anti-ManLAM IgG, 50% and 70% of the highest ASCA-positive CD patients were positive for anti-LAM ( $P \leq 0.0362$ , *vs* ASCA-low or ASCA-negative patients) and anti-ManLAM IgG ( $P \leq 0.0047$ , *vs* ASCA-low or ASCA-negative patients; Figure 3B), respectively. To

better visualize the extent of correlations between anti-mycobacterial IgG and ASCA, we plotted the extinction values obtained in the mycobacterial ELISA against those of the ASCA ELISA (Figure 4). All correlations were highly significant and ASCA correlated best with

**Figure 4** Correlation of ASCA with anti-mycobacterial IgG titers. Sera from 60 CD patients were randomly chosen and used for determination of ASCA titers and anti-mycobacterial IgG levels in the same experiment. Each dot represents one serum sample with the  $A_{450}$  obtained in the ASCA-specific ELISA (x-axis) and that obtained with ELISA specific for IgG against different mycobacterial lysates or purified LAM or ManLAM (y-axis).

IgG against *M. smegmatis* ( $r = 0.64$ ,  $P < 0.0001$ ), followed by anti-BCG and anti-ManLAM IgG ( $r = 0.53$ ,  $P < 0.0001$ ).

#### ASCA-positivity and MBL-deficiency synergistically associate with anti-mycobacterial IgG

Since deficiency for MBL associates with the ASCA-positive subgroup of CD patients [27, 28] we asked whether deficiency for MBL might also associate with elevated levels of anti-mycobacterial IgG. We found that similar to ASCA-positivity, MBL-deficiency was associated with higher proportions of anti-mycobacterial IgG-positive individuals for some but not all mycobacterial antigens tested (Figure 5), intriguingly, MBL-negativity synergistically contributed to increased frequencies of anti-mycobacterial IgG-positive individuals in the ASCA-positive/MBL-negative as compared to the ASCA-/MBL-double positive subgroup of CD patients. The synergistic effect that MBL-negativity and ASCA-positivity had regarding increased frequencies of anti-mycobacterial IgG positive individuals was most obvious when the ASCA-positive/MBL-negative group was compared with the ASCA-negative/MBL-positive group of CD patients: between 2.7-fold (from 13.0% to 35.3% for anti-*M. chelonae*) and 7.4-fold (from 8.7% to 64.7% for anti-*M. avium*) increased proportion of anti-mycobacterial IgG-positive individuals.

#### Anti-mycobacterial antibodies bind to yeast mannan

To determine potential cross-reactivities between anti-mycobacterial antibodies and ASCA, we affinity-purified eight highly ASCA-positive sera from CD patients on yeast mannan and compared original sera with the corresponding affinity purified antibodies for reactivity with yeast mannan (positive control), mycobacterial lysates and purified LAM and ManLAM. A tetanus toxoid-specific ELISA confirmed that affinity-purified serum antibodies were virtually free of contaminating, non-yeast mannan-specific IgG. Affinity-purified ASCA from individual patients showed individual reactivity patterns. While three of eight patients' ASCA reacted markedly with all mycobacterial preparations (patients No. 1, 4 and 7), 5 patients showed restricted reactivity (Figure 6A). On average, affinity-purified antibodies showed the highest degree of reactivity with LAM ( $73\% \pm 34\%$  of original sera) and lowest with MAP lysate ( $35\% \pm 16\%$  of original sera). The same 8 highly ASCA-positive sera were also affinity purified on *M. smegmatis* lysate and assessed for reactivity with yeast mannan and tetanus toxoid. All sera showed strongly reduced reactivity with yeast mannan after affinity-purification (Figure 6B).

#### Infection of mice with BCG leads to transient production of immunoglobulins that cross-react with *S. cerevisiae* mannan

To test, whether experimentally induced antibodies

**Figure 5** ASCA-positivity and MBL-negativity synergistically associate with anti-mycobacterial seroreactivity. CD patients' sera were grouped according to their ASCA and MBL status. ASCA-negative and ASCA-positive patients were separated into MBL-expressors ( $> 500$  ng/mL,  $n = 23$  and  $39$ , respectively) and MBL-low/deficient ( $\leq 500$  ng/mL,  $n = 7$  and  $17$ , respectively) individuals. From each group, average IgG levels against mycobacterial lysates or purified LAM or ManLAM  $\pm$  SEM were determined. Percentages of individuals per group with anti-mycobacterial IgG titers above the cut-off levels are shown. Significant differences are marked with asterisks. <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$ .

against mycobacteria may cross-react with *S cerevisiae* mannan, we infected mice with  $10^7$  live BCG, followed by an equal booster injection after 5 wk. Figure 7 shows that infection with BCG induced marked levels of BCG-lysate-specific IgM and moderate levels of specific IgG after 4 wk and up to 13 wk after the booster injection. Intriguingly, BCG infection led to transiently elevated titers of ASCA IgM and IgG which declined to background or near background levels within 2 mo post booster injection.

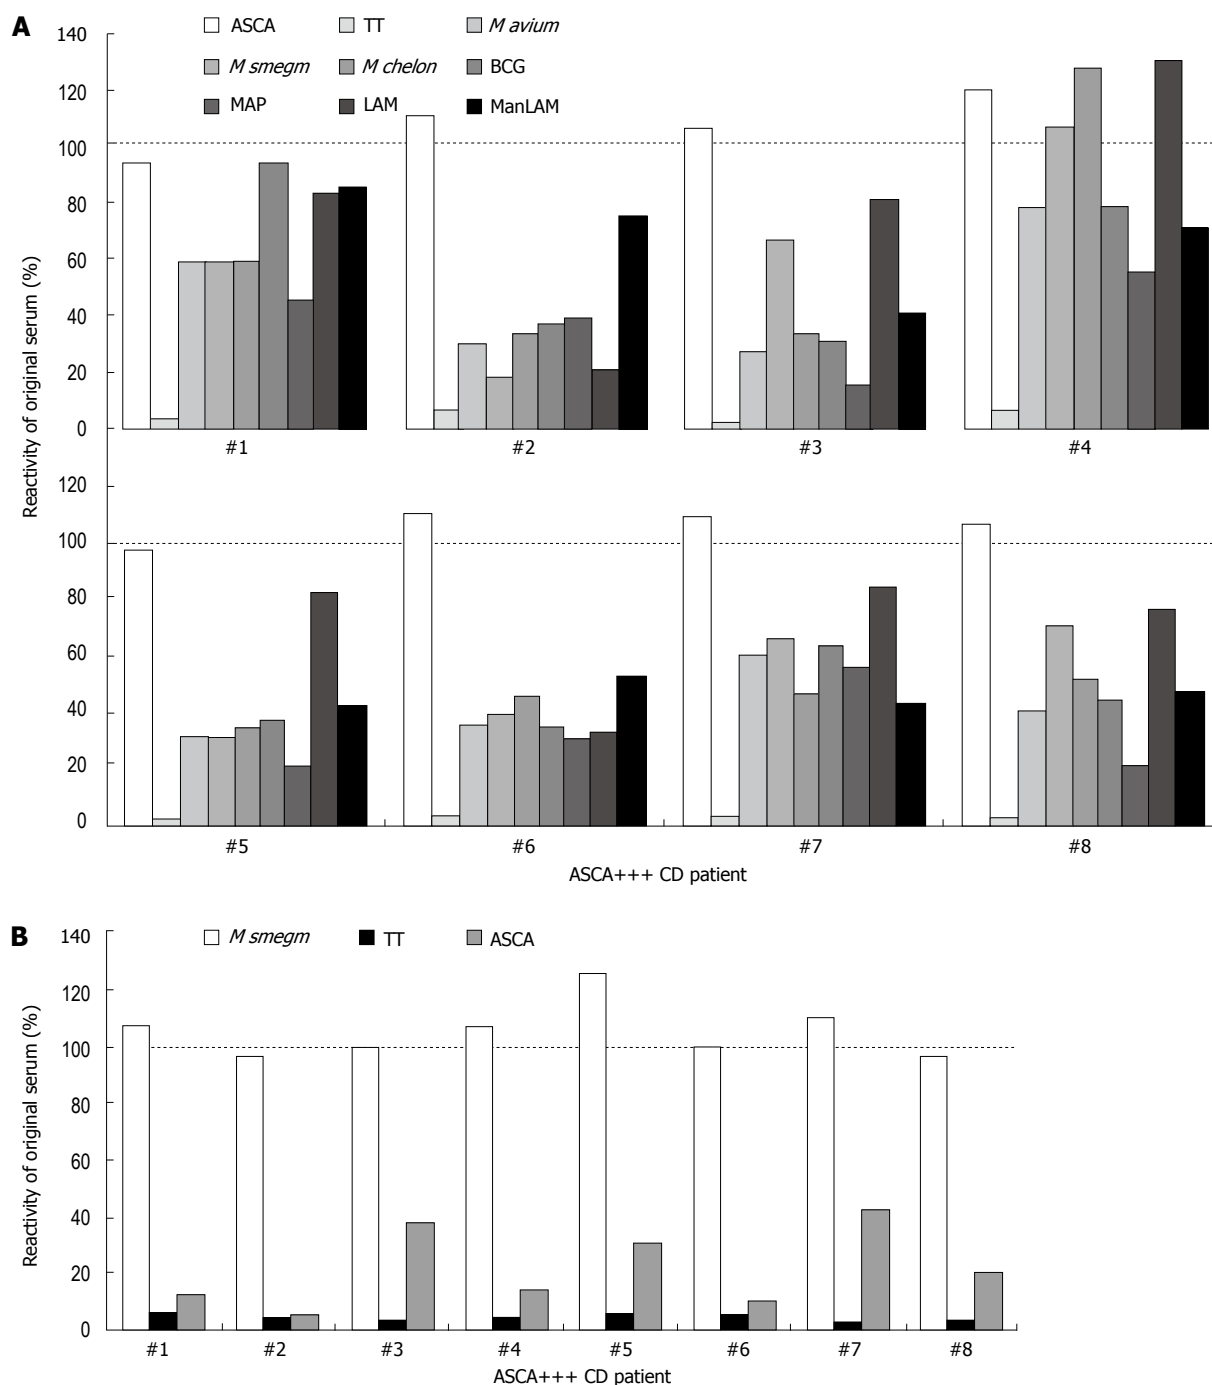

#### Higher frequency of anti-mycobacterial IgG-positive individuals in the subgroup of CD patients with fistulizing disease

In order to address the possible significance of anti-mycobacterial IgG in CD, patients were grouped according to the Montreal classification into UC-like (purely inflammatory), or stenosing or fistulizing disease phenotype (the latter two summarized as complicated disease). Sera from these groups of CD patients were compared for anti-mycobacterial IgG and ASCA by ELISA. ASCA were included because earlier reports indicate that ASCA associate with complicated disease<sup>[33,34]</sup> and increased risk for surgery months<sup>[35]</sup>. There was a weak tendency for patients with complicated disease to more often express anti-mycobacterial IgG compared to patients with UC-like disease (data not shown). On the other hand, a markedly higher frequency of patients expressed antibodies against mycobacterial lysates, but not purified LAM or ManLAM, when only the subgroup of patients with fistulizing disease was compared with UC-like disease (Figure 8). These differences were statistically significant for anti-*M avium* ( $P = 0.024$ ), anti-*M smegmatis* ( $P = 0.004$ ) and anti-MAP IgG ( $P = 0.045$ ). In contrast, the proportion of patients with stenoses expressing IgG against mycobacterial lysates was not markedly elevated compared to those with UC-like disease. Both subgroups with complicated

disease had a markedly higher proportion of individuals being positive for ASCA compared to UC-like disease. Here, the difference was statistically significant for the subgroup with stenoses compared to UC-like disease ( $P = 0.008$ , Figure 8). Finally, compared to patients with UC-like disease or stenoses, patients with fistulizing disease on average showed more individual seroreactivities per patient against the mycobacterial antigens tested ( $2.5$  vs  $1.5/1.6$ ,  $P = 0.050$ , Figure 8B).

## DISCUSSION

In the present study we have chosen a number of mycobacterial strains with more or less ubiquitous occurrence and - with the exception of BCG-originally isolated from patients suffering from mycobacterial infections to serve as antigens for ELISA with IBD patients' and control sera in order to assess a possible relationship between anti-mycobacterial antibodies and ASCA in CD. In addition, we used purified lipoarabinomannans with or without a richly mannosylated arabinose moiety (LAM from *M smegmatis* and ManLAM from *M tuberculosis*, respectively) because of similar oligomannose side chains as found in mannan from *S cerevisiae*, the specific antigen for ASCA. In agreement with published data<sup>[19,20]</sup>, terminal  $\alpha$ -1,3 linked mannose which is part of the dominant ASCA epitope was present at different extents in our mycobacterial preparations. In particular this epitope was strongly present in ManLAM from *M tuberculosis* while it was completely absent in LAM from *M smegmatis*. In accordance with that, *M smegmatis* lysate showed the weakest binding to GNL among all lysates tested. With the exception of non-mannose-capped LAM, we found significantly higher proportions of anti-mycobacterial IgG-positive individuals in CD compared to the healthy control group. We focused on IgG because initial screenings generally showed much lower levels

**Figure 6** ASCA strongly cross-react with mycobacterial antigens in a subgroup of ASCA-positive CD patients. **A:** Eight sera from highly ASCA-positive CD patients were incubated with membrane sections of yeast mannan Western blots containing the ASCA-reactive material, and bound antibodies were eluted. Eluted antibodies were titrated to yield comparable extinction values in the ASCA ELISA as with the original serum (approx. 100%, empty columns) and used at the corresponding dilution to assess reactivities against mycobacterial antigens. As a specificity control for affinity purification, eluted antibodies were also tested in a tetanus toxoid (TT) ELISA. **B:** The same 8 patients' sera were also affinity purified on nitrocellulose membranes decorated with *M. smegmatis* lysate. In analogy to A, eluted antibodies were adjusted for equal reactivity with *M. smegmatis* as the original sera (approx. 100%, empty columns) and tested at the corresponding dilution for reactivities against yeast mannan and TT.

or absence of specific IgA (data not shown). Previous studies have mainly focused on seroreactivities against selected antigens from MAP<sup>[22,36,37]</sup>. Naser *et al* have observed that a large proportion of CD, but neither UC patients nor controls had antibodies reactive with two recombinant antigens (75% and 89%, respectively) from their MAP genomic library<sup>[22]</sup>. In contrast, less than 30% of our CD patients showed broad MAP-specific

seroreactivity. Our results are comparable to those described by Polymeros *et al*, who found that sera of 42% of their small cohort of CD patients reacted with one or more MAP-derived peptides<sup>[37]</sup>. In our study UC patients showed-although less marked than CD patients - enhanced seroreactivity compared to healthy controls, in particular against some of the crude lysates. This is not surprising as enhanced seroreactivities against unusual,

**Figure 7** Antibody response of mice infected with *M bovis* BCG. C57BL/6 mice were intravenously infected with  $10^7$  viable *M bovis* BCG and the infection repeated after 5 wk. Serum was prepared from blood samples collected before infections, 4 wk after primary infection and 4 wk and 13 wk after secondary infection. Serum samples were tested for the presence of IgM (filled squares) and IgG (empty spheres) antibodies specific for *M bovis* BCG (left panel) and for *S cerevisiae* mannan (right panel). Results are shown as average  $A_{450}$  values of 4 animals  $\pm$  SE.

untypical or commensal antigens is not only a hallmark of CD but of IBD in general<sup>[38]</sup>.

While Polymeros *et al*<sup>[37]</sup> addressed a potential self-cross-reactive nature of anti-MAP antibodies in CD patients, in the present study, we were focusing on potential cross reactivities of CD patients' anti-mycobacterial antibodies with mannan from *S cerevisiae*. We could clearly demonstrate that the frequent seroreactivity against cell wall mannan from *S cerevisiae* (ASCA-positivity) in CD patients significantly correlated with seroreactivity not only against MAP, but also against antigens from all other mycobacteria that we tested. Importantly, correlations were best for *M smegmatis* lysate and purified ManLAM. The *M tuberculosis*-derived ManLAM used in the present study is characterized by highly mannosylated arabinose (similar to the ManLAM from BCG). While Stokes *et al* have also observed binding of GNL to *M tuberculosis*<sup>[39]</sup>, ManLAM from *M tuberculosis* should theoretically not contain the GNL-reactive  $\alpha$ -1,3 linked mannose residues according to biochemical analyses<sup>[40]</sup>. On the other hand, the phospho-myo-inositol-capped LAM of *M smegmatis* has no rich mannose-cap on its arabinose moiety<sup>[41,42]</sup> and shows no binding to GNL. Collectively, the good correlations between seroreactivities against *S cerevisiae* mannan and mycobacterial antigens shown in the present study do not solely depend on the presence of either the terminal  $\alpha$ -1,3 linked mannose residues or a rich mannose-cap. *M chelonae* is one of the rare mycobacterial strains with truly uncapped arabinose moieties on their LAM, also termed AraLAM or CheLAM<sup>[18]</sup>. On the other hand, this strain's lysate is very well recognized by GNL which may explain the increased reactivity with ASCA-positive CD patients' IgG.

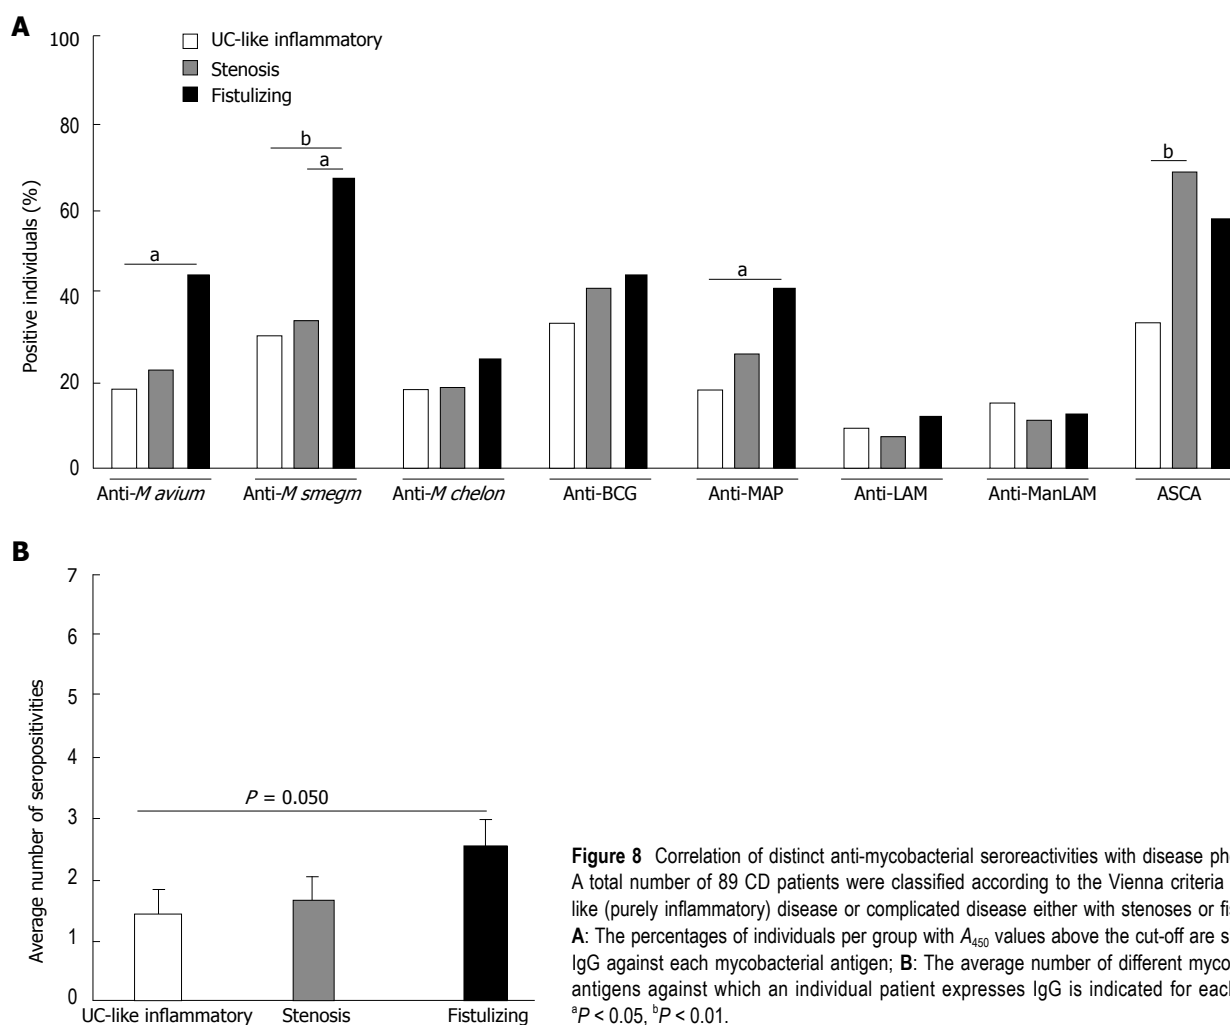

Even in the absence of the dominant ASCA epitope terminal  $\alpha$ -1,3 linked mannose there was a good and significant correlation of ASCA-positivity with seroreactivities against purified LAM, most strikingly if only those patients with high ASCA titers were considered.

Because in our cohort of CD patients MBL-deficiency associates with positivity for ASCA<sup>[27,28]</sup>, we wondered whether generation of anti-mycobacterial

antibodies may associate with this deficiency as well, and whether such an association may depend on certain strains with differential presence of the terminal  $\alpha$ -1,3 linked mannose motive and/or distinctly capped LAM. Indeed, we found an association of MBL deficiency with the prevalence of anti-mycobacterial antibodies. However, this association was not confined to strains with mannose-capped LAM and was not apparent for antibodies to BCG with rich mannose caps or *M chelonae* with the best binding to GNL apart from yeast mannan. It is known that MBL facilitates the entry of mycobacteria into host cells<sup>[43,44]</sup>. Therefore, in MBL-deficient persons, a stronger systemic immune response may be expected since the mycobacterial (cell wall) antigens are not rapidly eliminated by phagocytes.

The strong association of anti-mycobacterial antibodies with high ASCA titers with the observed synergistic effect of MBL-deficiency may be explained in different ways. First, it may be that these individuals have, due to a genetic predisposition, an increased reactivity to environmental (mannosylated) antigens. Alternatively there could be a true antibody cross-reactivity between the mannan antigens of *S cerevisiae* and mycobacteria. To address this question we affinity-purified ASCA from highly ASCA-positive CD patients and could show that these purified antibodies exert variable degrees of cross-reactivities between yeast mannan and mycobacterial lysates or purified (Man) LAM. On the other hand, affinity-purification of antibodies against *M smegmatis* lysate - the lysate that showed the highest degree of binding with affinity-purified ASCA-led to strongly reduced reactivity with yeast mannan compared to the original serum. Thus, while in some patients anti-mycobacterial IgG are mainly due to cross-reactive ASCA, in others, ASCA and anti-mycobacterial antibodies have separate specificities. In either case, the fact that affinity-purified anti-*M smegmatis* IgG only show weak or no reactivity with yeast mannan suggests that such cross-reactive antibodies only account for a minor fraction of total ASCA. This constellation makes it very unlikely that mycobacterial antigens play a role in the induction of ASCA. Since our purified LAM does not contain the terminal  $\alpha$ -1,3 mannose motif but shows a high degree of reactivity with affinity-purified ASCA, it has to be discussed whether the spectrum of antigens recognized by CD patients' ASCA goes beyond terminal  $\alpha$ -1,3 linked mannose side chains and may encompass other antigens such as peptide epitopes from the protein part of the mannan. In this context, it is of interest that according to a recent study CD patients contain antibodies that cross-react to an individual extent between  $\beta$ 2-glycoprotein I and yeast phosphopeptidomannans<sup>[45]</sup>.

Our experimental mouse model was to test whether mycobacterial infection is theoretically able to trigger induction of ASCA. For infection of mice we have chosen BCG because it is a commercial vaccination strain and is well established for infection and immunization studies in mice. Our finding that ASCA were only transiently expressed and declined by 2 mo post-booster

**Figure 8** Correlation of distinct anti-mycobacterial seroreactivities with disease phenotype. A total number of 89 CD patients were classified according to the Vienna criteria into UC-like (purely inflammatory) disease or complicated disease either with stenoses or fistulizing. **A:** The percentages of individuals per group with  $A_{450}$  values above the cut-off are shown for IgG against each mycobacterial antigen; **B:** The average number of different mycobacterial antigens against which an individual patient expresses IgG is indicated for each group. <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$ .

infection while BCG-specific IgM and IgG remained high, supports our conclusion from the results of the affinity-purification study that an immune reactivity to mycobacterial antigens is unlikely to trigger the induction of a stable phenotype of ASCA-positivity.

We were interested whether seroreactivity to mycobacterial antigens may associate with a certain disease phenotype. We observed that more patients with complicated disease (stenosing or fistulizing) expressed antibodies against mycobacterial lysates compared to patients with purely inflammatory disease. Since we observed strong associations of anti-mycobacterial antibodies with ASCA-positivity and ASCA have been shown to associate with complicated disease<sup>[33-35]</sup>, our findings were not unexpected. However, the fact that this trend was clearly confined to the subgroup with fistulizing disease, while ASCA-positivity even better associated with stenoses, is surprising. Possibly, ingested mycobacteria more easily gain access to systemic immune compartments for priming if the bowel wall is transmurally damaged. Regarding ASCA, the origin of this unusual immune response is still unknown and whatever it is may actually be involved in the progression to more severe CD phenotypes. Finally, patients with fistulizing disease more frequently showed seroreactivities against multiple mycobacterial antigens compared to those with UC-like disease. This

observation fits to data published by others showing a more severe phenotype of disease in patients with increasing numbers of seroreactivities to various intestinal (commensal) antigens<sup>[46]</sup>.

In conclusion, we were able to demonstrate that ASCA-positive patients had significantly more immune reactivities to mycobacterial antigens. In a subgroup of ASCA-positive CD patients, anti-mycobacterial immunoglobulins at least partially represent cross-reactive ASCA, while in others there seem to be separate ASCA and anti-mycobacterial antibodies that do not cross-react. Furthermore, purified anti-*M. smegmatis* IgG showed low or no binding to yeast mannan. Therefore, we postulate that our results reflect more the predisposition of CD patients to develop increased immune reactivities to various ubiquitous antigens in general and mannosylated antigens in particular, rather than a role of mycobacteria in the induction of ASCA.

## ACKNOWLEDGMENTS

The authors would like to thank Martin Sauter for technical assistance with purification and characterization of *S. cerevisiae* mannan, Beatrice Flogerzi for lab-technical assistance, Irène Garcia for help with mycobacterial infection, and Linda Bolzern for carefully reading the manuscript.

## COMMENTS

## Background

A subgroup of patients with Crohn's disease (CD) develops antibodies against *S cerevisiae* cell wall mannan (ASCA). The mechanism of ASCA generation is still unclear. It is possible that some opportunistic or pathogenic infectious microorganism may be the initial inducer of this unusual antibody response because similar (cell wall) mannans also occur in other microorganisms such as mycobacteria with their lipoarabinomannan (LAM).

## Research frontiers

It has been shown that the opportunistic pathogen *Candida albicans* is able to experimentally induce ASCA (Standaert-Vitse *et al* 2006) and we have shown that Crohn's patients' ASCA cross-react with cell wall mannans from different yeast strains including *C albicans* (Schaffer *et al* 2007). In contrast to yeast, there exists a highly controversial debate on a possible role for mycobacteria in the etiopathogenesis of Crohn's disease.

## Innovations and breakthroughs

Our study clearly shows that (1) mycobacterial infection is very unlikely the origin of ASCA since anti-mycobacterial antibodies and ASCA in an individual patient are either non-overlapping or the former only represents a minor part of all antibodies recognizing yeast mannan; and (2) the correlation of antibodies against mycobacterial antigens with those against yeast mannan reflects - apart from pure cross-reactivity in some patients - increased predisposition for adaptive immune responses against ubiquitous antigens, especially observed in patients with a severe disease phenotype.

## Applications

The findings in the present study represent an important basis for further research on the role of antimicrobial immune responses in the pathogenesis of Crohn's disease. Furthermore, antimicrobial antibody patterns may define distinct subgroups of Crohn's patients requiring individual treatment approaches.

## Peer review

Similar to ASCA, seroreactivity against mycobacteria may define CD patients with complicated disease and a predisposition for immune responses against ubiquitous antigens. Mycobacterial infection does not likely play a role in ASCA induction.

151 sporadic colorectal cancer patients. The promoter methylation of tumor-related genes was determined by methylation-specific PCR. Eighty six patients from whom fresh tumor samples were obtained and 81 controls were also examined for serum folate and vitamin B<sub>12</sub> concentrations by a commercial radioimmunoassay kit.

**RESULTS:** We found 29.1% of cases had tumors with at least one methylated gene promoter. In case-case comparison, we did not find a significant association between methylation in tumors and any single genotype. However, in comparison to controls with the CC genotype, an increased risk of tumor methylation was associated with the CT genotype (OR = 2.5; 95% CI, 1.1-5.6). In case-case comparisons, folate/vitamin B<sub>12</sub> levels were positively associated with tumor methylation. Adjusted odds ratios for tumor methylation in cases with high (above median) *versus* low (below median) serum folate/vitamin B<sub>12</sub> levels were 4.9 (95% CI, 1.4-17.7), and 3.9 (95% CI, 1.1-13.9), respectively. The frequency of methylated tumors was significantly higher in high methyl donor than low methyl donor group, especially in those with *MTHFR* CT (*P* = 0.01), and CT/TT (*P* = 0.002) genotypes, but not in those with the CC genotype (*P* = 1.0).

**CONCLUSION:** We conclude that high concentrations of serum folate/vitamin B<sub>12</sub> levels are associated with the risk of promoter methylation in tumor-specific genes, and this relationship is modified by *MTHFR* C677T genotypes.

### Abstract

**AIM:** To evaluate joint effects of *Methylenetetrahydrofolate reductase* (*MTHFR*) C677T genotypes, and serum folate/vitamin B<sub>12</sub> concentrations on promoter methylation of tumor-associated genes among Iranian colorectal cancer patients.

**METHODS:** We examined the associations between *MTHFR* C677T genotype, and promoter methylation of *P16*, *hMLH1*, and *hMSH2* tumor-related genes among

genotype affects promoter methylation of tumor-specific genes in sporadic colorectal cancer through an interaction with folate/vitamin B<sub>12</sub> status. *World J Gastroenterol* 2008; 14(23): 3662-3671 Available from: URL: <http://www.wjgnet.com/1007-9327/14/3662.asp> DOI: <http://dx.doi.org/10.3748/wjg.14.3662>

## INTRODUCTION

Colon cancer (CLC) is one of the most common cancers in the world, with high rates in Western countries<sup>[1]</sup>. A significant increase in CLC incidence with the predominant localization in the left colon has also been reported in Iran over the last decade<sup>[2,3]</sup>. However, little is known about the molecular mechanism of CLC in this region.

One of the pathways by which that CLC can progress involves transcriptional silencing by hypermethylation of CpG islands referred as methylator phenotype (CIMP<sup>+</sup>)<sup>[4]</sup>. The CIMP<sup>+</sup> in CLC is characterized by frequent hypermethylation of specific CpG sites, including those present in the promoter regions of tumor suppressor genes such as the cell cycle regulator, *p16* and genes involved in DNA mismatch repair like *bMLH1*<sup>[4]</sup>. The *bMLH1* promoter region is methylated in about 90% of microsatellite unstable (MSI-positive) colon cancers that leads to the silencing of *bMLH1* expression<sup>[5]</sup>. The CIMP<sup>+</sup> phenotype may be the result of more widespread aberration in methyl-group metabolism in cancer cells.

Interaction of the epigenome with the environment, including nutrition, can alter patterns of gene expression. It has been proposed that polymorphisms in folate-metabolizing enzymes and genes involved in DNA methylation are associated with colon cancer. *MTHFR* is a key enzyme regulating folate metabolism, which affects DNA methylation and synthesis. *MTHFR* converts 5, 10-methylenetetrahydrofolate to 5-methyl tetrahydrofolate, which is required for homocysteine methylation to methionine. Methionine is then activated to S-adenosylmethionine, a universal methyl donor in numerous transmethylation reactions, including methylation of DNA, RNA, proteins, and other molecules<sup>[6]</sup>. The *MTHFR* gene is polymorphic with single nucleotide variants within codon 677 in exon 4 (C to T, Ala to Val). This variant encodes a thermolabile enzyme with reduced activity that leads to a reduced plasma folate level<sup>[7]</sup>.

Several case-control studies have shown a reduced risk of CLC for homozygous *MTHFR* TT individuals. The protective effect appears to depend on an adequate level of dietary folate intake, gender, age, and location of the tumor in the proximal or distal colon<sup>[8,9]</sup>. In some circumstances, the *MTHFR*-TT genotype seems to increase the risk of CLC<sup>[10,11]</sup>. It has been suggested that deficient activity of *MTHFR* affects DNA methylation status through an interaction with folate status<sup>[12]</sup>. Several data provide evidence that individuals with the common C677T mutation in the *MTHFR* gene and with low levels of folate had a diminished level of DNA methylation

compared with those with the C/C wild type. Folate deficiency may be involved in carcinogenesis through impaired synthesis and repair of DNA, or by causing global hypomethylation of DNA, a possible early event in carcinogenesis<sup>[13]</sup>. Although a protective role against cancer was suggested for the high dietary folate intake, epidemiological evidence has not consistently shown a protective effect of high folate intake against CLC<sup>[14,15]</sup>. There are few studies addressing joint effects of *MTHFR* C677T genotypes, and methyl donor coenzymes status on promoter methylation of tumor-associated genes in CLC<sup>[16,17]</sup>. In the current study we investigated the role of *MTHFR* C677T genotype, and serum folate/vitamin B<sub>12</sub> concentrations on methylation of CpG islands at *p16*, *bMLH1*, and *bMSH2* tumor-associated genes among Iranian sporadic CLC patients.

## MATERIALS AND METHODS

### Study population, and samples

A total of 151 sporadic primary CLC tumor samples (86 fresh and 65 formalin fixed and paraffin embedded) as well as corresponding normal mucosa were collected from surgical patients at 3 hospitals of the Shiraz University of Medical Sciences in Shiraz, Southern Iran from July, 2003 to September, 2005. Institutional review board approval was granted for this study. The fresh samples were snap frozen in liquid nitrogen immediately after resection and stored at -70°C until processing. All samples were evaluated and subjected to histological diagnosis by an expert pathologist, who also selected representative tissue sections for DNA extraction, and further molecular analyses. The splenic flexure was used as the anatomical boundary to define proximal and distal CLC. Sociodemographic characteristics such as age and gender were obtained by completion of a detailed questionnaire.

### Extraction of DNA and *MTHFR* genotyping

Genomic DNA was extracted from micro-dissected formalin-fixed, paraffin embedded tumor samples and adjacent normal tissues using the pinpoint slide DNA isolation kit (ZYMORESEARCH, CA, USA). We used the standard phenol/chloroform method for DNA extraction from fresh tumor samples. Genotyping of *MTHFR* at codon 677 of DNA from control and CLC cases was performed using a modification of the mutagenically separated PCR (MS-PCR) method described by Hill and FitzPatrick<sup>[18]</sup>. Genotyping for *MTHFR* involved analysis of PCR product size by electrophoresis on 3% agarose gels. PCR reactions were carried out in a volume of 50 µL containing 50 ng DNA, 1 × polymerization buffer (MBI Fermentas, Lithuania), 1.5 mmol/L MgCl<sub>2</sub>, 0.2 mmol/L dNTP, and 1.5 U Taq polymerase. The primers and concentrations used for PCR reactions were as follows: forward mutant (29 bases) 0.35 µmol/L 5'-CACTTGAAGGAGAAGGTGTCTGCGGGACT-3', forward normal (49 bases) 0.19 µmol/L 5'-GCTTTGAGGCTGACCTGAAGA-CCTTGAAGGAGAAG GTGTCTGCGGCAGC-3'

and the reverse primer (20 bases) 0.23  $\mu\text{mol/L}$  5'-TCACCTGGATGGGAAAGATC-3'. The two forward primers are complementary to the normal (677C) and mutant (677T) alleles and differed in length by 20 bases at their 5' ends. The cycling parameters were 5 min at 95°C followed by 35 cycles of 45 s at 95°C, 1 min at 55°C, and 45 s at 72°C followed by a single 10-min extension at 72°C. Twenty  $\mu\text{L}$  of each reaction mixture was separated on agarose gel and stained with ethidium bromide and visualized under UV illumination.

### Serum folate and vitamin B<sub>12</sub> measurement and methylation specific PCR (MSP)

Folate and vitamin B<sub>12</sub> measurements were limited to sera from 86 patients with freshly studied tumors and 81 age and sex matched normal controls, selected among healthy volunteers from the general population with no history of any cancer. Blood samples were drawn from patients before operation and serum was prepared within two hours of blood collection. Sera were frozen immediately at -70°C until used. The concentrations of folate and vitamin B<sub>12</sub> in each specimen were measured in duplicate by a commercial radioimmunoassay kit (SimulTRAC-SNB RIA, DRG International Inc. USA) using a gamma counter (Contron, Switzerland). We determined the *p16*, *bMLH1*, and *bMSH2* promoter methylation status by chemical treatment with sodium bisulfite and subsequent MSP as described<sup>[19]</sup>. In brief, this technique uses bisulfite modification to convert unmethylated, but not methylated, cytosine to uracil. MSP utilizes this difference to amplify specifically either methylated or unmethylated DNA. The sequences of primers used for amplification of the promoter region of each of the 3 genes were as follows: *p16* methylated, sense 5'-TTATTAGAGGGTGGGGC-GGATCGC-3' and antisense 5'-GACCCCGAACC GCGACCGTAA-3', which produce a 150 bp fragment; *p16* unmethylated: sense 5'-TTATTAGAGGGTGGGGTGGATTGT-3' and antisense 5'-CAACCCCAAACCACAACCATAA-3', which produce a 151 bp fragment; *bMLH1* methylated, sense 5'-ACGTAGACG-TTTTATTAGGGTCGC-3' and antisense 5'-CCTCATCGTAACTACCCGCG-3', which produce a 112 bp fragment; *bMLH1* unmethylated, sense 5'-TTTTGATGTAGATGTTTTATTAGGGTTGT-3' and antisense 5'-ACCACCTCATCATAACTACCCACA-3', which produce a 124 bp fragment; *bMSH2* methylated, sense 5'-TCGTGGTTCGGACGTCGTTTC-3' and antisense 5'-CAACGTCTCCTTCGACTACACCGG-3', which produce a 133 bp fragment; *bMSH2* unmethylated, sense 5'-GGTTGTTGTGGTTGGATGTTGTTT-3' and antisense 5'-CAACTACAACATCTCCTTCAAC TACACCA-3', which produce a 144 bp fragment. The hot-started PCR reactions were performed in a 50  $\mu\text{L}$  reaction volume containing 25 pmol of each of sense and antisense primer, 0.2 mmol/L dNTPs, and 80 ng bisulfite-modified DNA in 1× PCR buffer provided by Taq enzyme supplier. The reaction mixture was denatured at 95°C for 5 min, after which 1.5 U Taq polymerase was added; then amplified by 40 cycles, each consisting of 30 s denaturation at 95°C, 45 s annealing

Table 1 Frequency distributions of selected characteristics in CLC patients and control subjects

Variables	Cases			Control (n = 81)	P <sup>1</sup>

at 58°C, and 30 s polymerization at 72°C, followed by a single 10-min extension at 72°C.

### Statistical analysis

Statistical analysis was performed using the SPSS version 11.5 software package (Chicago, IL). Associations between methylation of loci and clinical, biological and genotypic features were evaluated using Chi square and Fisher's exact test as appropriate. Logistic regression was used to calculate odds ratio (OR) and 95% confidence intervals (95% CI). We adjusted for covariates, specifically including age, gender, and smoking status. Comparing serum folate and vitamin B<sub>12</sub> levels in cases and controls was performed using two-sided *t*-test, Mann-Whitney test, and Kruskal-Wallis test appropriately.

## RESULTS

### Distribution of selected characteristics of cases and controls

Selected characteristics of the study population are presented in Table 1. One hundred and fifty one patients and 81 controls entered the study. The distribution was similar in cases and controls by virtue of the study design. Sixty percent (91) of patients had distal CLC and 40% (60) had proximal CLC. Cases were more likely to be males and to be non-smokers. No statistically significant differences were found between cases and controls or between proximal and distal cancer cases with respect to distributions of age, and smoking status. The frequency of distal CLC in males and females was 68.9% and 47.5% (Table 1), respectively, indicative of a significantly higher left CLC incidence in males than females (OR = 2.65; 95% CI, 1.3-5.2).

### MTHFR genotypes and the methylation status of tumor-associated genes promoter

Illustrative examples of genotyping of *MTHFR* gene are shown in Figure 1. In 42 patients for whom we performed genotyping in both the cancer tissue and adjacent normal tissue, the typing results were identical in the two samples. CpG island promoter

**Figure 1** Representative example of MS-PCR assay for genotyping of codon 677 of *MTHFR* gene. For PCR-primers and reaction conditions see methods. In case of the *MTHFR* 677 C allele, a product with 168 base pairs (bp) in length was generated, whereas the *MTHFR* 677 T allele yielded a 148-bp product. The differently sized allele-specific PCR products were separated by agarose gel electrophoresis. In 42 patients genotyping was performed in both cancer tissue (T) and adjacent normal tissue (N). Lanes 2-5 in the lower panel show heterozygote (CT) samples. M: DNA size marker.

hypermethylation was analyzed in the primary tumors by methylation specific PCR as described in “MATERIALS AND METHODS”. Illustrative examples are shown in Figure 2. Table 2 summarizes the association of promoter methylation of genes and *MTHFR* genotype, and other clinical-biological characteristics of CLC patients. Several studies have reported age-dependent variation in the frequency of the *MTHFR* genotypes<sup>[20,21]</sup>. Therefore, we divided both CLC and control groups into  $\geq 60$  and  $< 60$ -year old groups. The median age of CLC patients (60 years) was chosen for this division. The most frequently methylated locus was *p16* (19.9 %; 30 of 151), followed by *hMLH1* (13.2 %; 20 of 151), and *hMSH2* (2.6 %; 4 of 151). Eight of 151 (5.3 %) of tumors had both P16 and *hMLH1* CpG island hypermethylation while 2 of 151 (1.3%) had both *hMLH1* and *hMSH2* promoter hypermethylation. None of the tumors had simultaneous CpG island hypermethylation of all three genes. There were no significant differences in association of methylation of any individual gene investigated by age or sex of patients. The frequency of tumor methylation (tumors with at least one gene methylated) was 44/151 (29.1%). The latter group of tumors is collectively referred to as “methylated tumors”. A significantly higher risk of tumor methylation was found in females (OR = 2.3; 95% CI, 1.1-5.04) (Table 2). Gene promoter methylation was also strongly associated with tumor site, the highest frequency (more than 97%) of methylation occurring in the proximal tumors.

We confronted *MTHFR* genotype with the methylation of tumors using the CC genotype as the reference group. Results from case-case comparison, showed no statistically significant genotype dependent differences in the frequency of any specific gene promoter methylation (Table 2). In comparison to cases with the CC genotype, we did not find any significant association between tumor methylation or “methylated tumors”, defined above and any single genotype in the entire group of patients, but cases with the CT genotype were slightly more likely to have methylated tumors (OR = 1.9; 95% CI, 0.9-4.2). Results from the case-control comparison, showed that the CT genotype was significantly associated with tumor methylation in the entire group of patients (OR = 2.5; 95% CI, 1.1-5.6;

**Figure 2** Representative examples of MSP reactions for promoter methylation analysis of *p16*, *hMLH1*, and *hMSH2* genes in primary CLC tumors. The presence of a visible PCR product in those lanes marked U indicates the presence of unmethylated genes; the presence of a product in those lanes marked M indicates the presence of methylated genes. Lane 1 indicates the 50 bp DNA size marker.

Table 3). More than five-fold increased risk of tumor methylation was also observed for the CT genotype, in male CLC cases compared with age-matched male controls. The CT genotype also presented significantly increased tumor methylation in the proximal and in the older age group (OR = 2.7, 95% CI, 1.2-6.2; OR = 3.8, 95% CI, 1.2-12, respectively). The same trend was also observed for CT + TT genotypes. These results suggest that the C677T genotype of *MTHFR* can predispose some of CLC patients to the methylation of genes promoter.

### Serum folate/vitamin B<sub>12</sub> status and genes promoter methylation

Due to the previously observed interaction between folate and the *MTHFR* genotype in CLC<sup>[22]</sup>, we investigated the influence of serum folate/vitamin B<sub>12</sub> levels on tumor methylation in 86 fresh tissue samples in which their corresponding blood samples were also available. We observed no significant differences in serum folate/vitamin B<sub>12</sub> levels between cases and controls (Table 4). There were also no differences in association of serum folate/vitamin B<sub>12</sub> levels by sex, and tumor location. Comparing two age groups of patients, a trend for higher serum folate/vitamin B<sub>12</sub> levels was observed in older age group, with the older cases presenting 15% higher serum folate ( $P = 0.04$ ).

In case-control comparisons, we found no significant difference in serum folate/vitamin B<sub>12</sub> levels by *MTHFR* genotypes (data not shown). However, in case-case comparisons, serum folate levels appear to be associated with *MTHFR* genotypes (Table 5). Patients with the homozygous TT genotype had significantly lower concentrations of folate in their blood than those with CT or CC genotypes (Mann-Whitney test,  $P = 0.007$  and  $P = 0.03$ , respectively). We found no significant difference in serum vitamin B<sub>12</sub> concentrations between subjects with the CC and TT genotypes.

To test the association between serum folate/vitamin B<sub>12</sub> levels and methylation of genes promoter and tumors methylation, we stratified serum folate/

<sup>1</sup>*P*-values for methylated and unmethylated cases, and genotype comparison, Mann-Whitney, *t*-test and Kruskal Wallis where appropriate; <sup>2</sup>Median was taken as cut off point for low and high categorical value for serum folate/vitamin B<sub>12</sub> levels (5.5 ng/mL, and 240 pg/mL, respectively); <sup>3</sup>*P*-value from Fisher's exact test; <sup>4</sup>Since we did not have enough TT cases, the association of serum methyl donors and tumor methylation was not determined in these individuals; <sup>5</sup>Comparison with the CC genotype, cases only.

hypermethylation within the promoter of *p16* gene, but not in either *bMLH1* or *bMSH2* genes, was higher in CLCs derived from patients with high serum folate (*P* = 0.04) and vitamin B<sub>12</sub> (*P* = 0.02) when compared with CLCs from patients with low serum folate/vitamin B<sub>12</sub> levels status (Table 2).

The association between tumor methylation and serum folate/vitamin B<sub>12</sub> levels is shown in Table 4. A small trend for higher levels of serum folate was found

in the entire group of patients with methylated tumors compared to those with unmethylated tumors (*P* = 0.06). The percentage of methylated tumors in patients with high serum methyl donors was also higher than those with low serum methyl donors (80% in high folate group, and 75% in high B<sub>12</sub> group; *P* = 0.02), whereas no such difference was found for unmethylated tumor group (Table 4). The OR for tumor methylation was 4.9 (95% CI, 1.4-17.7) for patients with high serum folate

versus low serum folate (Table 2). The risk of tumor methylation was also positively associated with serum vitamin B<sub>12</sub> status (OR = 3.9, 95% CI, 1.1-13.9). The high serum folate/vitamin B<sub>12</sub> levels were particularly associated with tumor methylation in males ( $P = 0.02$ ), but not in females ( $P = 0.4$ , Table 4). The association was also age and site dependent, being significant for older cases and those with proximal tumors (Table 4). Since we did not have enough distal methylated tumors, we could not examine the association of tumor methylation with serum folate status in such tumors.

### Joint effects of serum methyl donors, and *MTHFR* C677T genotypes on promoter methylation of tumor-associated genes

To investigate further whether the relationship between serum folate/vitamin B<sub>12</sub> status and DNA methylation is modified by the *MTHFR* genotype, we evaluated the joint effects of *MTHFR* codon 677 genotypes and serum folate/vitamin B<sub>12</sub> levels on tumor methylation. The combined effects of serum folate/vitamin B<sub>12</sub> levels and *MTHFR* polymorphism on tumor methylation are presented in Table 5. While the *CC* genotype showed no association with serum folate/vitamin B<sub>12</sub> levels with respect to tumors methylation, the *CT* and *CT/TT* genotypes of *MTHFR* exhibited a significant association of tumor methylation with high serum methyl donors. Insufficient *TT* cases eliminated the ability to examine their association with serum methyl donors and tumor methylation in these individuals. The frequency of methylated tumors was significantly different between cases with high and low serum methyl donors only in those with the *CT* and *CT/TT* genotype, but not with the *CC* genotype. More than 90% of methylated tumors in cases with *CT* and *CT/TT* genotypes had high serum methyl donors (Table 5). Among *CC* individuals no significant differences in mean serum folate/vitamin B<sub>12</sub> levels between cases with methylated and unmethylated tumors or an association between tumor methylation and folate/vitamin B<sub>12</sub> levels was observed. Therefore, the 677T allele seems to increase the risk of methylation associated with high serum folate/vitamin B<sub>12</sub>. We conclude that for the heterozygous or homozygous *C677T* genotypes, increased concentrations of folate and vitamin B<sub>12</sub> are associated with increased risks of tumor methylation. Our data suggest that the *MTHFR* *C677T* genotype might be a genetic modifier of the effect of the folate/vitamin B<sub>12</sub> status on the risk of methylation of genes promoter.

## DISCUSSION

It is well established that loss of proper gene expression in human cancer can occur through epigenetic mechanisms. The effect of a common polymorphism in the *MTHFR* gene (*C677T*) on colorectal cancer risk in relation to folate status is controversial. Both global DNA hypomethylation and gene promoter hypermethylation associated with the *MTHFR* *TT* genotype under low folate intake have been reported<sup>[12]</sup>.

In the present study, we investigated the association between the *MTHFR* *C677T* genotype and methylation of three putative tumor-associated genes, *p16*, *hMLH1*, and *hMSH2*, in 151 unselected series of sporadic CLC.

In our study (Table 2) the number of CLCs with at least one gene methylated was higher in females than males, and in those with proximal tumor location than those with distal tumors. Proximal tumor location, higher frequency in female subjects, and older age are characteristics that were previously associated with CIMP+ CLC<sup>[4,10]</sup>.

In comparison to controls, *MTHFR* *C677T* allele was associated with the elevation of tumor methylation in the entire group of cases, as well as in males and older patients (Table 3). Therefore, our finding is consistent with those reports in which increased genes promoter methylation was associated with the *MTHFR* *C677T* genotype in CLC<sup>[10,23]</sup>. We found no apparent association between methylation of any of the individual gene examined and the *MTHFR* genotypes. Therefore, DNA methylation at specific loci appears to be random. Consistent with a previous report that there are more frequent CIMP+ proximal tumors in subjects with alleles conferring low *MTHFR* enzyme activity<sup>[23]</sup>, the majority of methylated tumors with 677T variants in our study were also located in the proximal colon (Table 3).

Vitamin B<sub>12</sub> and folate are two important cofactors of methyl-group metabolism. We noted a trend for association between serum folate/vitamin B<sub>12</sub> levels and gene promoter methylation (Table 2). Higher serum folate and vitamin B<sub>12</sub> levels were strongly associated with promoter methylation of the key tumor suppressor gene *p16* ( $P = 0.04$ , and  $P = 0.02$ , respectively). There was also a trend, although not statistically significant, in the association between the serum folate/vitamin B<sub>12</sub> levels with promoter methylation of *hMLH1* and *hMSH2* genes.

Given the interaction between folate and the *MTHFR* genotype for CLC risk, we stratified the analyses of tumor methylation based on *MTHFR* genotypes and serum folate/vitamin B<sub>12</sub> status (Tables 4 and 5). In case-case comparisons, we found no significant difference in methyl donor status by age, sex, or tumor location. However, the serum folate level was significantly lower in cases homozygous for the *C677T* variant compared to those with the *CT* and *CC* genotypes ( $P = 0.04$ , Table 5). We found the *TT* variant of *MTHFR* associated with lower levels of folate in patient's sera. Although the blood folate level is mainly determined by dietary intake, the *MTHFR* *C677T* polymorphism might modify its metabolism and serum concentration<sup>[24]</sup>.

In our study, we found significant differences in the serum folate and vitamin B<sub>12</sub> levels in patients with methylated and unmethylated tumors (Table 4). None of the patients in our study used vitamin supplementation. Therefore, the increased tumor methylation observed in our study was associated with the high serum methyl donor status in physiological range. We noted also the same trend in the association between serum vitamin B<sub>12</sub> levels and tumor methylation (Table 4). Therefore, our data are consistent with those reports where a

positive association of dietary folate intake with DNA methylation and CLC risk was observed<sup>[25,26]</sup>.

Both folate deficiency and the *MTHFR* C677T polymorphism have been previously linked to global DNA hypomethylation in lymphocytes and colon tissue<sup>[27,28]</sup>. However, few studies have addressed the joint effects of methyl donors in blood and *MTHFR* genotypes on promoter-specific DNA methylation in malignancies<sup>[12,29]</sup>. Here, we assessed the association between methylation of genes promoter, the circulating levels of folate/vitamin B<sub>12</sub> and the influence of the *MTHFR* 677 genotypes in CLC patients. While no significant difference in serum folate/vitamin B<sub>12</sub> status was observed between those with methylated and unmethylated tumors in CC individuals, the CT, and CT/TT genotypes of *MTHFR* exhibited a significant positive correlation with elevated folate/vitamin B<sub>12</sub> levels for promoter methylation silencing (Table 5). Previously, an interaction between dietary folic acid and vitamin B<sub>12</sub> supplementation with promoter methylation in colorectal adenomas has been suggested, especially for subjects with *MTHFR* TT genotype<sup>[16,30]</sup>. Because we did not have enough TT cases, we could not evaluate correlation of serum folate levels with tumor methylation in these individuals. Among our study group there was only one TT individual with a methylated tumor who also had higher serum folate/vitamin B<sub>12</sub> level than TT cases with unmethylated tumors (Table 5). Genomic DNA methylation in leukocytes and in transformed human lymphoblasts was shown to be positively correlated to folate status in those with the TT genotype, but not with wild-type *MTHFR* CC genotype<sup>[12,27,31]</sup>. An inverse trend of serum and erythrocyte folate with DNA hypomethylation was also reported in normal colonic mucosa<sup>[28]</sup>.

In some studies, no interaction was reported between either *MTHFR* genotype and folate intake in association with CIMP + colon tumors<sup>[17,32]</sup>. Further investigation is needed focusing on ethnic variations in the relationships between the *MTHFR* polymorphism, folate intake, and tumors methylation in CLC. The majority of previous case-control studies have assessed dietary folate or vitamin B intake from questionnaires rather than their blood measurements, a procedure which is prone to some degree of miscalculation. Moreover, other factors like alcohol intake and iron status may be related to folate availability and biological activity<sup>[33]</sup>. In the present work, the direct measurement of serum folate/vitamin B<sub>12</sub> was correlated with CLC and tumor methylation. It has been previously reported that the colonic mucosal folate concentration correlates directly with serum folate concentration in the physiological range at each time point<sup>[34]</sup>. Therefore, the serum folate measurement could be an accurate reflection of the folate status in the colonic mucosa. High intracellular concentrations of folate intermediates are associated with aberrant methylation within promoter regions of cancer – associated genes in colorectal tumors<sup>[35]</sup>.

There is evidence that the epigenetic mechanism of gene silencing by methylation may play a differential role in proximal versus distal colon carcinogenesis. A different role for the *MTHFR* 677 TT genotype in the

tumorigenesis of proximal and distal CLC has been also suggested<sup>[8]</sup>. Our finding of an increased risk of tumor methylation associated with high serum folate/vitamin B<sub>12</sub> levels in those with proximal tumors, and in older patients (Table 4) might be related to the previous observation of a high concentration of folate in tumors from older patients and proximal CLC<sup>[35]</sup>.

Our results indicate that a high serum folate/vitamin B<sub>12</sub> in combination with a heterozygous or homozygous C677T *MTHFR* genotype, predisposes tumor-specific genes to promoter hypermethylation. Conversely, folate could be protective or have no effect in developing CLC in subjects with the wild type *MTHFR* 677 CC genotype. The *MTHFR* C677T mutation reduces MTHFR activity, which leads to lower levels of 5-methylTHF in individuals with a marginal folate status. However, in the presence of high folate levels, the negative effect of *MTHFR* TT on the efficiency of the methylation process might be masked possibly by maximizing the catalytic activity of MTHFR<sup>[36]</sup>. Indeed, under conditions of high folate status no differences in the Km or Vmax values were detected between the wild type and mutant enzymes<sup>[37]</sup>. Therefore, hypermethylation of CpG islands could occur in individuals with the *MTHFR* 677T allele under high folate status.

A major draw-back of the present study is the fact that the serum data collection occurred after the onset of tumor formation. Although, more studies are needed to determine whether *MTHFR* C677T genotypes, together with high serum folate/vitamin B<sub>12</sub> levels, could serve as risk factors for the CIMP + CLC subgroup, the findings of this study are in agreement with other recent reports which together provide additional evidence for caution in the mandatory fortification of cereals with folic acid.

We would like to thank Dr. Rose M Johnstone of McGill University for her critical review of the manuscript.

## COMMENTS

### Backgrounds

Transcriptional silencing of tumor suppressor genes by hypermethylation of capillary blood gases (CpG) islands located in the promoter region is very common in human colorectal cancer. *P16*, *hMLH1*, *hMSH2* are key tumor suppressor genes frequently silenced by promoter methylation in sporadic colon cancer (CLC). Methylentetrahydrofolate reductase (*MTHFR*) C677T genotype has been associated with reduced enzyme activity and altered cellular folate composition. In this study, we investigated the association between serum folate/vitamin B<sub>12</sub>, *MTHFR* C677T genotype, and promoter methylation of three tumor-associated genes in solid tumors among sporadic CLC patients.

### Research frontiers

Dietary folate/vitamin B<sub>12</sub> intake and *MTHFR* C677T genotype was suggested to protect against colorectal cancer. However, only a few studies have addressed the joint effects of circulating levels of folate/vitamin B<sub>12</sub> and the *MTHFR* C677T genotype on the risk of epigenetic inactivation of specific tumor suppressor genes in CLC patients.

### Innovations and breakthroughs

Our data indicate that serum folate/vitamin B<sub>12</sub> levels are directly associated with the DNA hypermethylation of CpG island within promoter of the tumor specific genes and to the C677T genotype of *MTHFR*. We identified that

the T allele of *MTHFR* has strong influence on the risk of tumor methylation associated with high serum folate/vitamin B<sub>12</sub> levels.

### Applications

The results from the study support other recent reports that high folate and vitamin B<sub>12</sub> status might serve as risk factors for CLC. This study provides additional evidence for caution in terms of CLC risk because of the mandatory fortification of cereals with folic acid in certain countries.

### Peer review

This is a population-based, case-controlled, molecular epidemiological study on the interaction of *MTHFR* C677T genotype and circulating folate/vitamin B<sub>12</sub> with the CpG island hypermethylation of tumor-associated genes in sporadic colorectal cancer. This result indicated that for the *MTHFR* C677T genotypes, increased concentrations of folate and vitamin B<sub>12</sub> are associated with increased risks of tumor methylation. This demonstration might give a suggestion to protect against colorectal cancer, at least, in Iranian sporadic CLC population.

### Abstract

**AIM:** To determine the effect of ellagic acid on apoptosis and proliferation in pancreatic cancer cells and to determine the mechanism of the pro-survival effects of ellagic acid.

**METHODS:** The effect of ellagic acid on apoptosis was assessed by measuring Phosphatidylserine externalization, caspase activity, mitochondrial membrane potential and DNA fragmentation; and proliferation by measuring DNA thymidine incorporation. Mitochondrial membrane potential was measured in permeabilized cells, and in isolated mitochondria. Nuclear factor  $\kappa$ B (NF- $\kappa$ B) activity was measured by electromobility shift assay (EMSA).

**RESULTS:** We show that ellagic acid, a polyphenolic compound in fruits and berries, at concentrations 10 to 50 mmol/L stimulates apoptosis in human pancreatic adenocarcinoma cells. Further, ellagic acid decreases proliferation by up to 20-fold at 50 mmol/L. Ellagic acid stimulates the mitochondrial pathway of apoptosis associated with mitochondrial depolarization, cytochrome C release, and the downstream caspase

### INTRODUCTION

Pancreatic cancer is a very aggressive disease and is the fourth most common cause of death in Western countries with almost the same rate of incidence and mortality per year<sup>[1,2]</sup>. Pancreatic cancer is very resistant to radio- and chemo-therapies. One reason for that is the resistance of pancreatic cancer cells to apoptosis<sup>[3]</sup>.

During the past decade, significant progress has been achieved in understanding the molecular mechanisms of apoptosis<sup>[4]</sup>. The information obtained suggests that the commitment to apoptosis occurs through activation of caspases, a unique family of cysteine proteases<sup>[4]</sup>. Caspases are synthesized as inactive precursors and are, generally, activated by proteases including caspases themselves. Thus, caspases can function in an activation cascade.

Cancer cells protect themselves from apoptosis by

upregulation of prosurvival mechanisms. Activation of the transcription factor NF- $\kappa$ B is a key pro-survival mechanism in cancer cells<sup>[5,6]</sup>. NF- $\kappa$ B is constitutively active in pancreatic cancer cells, and its inhibition leads to pancreatic cancer cell death and inhibition of tumor development<sup>[7]</sup>.

Ellagic acid (C<sub>14</sub>H<sub>6</sub>O<sub>8</sub>) is a polyphenolic compound present in fruits and berries such as pomegranates, strawberries, raspberries and blackberries. It has anticarcinogenic, antioxidant and antifibrosis properties<sup>[8-11]</sup>. The anticarcinogenic effect of ellagic acid was shown in several types of cancers including skin, esophageal, and colon cancers<sup>[11,12]</sup>. However, the effects of ellagic acid on pancreatic cancer have not been studied. Furthermore, the mechanisms mediating anticancer effect of ellagic acid, in general, remain unknown.

There is a growing interest in natural compounds for enhancing cancer prevention and treatment. In this study, we show that ellagic acid induces apoptosis and decreases proliferation in pancreatic cancer cells. We demonstrate that ellagic acid stimulates apoptosis in pancreatic cancer cells through inhibiting transcription factor NF- $\kappa$ B activity.

## MATERIALS AND METHODS

### Reagents

Ac-Asp-Glu-Val-Asp-7-amino-4-methylcoumarin (Ac-DEVD-AMC) was from Peptide Institute, Inc (Osaka, Japan). Antibody against cytochrome C was from BD Biosciences (San Diego, CA). CAPE was from biomol (Plymouth meeting, PA). Ellagic acid and all other reagents were from Sigma Chemical (St. Louis, MO).

### Cell culture

Human pancreatic adenocarcinoma cell lines, the poorly differentiated MIA PaCa-2 and the moderately differentiated PANC-1, were obtained from the American Type Culture Collection (Manassas, VA). MIA PaCa-2 and PANC-1 cells were grown in 1/1 D-MEM/F-12 medium (GIBCO Invitrogen Corporation, Grand Island, NY) supplemented with 15% fetal bovine serum (FBS), 4 mmol/L L-glutamine, and 1% antibiotic/antimycotic solution (Omega Scientific, Tarzana, CA). Cells were maintained at 37°C in a humidified atmosphere containing 5% CO<sub>2</sub> and were used between passages 4 and 12.

MIA PaCa-2 and PANC-1 cells were plated at a density of  $2 \times 10^6$ /mL on 100-mm culture dishes, cultured for up to 48 h in D-MEM/F-12 medium supplemented with FBS, glutamine and the antibiotic/antimycotic solution, collected, and processed for the specified analyses. Inhibitors or vehicle were added to the culture medium just before plating out the cells.

### Preparation of cytosolic and membrane fractions

Cells were resuspended in a lysis buffer (250 mmol/L sucrose, 20 mmol/L HEPES, 10 mmol/L KCl,

1 mmol/L Na-EGTA, 1 mmol/L Na-EDTA, 2 mmol/L MgCl<sub>2</sub>, pH 7.0), allowed to swell for 30 min at 4°C, and then disrupted by 80 strokes in a Dounce homogenizer. Homogenates were centrifuged at 1000 *g* for 5 min to pellet nuclei and cell debris. Supernatants were centrifuged at 16000 *g* for 30 min, and the cytosolic fractions (supernatants) were collected. Pellets (heavy membranes enriched with mitochondria) were lysed in RIPA buffer (0.15 mol/L NaCl, 50 mmol/L Tris, 1% deoxycholic acid, 1% Triton X-100, 0.1% sodium dodecyl sulfate, pH 7.2) for 1 h. To determine the quality of cytosolic and mitochondrial separation, both fractions were assessed by immunoblotting for the mitochondrial marker cytochrome C oxidase subunit IV (COX IV).

### Western blot analysis

Cells were incubated in a lysis buffer (0.5 mmol/L EDTA, 150 mmol/L NaCl, 50 mmol/L Tris, 0.5% Nonidet P-40, pH 7.5) for 30 min at 4°C. The lysis buffer was supplemented with 1 mmol/L PMSF, 5 g/mL each of protease inhibitors pepstatin, leupeptin, chymostatin, antipain, and aprotinin. Cell lysates were centrifuged for 10 min at 13000 *g*. Supernatants were collected and proteins were separated by SDS-PAGE (Invitrogen) and electrophoretically transferred to nitrocellulose membranes. Non-specific binding was blocked with 5% milk in Tris-buffered saline (4 mmol/L Tris base, 100 mmol/L NaCl, pH 7.5). Membranes were washed in Tris-buffered saline containing 0.05% Tween 20 (TTBS) and incubated for 2 h with the indicated primary antibodies and then for 1 h with horseradish peroxidase-conjugated secondary antibody. Blots were developed with the Supersignal Chemiluminescent Substrate (ECL) (Pierce).

### Measurements of apoptosis

**Apoptosis parameters were measured as previously described<sup>[13-16]</sup>:** Internucleosomal DNA fragmentation was measured by using Cell Death Detection ELISA<sup>Plus</sup> kit (Roche Molecular Biochemicals, Mannheim, Germany) according to the manufacturer's instructions.

**Phosphatidylserine (PS) externalization:** PS externalization was analyzed with the Annexin-V (AnV)-FLUOS Staining Kit from Roche Biochemicals (Indianapolis, IN) as we described before<sup>[13]</sup>. Cells were collected and resuspended at a density of  $1 \times 10^6$  cells in 500  $\mu$ L of binding buffer containing 2  $\mu$ L AnV and 1  $\mu$ L propidium iodide (PI), incubated in the dark for 30 min at room temperature, and analyzed by flow cytometry.

**Effector caspase (DEVDase) activity:** DEVDase activity was measured by a fluorogenic assay in whole cell lysates using DEVD-AMC as a substrate, as we described before<sup>[13]</sup>. The lysate (50-100  $\mu$ g of protein) was incubated with 10  $\mu$ mol/L substrate

in a reaction buffer (25 mmol/L HEPES (pH 7.5), 10% sucrose, 0.1% CHAPS, 10 mmol/L DTT) at 37°C. Caspase substrate cleavage releases AMC, which emits fluorescent signal with 380 nm excitation and 440 nm emission. Fluorescence was calibrated using a standard curve for AMC.

#### **Measurement of mitochondrial membrane potential ( $\Delta\psi_m$ )**

Changes in  $\Delta\psi_m$  were detected with the potential-sensitive probes 3, 3' dihexyloxa-carbocyanine DiOC6 (3) (Molecular Probes, Eugene, OR). Cells were incubated with 100 nmol/L DiOC6 (3) for 30 min at 37°C in the dark, washed twice with PBS, and analyzed on a FACScan using FL-1. To completely dissipate  $\Delta\psi_m$ , cells were treated with the uncoupling agent CCCP (50  $\mu$ mol/L) for 1 h before DiOC6 (3) staining.

#### **Registration of mitochondrial respiration and membrane potential in cells permeabilized with digitonin**

MIA PaCa-2 cells ( $5 \times 10^6$ ) were washed twice with PBS and resuspended in 50  $\mu$ L DMEM/F12 medium without serum. The medium for mitochondrial functional assays contained 250 mmol/L sucrose, 22 mmol/L KCl, 22 mmol/L triethanolamine (pH 7.4), 3 mmol/L  $MgCl_2$ , 5 mmol/L  $KH_2PO_4$ , 0.5% BSA. Glutamate (10 mmol/L) and malate (2 mmol/L) were used as mitochondrial respiratory substrates. Digitonin at concentration 0.001% was added to cell suspension to permeabilize plasma membrane and to allow substrates and chemicals to reach mitochondria immediately after addition into reaction medium. The measurements were performed at 25°C. Membrane potential and oxygen consumption were monitored simultaneously in a 1-mL custom-made chamber. Oxygen consumption was measured using a Clark-type electrode (Instech Lab., Plymouth Meeting, PA) connected to an oxygen meter (Yellow Springs Instruments, Yellow Springs, OH). Mitochondrial membrane potential was registered in the presence of 1  $\mu$ mol/L tetraphenyl phosphonium ( $TPP^+$ ) using a  $TPP^+$ -sensitive electrode connected to an amplifier (Vernier Software, Beaverton, OR). An increase in  $\Delta\psi_m$  causes  $TPP^+$  uptake by mitochondria and, correspondingly, a decrease in external  $TPP^+$  measured with the electrode.

Another approach applied to measure  $\Delta\psi_m$  is by using  $\Delta\psi_m$ -sensitive fluorescent probe tetramethylrhodamine methyl ester (TMRM; Molecular Probes, Eugene, OR). Changes in the fluorescence intensity were measured in the cell suspension containing 0.5  $\mu$ mol/L TMRM in the 2-mL cuvette in a RF-1501 spectrofluorophotometer (Simadzu, Japan) with 543 nm excitation, and 578 nm emission.  $\Delta\psi_m$ -driven mitochondrial uptake of TMRM causes TMRM quenching, which results in decreased fluorescence intensity.

#### **Isolation of mitochondria**

Mitochondria from Mia PaCa-2 cells were isolated using

differential centrifugation. Cells (approximately  $2 \times 10^8$ ) were homogenized using motor-driven tissue grinder in the isolation buffer containing 320 mmol/L sucrose, 10 mmol/L Tris-HCl (pH 7.4), 0.5 mmol/L EGTA, 0.5 mmol/L EDTA and 0.2% BSA. Unbroken cells were spun down by centrifugation at 500 g for 5 min, followed by nuclei centrifugation at 2000 g for 3 min. The resulting supernatant containing mitochondria was spun down at 12500 g for 10 min; then mitochondria were washed in a washing buffer containing 320 mmol/L sucrose and 10 mmol/L Tris-HCL (pH 7.4); and finally the mitochondrial pellet was re-suspended in the washing buffer. The obtained mitochondrial suspension contained 8 to 12 mg protein/mL as determined by the Bradford protein assay (BioRad Laboratories). All isolation steps were performed at 4°C, and the mitochondria were kept on ice all the time. Mitochondrial membrane potential and oxygen consumption were measured using  $TPP^+$ -sensitive and Clark-type electrodes correspondingly in the same incubation buffer as described above for digitonin-permeabilized cells.

#### **Measurement of cytochrome C release from isolated mitochondria**

MIA PaCa-2 cell mitochondria were incubated in the absence or presence of ellagic acid for 10 min. Aliquots of mitochondrial suspension were collected, centrifuged at 13500 g for 10 min at 4°C, and cytochrome C levels in the mitochondria (pellet) and the medium (supernatant) were measured by Western blot as previously described<sup>[13]</sup>.

#### **Preparation of nuclear extracts and electromobility shift assay (EMSA)**

Preparation of nuclear extracts and EMSA have been described in detail<sup>[17-19]</sup>. Briefly, pancreatic cancer cells were lysed on ice in a hypotonic buffer A<sup>[17]</sup> supplemented with 1 mmol/L PMSF, 1 mmol/L DTT, and protease inhibitor cocktail containing 5  $\mu$ g/mL each of pepstatin, leupeptin, chymostatin, antipain, and aprotinin. Cells were left to swell on ice for a 20 min to 25 min period; 0.3% Igepal CA-630 was then added, and the nuclei were collected by microcentrifugation. The nuclear pellet was resuspended in a high-salt buffer C<sup>[17]</sup> supplemented with 1 mmol/L PMSF, 1 mmol/L DTT, and the protease inhibitor cocktail described above. After incubating at 4°C, membrane debris was pelleted by microcentrifugation for 10 min, and the clear supernatant (nuclear extract) was aliquoted and stored at -80°C. Protein concentration in the extracts was determined by the Bio-Rad protein assay (Bio-Rad Laboratories, Hercules, CA).

For the EMSA, aliquots of nuclear extracts with equal amounts of protein (5-10  $\mu$ g) were mixed in 20- $\mu$ L reactions with a buffer containing 10 mmol/L HEPES (pH 7.8), 50 mmol/L KCl, 0.1 mmol/L EDTA, 1 mmol/L DTT, 10% glycerol, and 3  $\mu$ g poly (dI-dC). Binding reactions were started by the

**Figure 1** Ellagic acid stimulates apoptosis in pancreatic cancer cells. MIA PaCa-2 (A, C) and PANC-1 (B) cells were cultured for 48 h in the presence or absence of indicated doses of ellagic acid. Internucleosomal DNA fragmentation was measured using the Cell Death Detection ELISA kit (A, B); Dead cells were assessed by flow cytometry using AnV/PI staining (C). AnV<sup>+</sup>/PI<sup>+</sup> and AnV<sup>+</sup>/PI<sup>-</sup> cells were considered dying through apoptosis and/or secondary necrosis. Values are normalized to control (A, B). Values are mean  $\pm$  SE ( $n = 3$ ), <sup>a</sup> $P < 0.05$  vs control.

**Figure 2** Ellagic acid inhibits proliferation in pancreatic cancer cells. MIA PaCa-2 (A, C) and PANC-1 (B) cells were cultured for 48 h in the presence or absence of indicated doses of ellagic acid. Proliferation was assessed by measuring (<sup>3</sup>H) thymidine incorporation into DNA. The results are representative of at least 3 independent experiments, <sup>a</sup> $P < 0.05$  vs control.

addition of <sup>32</sup>P-labeled DNA probe and incubated at room temperature for 20 min. The oligo probe 5'-GCAGAGGGGACTTTCGAGA-3' containing  $\kappa$ B binding motif (underlined) was annealed to the complementary oligonucleotide and end-labeled by using T4 polynucleotide kinase. Samples were electrophoresed on a native 4.5% polyacrylamide gel at 200 V in 0.5 TBE buffer (1  $\times$  TBE: 89 mmol/L Tris base, 89 mmol/L boric acid, 2 mmol/L EDTA). Gels were dried and densitometrically quantified in the Phosphor-Imager (Molecular Dynamics, Sunnyvale, CA). In pancreatic cancer cells, the NF- $\kappa$ B band has two components: the upper component corresponds to the p50/p65 heterodimer and the lower component to the p50/p50 homodimer. In the present study, we quantified the total (combined) intensity of the NF- $\kappa$ B band.

### Cell transfection

For this a luciferase reporter gene system was used. Briefly, MIA PaCa-2 cells were simultaneously transfected with the 4KBwt-pRL-TK luciferase plasmid, which expresses the NF- $\kappa$ B inhibitor I- $\kappa$ B and pRL-TK luciferase (as a reference) using the Nucleofector™ II (Amaxa Inc, Gaithersburg, MD) according to the manufacturer protocol. The transfection efficiency and NF- $\kappa$ B transcriptional activity was assessed by using the Dual-Luciferase Reporter Assay System (Promega Corporation, Madison WI).

### Statistical analysis

Results are expressed as mean  $\pm$  SE from at least 3 independent experiments. Statistical analysis was done using the unpaired Student's *t*-test.  $P < 0.05$  was considered statistically significant.

## RESULTS

### Ellagic acid stimulates apoptosis and inhibits proliferation of pancreatic cancer cells

Ellagic acid dose-dependently increased apoptosis in PaCa cells (Figure 1). To measure apoptosis we used 2 approaches. First, we showed that ellagic acid stimulates apoptotic internucleosomal DNA fragmentation in MIA PaCa-2 (Figure 1A) and PANC-1 cells (Figure 1B). Second, we used flow cytometry and AnV/PI staining to measure the percentage of dead cells as described in Experimental Procedures. We previously showed that the AnV<sup>+</sup>/PI<sup>-</sup> group includes cells at early stages of apoptosis, whereas the AnV<sup>+</sup>/PI<sup>+</sup> group includes both necrotic cells and apoptotic cells associated with secondary necrosis<sup>[13]</sup>. Ellagic acid increased the percentage of dead MIA PaCa-2 cells (i.e. stained positively for both AnV and PI or for AnV alone) (Figure 1C).

Next, we measured the effect of ellagic acid on proliferation of PaCa cells. The results in Figure 2 show that ellagic acid dose-dependently inhibited proliferation of both MIA PaCa-2 and PANC-1 cell lines as measured by <sup>3</sup>H thymidine incorporation (Figure 2A and B). The effect was most pronounced at 50  $\mu$ mol/L (almost 20 fold inhibition in MIA PaCa-2 cells).

**Figure 3** Ellagic acid induces loss of mitochondrial membrane potential, cytochrome C release, and caspase-3 activation in pancreatic cancer cells. MIA PaCa-2 (A-C) and PANC-1 (B) cells were cultured for 48 h in the presence or absence of indicated doses of ellagic acid or broad-spectrum caspase inhibitor zVAD-fmk (100  $\mu\text{mol/L}$ ). **A:** Changes in  $\Delta\psi_m$  were measured by flow cytometry using the potential-sensitive probe 3,3'-diethyloxa-carbocyanine DiOC6 (3); **B:** Cytochrome C release was assessed by measuring cytochrome C levels in both cytosolic and mitochondria-enriched membrane fractions using Western blot analysis. Blots were re-probed for cytochrome C oxidase (COX IV), a specific mitochondrial marker. Western blots of cytosolic fractions re-probed for actin to confirm equal protein loading; **C** and **D:** Caspase-3 activity was assessed by measuring the DEVDase (caspase-3 like) activities in cell lysates using a fluorometric assay with a specific substrate. The results are representative of at least 3 independent experiments. Values are normalized to control (**C** and **D**). Values are mean  $\pm$  SE ( $n = 3$ ), \* $P < 0.05$  vs control.

### Ellagic acid induces mitochondrial depolarization, cytochrome C release, and caspase activation in pancreatic cancer cells

To determine the signaling pathway mediating the proapoptotic effect of ellagic acid, we measured the effects of ellagic acid on mitochondrial membrane potential ( $\Delta\psi_m$ ), cytochrome C release, and caspase-3 activity. Ellagic acid decreased  $\Delta\psi_m$  as measured by flow cytometry using the potential-sensitive probe DiOC6 (3). Depolarization was already evident at 10  $\mu\text{mol/L}$ , and was very pronounced at 50  $\mu\text{mol/L}$  ellagic acid (Figure 3A). Ellagic acid also dose-dependently stimulated cytochrome C release, which manifests by its decrease in mitochondria-enriched membrane fractions and its increase in cytosolic fractions (Figure 3B). The increased cytochrome C release was associated with downstream activation of caspase-3 in MIA PaCa-2 (Figure 3C) and PANC-1 (Figure 3D) cells.

These data together indicate that ellagic acid induces the mitochondrial pathway of apoptosis associated with mitochondrial depolarization, cytochrome C release, and downstream caspase activation.

### Ellagic acid does not directly affect mitochondria function in pancreatic cancer cells

To test the effect of ellagic acid on mitochondria we isolated functional mitochondria from MIA PaCa-2 cells

and measured the effect of ellagic acid on mitochondria respiration, membrane potential, and cytochrome C release (Figure 4). The respiratory control ratio of isolated mitochondria with succinate as a respiratory substrate in all the experiments was greater than 4 in all the experiments. Ellagic acid affected neither oxygen consumption measured with Clark electrode (Figure 4A) nor  $\Delta\psi_m$  measured with TPP<sup>+</sup> electrode (Figure 4B). The protonophore CCCP, which we used as a positive control, depolarized mitochondria (Figure 4B). In agreement with these results, ellagic acid did not increase cytochrome C release from isolated mitochondria into the incubation medium (Figure 4C).

We next assessed the possibility of ellagic acid's effect in permeabilized cells. For this purpose, MIA PaCa-2 cells were permeabilized with digitonin as described by Ohno *et al*<sup>[20]</sup>. Ellagic acid did not induce any discernable effect on the mitochondrial membrane potential in digitonin-permeabilized cells as measured with TPP<sup>+</sup> electrode (Figure 5B) or by using TMRM fluorescent dye (Figure 5C). CCCP was applied to completely dissipate  $\Delta\psi_m$  (Figure 5B and C). Similarly, ellagic acid did not have any effect on mitochondrial respiration in permeabilized cells (Figure 5A).

The results in Figures 4 and 5 indicate that ellagic acid does not directly affect mitochondria functions in pancreatic cancer cells.

**Figure 4** Ellagic acid does not directly affect the function of isolated mitochondria. Mitochondria were isolated from MIA PaCa-2 cells cultured in the absence of ellagic acid. **A:** Oxygen consumption was measured using a Clark-type electrode connected to an oxygen meter; **B:** Mitochondrial membrane potential ( $\Delta\psi_m$ ) was monitored in the presence of 2  $\mu$ mol/L tetraphenyl phosphonium (TPP<sup>+</sup>) using a TPP<sup>+</sup>-sensitive electrode connected to an amplifier. Protonophore CCCP (10  $\mu$ mol/L) was added to dissipate  $\Delta\psi_m$ ; **C:** Cytochrome C levels were measured in the incubation medium and the mitochondrial pellet by Western blot analysis. The results are representative of 3 independent experiments.

### Ellagic acid and NF- $\kappa$ B inhibition act through the same mechanism to stimulate apoptosis

We hypothesized that ellagic acid induced the mitochondrial pathway of apoptosis through blocking a key upstream pro-survival mechanisms, namely NF- $\kappa$ B. NF- $\kappa$ B is a key transcription factor, which is usually activated and has anti-apoptotic role in cancer cells including pancreatic cancer<sup>[4]</sup>. We found that ellagic acid dose-dependently decreased NF- $\kappa$ B binding activity in both MIA PaCa-2 and PANC-1 cell lines (Figure 6A).

We further showed that a pharmacologic inhibitor of NF- $\kappa$ B caffeic acid phenethyl ester (CAPE) stimulated apoptosis in PaCa cells, and that in the presence of CAPE there was no additional stimulation of apoptosis by ellagic acid (50  $\mu$ mol/L) (Figure 6B). Further, transfection of MIA PaCa-2 cells with 4KBwt-pRL-TK plasmid completely blocked NF- $\kappa$ B transcriptional activity (Figure 6C), and at the same time stimulated apoptosis as measured by DNA fragmentation by > 5-fold (Figure 6D). The addition of ellagic acid to the transfected cells did not further increase DNA fragmentation (Figure 6D), confirming

**Figure 5** Ellagic acid does not directly affect mitochondria function in permeabilized MIA PaCa-2 cells. MIA PaCa-2 cells were permeabilized with 0.001% digitonin. **A:** Oxygen consumption was measured using a Clark-type electrode connected to an oxygen meter; **B:** Changes in  $\Delta\psi_m$  were monitored in the presence of 2  $\mu$ mol/L tetraphenyl phosphonium (TPP<sup>+</sup>) using a TPP<sup>+</sup>-sensitive electrode connected to an amplifier; **C:** Changes in  $\Delta\psi_m$  were monitored using the  $\Delta\psi_m$ -sensitive fluorescent probe tetramethylrhodamine methyl ester (TMRM); changes in the fluorescence intensities were measured using the excitation at 543 nm and the emission at 578 nm. Protonophore CCCP (10  $\mu$ mol/L) was added to dissipate  $\Delta\psi_m$ .

that ellagic acid causes apoptosis through inhibition of NF- $\kappa$ B.

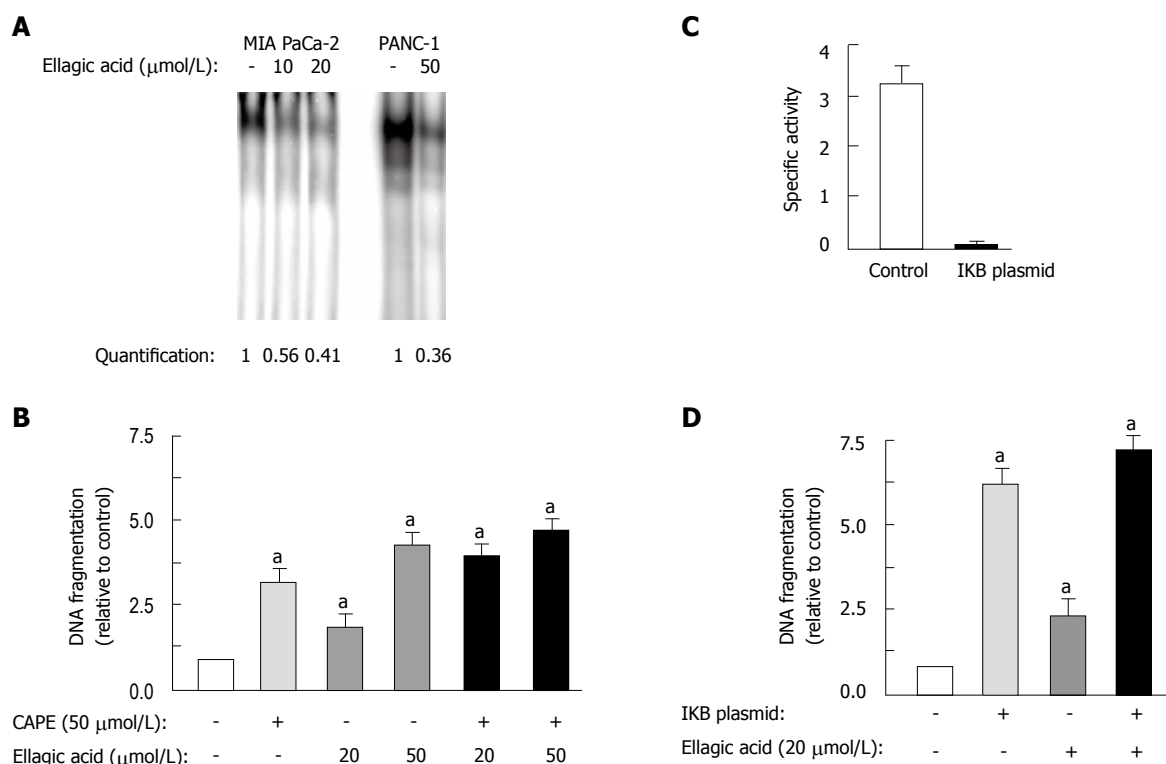

## DISCUSSION

Our study aimed to investigate the effect of ellagic acid on cell death and proliferation of pancreatic cancer cells and to determine the mechanism through which ellagic acid affects cell survival. We used the poorly differentiated MIA PaCa-2 and moderately differentiated PANC-1 human pancreatic carcinoma cell lines, which both display K-ras and p53 mutations characteristic of pancreatic cancer.

We found that ellagic acid: (1) stimulated apoptosis and inhibited proliferation of pancreatic cancer cells; (2) activated the mitochondrial death pathway associated with loss of  $\Delta\psi_m$ , cytochrome C release and caspase-3 activation without directly affecting the mitochondria; and (3) inhibited NF- $\kappa$ B activity in pancreatic cancer cells.

Mechanisms through which ellagic acid inhibits NF- $\kappa$ B remain to be investigated.

One mechanism through which NF- $\kappa$ B inhibits apoptosis is up-regulation of the anti-apoptotic Bcl-xL

**Figure 6** Ellagic acid decreases the activity of the transcription factor NF- $\kappa$ B. The effects of ellagic acid and pharmacological or molecular inhibition of NF- $\kappa$ B on apoptosis are not additive. MIA PaCa-2 (**A** and **B**) cells were cultured for 48 h in the presence or absence of indicated doses of ellagic acid. MIA PaCa-2 cells were transfected with 4KBwt-pRL-TK luciferase plasmid and pRL-TK luciferase as a control using the Nucleofector™ II electroporation system (**C** and **D**). **A**: NF- $\kappa$ B binding activity was measured as described in Experimental procedures; **B** and **D**: Internucleosomal DNA fragmentation was measured using the Cell Death Detection ELISA kit; **C**: NF- $\kappa$ B transcriptional activity was assessed using the dual-Luciferase Reporter Assay System assay. Results are representative of at least 3 independent experiments. Values are normalized to control (**B** and **D**). Values are mean  $\pm$  SE ( $n = 3$ ), <sup>a</sup> $P < 0.05$  vs control.

**Figure 7** Representative scheme of the proposed mechanism of induction of apoptosis by ellagic acid.

protein. Bcl-xL, in turn, blocks mitochondrial permeabilization resulting in inhibition of cytochrome C release as well as preventing mitochondrial depolarization<sup>[21-23]</sup>. Our data indicate that ellagic acid decreases NF- $\kappa$ B activity, leading to activation of the mitochondrial proapoptotic pathway and resulting in cytochrome C release and caspase activation. This scheme is depicted in Figure 7.

Our data indicate that ellagic acid inhibits proliferation of pancreatic cancer cells, similar to that in published data of other cells<sup>[21,24-28]</sup>. Ellagic acid completely abolished proliferation at high concentration, whereas it only increased apoptosis by 2.5-fold. The contribution of necrosis might account for the decreased proliferation.

Our results as well as the published data on the

potent inhibitory effect of ellagic acid on the vascular endothelial growth factor receptor and platelet-derived growth factor receptor leading to the inhibition of their signaling<sup>[29]</sup>, indicate that ellagic acid is a powerful phenolic compound with proapoptotic and anti-proliferation effects in cancer cells. Understanding the mechanism of action of ellagic acid will allow us to test the effect of the compound alone or in combination with other compounds on cancer growth and survival in an orthotopic model of pancreatic cancer<sup>[30]</sup>.

In summary, the present study shows that ellagic acid induces apoptosis and decreases proliferation in pancreatic cancer cells. This phenolic compound stimulates mitochondrial depolarization, cytochrome C release and caspase activation. Ellagic acid has no direct effect on mitochondria. One mechanism by which it stimulates the mitochondrial death pathway is through inhibiting the transcription factor NF- $\kappa$ B, a major prosurvival factor in pancreatic cancer cells. There is an increasing interest in the use of natural products for cancer treatments. Our results suggest a potential therapeutic role for ellagic acid in the treatment of pancreatic cancer.

## COMMENTS

### Background

Pancreatic cancer is very resistant to radio- and chemo-therapies. Recently,

there is a growing interest in natural compounds for enhancing cancer prevention and treatment. Ellagic acid is a phenolic compound present in fruits and berries such as pomegranates, strawberries, raspberries and blackberries. It has anticarcinogenic, antioxidant and antifibrosis properties. In the present study the authors investigate the effect of ellagic acid on pancreatic cancer cell proliferation and resistance to death.

### Research frontiers

The article focuses on the regulation of pancreatic cancer cell death by a phenolic compound, ellagic acid.

### Innovations and breakthroughs

The present study shows that ellagic acid induces apoptosis and decreases proliferation in pancreatic cancer cells. It was shown for the first time that ellagic acid stimulates mitochondrial depolarization, cytochrome C release and caspase activation. Ellagic acid has no direct effect on mitochondria. One mechanism by which it stimulates the mitochondrial death pathway is through inhibiting transcription factor NF- $\kappa$ B, a major prosurvival factor in pancreatic cancer cells.

### Applications

The data of this article demonstrate the anti-cancer properties of ellagic acid as well as its mechanism of action. By knowing the mechanism of action of ellagic acid, it can be used in combination with other drugs that target other pro-survival proteins to increase apoptosis in pancreatic cancer cells.

### Peer review

This is a carefully performed study with novel findings that have the potential for therapeutic application in pancreatic cancer. It examines the effect of a naturally occurring polyphenolic compound, ellagic acid, on pancreatic cancer cell function, in particular, apoptosis and proliferation. The authors report that ellagic acid stimulates apoptosis of two pancreatic cancer cell lines and the decreased proliferation of ellagic acid-treated cells.
